The **method of measurement** was the Kelvin double-ridge method and the **apparatus** used consisted of the following: A manganin standard resistance (very accurate) of .00125 ohm which would carry 200 amperes without appreciable heating. For the proportional arms two 100-ohm coils for the a and α resistances, kept fixed, and for the b and β resistances two plug decade resistance boxes of 10,000 ohms capacity and variable in steps of 1 ohm. The resistance in these latter was varied to secure a balance. The source of current was three small storage cells joined in parallel, and a rheostat held the current at between 10 and 20 amperes. A key was used in the battery circuit. The galvanometer was a Leeds and Northrup H form galvanometer of the suspended-coil D'Arsonval type. It was undamped upon open circuit. Its approximate constants were: Resistance of coil, 550 ohms; complete period, 7 seconds; megohm sensibility, 1 scale division deflection on a scale 1000 scale divisions from its mirror with 1 volt and 290 megohms in circuit.

Since it was necessary to accurately regulate and measure the temperature of the bar, a tin trough was provided in which the bar could be placed and kept underneath oil. Paraffin oil

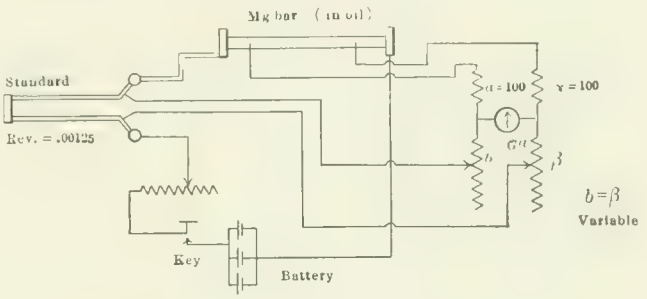

FIG. I.—DIAGRAM OF CONNECTIONS.

(instead of kerosene to avoid fire risk) was used. In the bottom of the trough was a solenoid of cotton-insulated german silver wire through which current from the 110-volt mains could be passed for the purpose of heating the oil.

The temperatures were read with two accurate mercury thermometers.

The **connections** employed are given in Fig. 1.

The **procedure** was first to heat the oil to about 156° C. and to vary the ratio coils, b and β, until a rough balance was secured. The current was then cut off from the heating coil and the oil was vigorously stirred with a wooden paddle. When the temperature was uniform throughout the tank an accurate balance of the bridge was obtained by varying b and β together. As the galvanometer was sensitive to changes in the resistances, b, β, of less than one ohm, and as these resistances could not be varied in smaller steps the simple plan was adopted of setting the values of b and β so that, for an exact balance, the oil must cool down a degree or two. Then, at the moment the galvanometer showed no deflection when the key was closed, a reading was taken of the temperature of the oil. This reading of temperature and the setting of b ($b = \beta$) was recorded. The oil was then allowed to cool a few degrees further, and a new reading was taken with a new setting of b and β. Altogether 37 readings were taken while the oil cooled from 154.8° to 21.4° C. As the temperature of the oil approaches room temperature the cooling proceeds very slowly and the last few readings were taken at widely separate intervals.

The process might have been hastened by pouring into the can artificially cooled oil.

After the run was finished careful measurements were made of the resistances a and α, including the lead wires to redetermine their resistances. They were found to be each 100 ohms within 0.02 per cent, and were called exactly 100 ohms. The following table exhibits the **data obtained**, together with some obvious deductions.

Observers A, B, C, Nov. 13, 14 and 20

In column 1 are recorded the temperatures of the oil taken each time after the oil had been vigorously stirred. In column 2 are given the values of b and β. In column 3 are given the resistances in micro-ohms per centimeter cube. In column 4 are given the reciprocal values of column 3, namely, the conductivity in mega-mhos. In column 5 are made some remarks relating especially to the time of taking the readings.

Various **deductions** might be made from the above data. Of special interest we note that the resistivity increases very nearly directly as the temperature. We are, therefore, justified in finding the value of the temperature coefficient from the formula,

$$\alpha = \frac{R_T - R_t}{R_t T - R_1 t} \qquad 0.00418,$$

when we use the temperatures $t = 21°$ and $T = 154.8°$ and the resistivities corresponding to these temperatures. Applying this coefficient we find

Resistivity of magnesium at 20° C. = 4.564 × 10^{-6} ohm.

The **probable precision** of the above results cannot be ascertained from this single determination for unrecognized systematic errors may have entered. As the measurements were made, however, with much care and all the resistances were known to be accurate to better than 1/20 per cent, the presumption is strong that the accuracy of 1/5 per cent, aimed for, has been obtained. It would, however, be unscientific to claim this precision as having been certainly obtained. To give the determination a very high probability of precision, within a specified per cent it would be necessary to repeat the measurements with the dimensions of the specimen changed and with the use of different ratio coils, standard and thermometer, if any of these were under suspicion. As a matter of fact, this same sample was measured about a year previously, at which time it had not been milled down and its dimensions were greater. A different standard, ratio coils and thermometer were also employed. The value then found for the resistivity at 20° C. was 4.564 × 10^{-6} ohm.

This differs from the above result by about 0.11 per cent. Thus it may be concluded with a high degree of probability that the value last obtained is correct within 1/5 per cent, the precision sought.

To make the exhibition of the results of the measurements complete, curves giving the relations of resistivity and conductivity, to temperature were plotted upon a large-size sheet of cross-section paper.

In any case where a number of observations are made of two quantities, where one is a function of the other, the most probable relations between the quantities are best exhibited by means of a curve. The curves drawn belonging to the above measurement are not given here because of lack of space.

Palmer Physical Laboratory, Princeton, N. J.

Magnetic Separation of Zinc Iron Ores as Found in Southwestern Wisconsin.

By Otto E. Ruhoff.

The object chiefly in view in making the tests to be described was to get further information on the possibility of carrying out a magnetic separation of blende-pyrite ores such as occur in southwestern Wisconsin, without reducing the percentage of sulphur in the tailings to such a point that the buyers of iron pyrite will no longer take them for the manufacture of sulphuric acid. Experiments along similar lines were carried on several years ago by O. L. Kowalke, of the Chemical Engineering Department of the University of Wisconsin, the results of which were published in Vol. 13 of the *Proceedings* of the American Electrochemical Society (this journal, Vol. VI, page 241).

In the present method of magnetic separation, as carried on in the Wisconsin district mentioned, the roast is carried on under strongly oxidizing conditions. The percentage of sulphur in the tailings is usually reduced to between 25 and 30 per cent, while the minimum requirements of acid manufacturers are 35 per cent of sulphur, with preferably 40 per cent or more.

The first method of attack seemed to lie in a substitution of non-oxidizing conditions for the strongly oxidizing conditions at present in use. The iron pyrite would in this way probably be converted to the magnetic sulphide, probably of the composition Fe_7S_8, instead of the magnetic oxide Fe_3O_4. In order to recover still more of the sulphur the most suitable procedure seemed to be to distill off a portion of the sulphur, avoiding the presence of non-condensable gases of any sort in order to avoid the loss of sulphur that these would occasion.

The first step was to determine what conditions of time and temperature were most suitable to get the right kind of a roast. The ore used contained about 18 per cent of zinc, corresponding to 27 per cent of zinc sulphide, so that there were about 70 per cent of iron pyrite present.

In the first tests a small electric tube furnace was used. This had a length of 13¼ in. and the diameter was large enough to take a ½-in. quartz tube. The furnace was wound with nichrome ribbon and when used with a 110 volt current had to have a lamp bank in series with it. From 12 to 20 amperes were required to get it up to heat.

A plug of asbestos fiber was placed in the middle of the quartz tube and on one side of this there were placed 50 grams of ore, occupying 6½ in. On the other side of the asbestos plug a Hoskins couple was placed to determine the temperature.

It was desired to distill off as little sulphur as possible and

still get a magnetic product. In the first two runs difficulty was experienced in watching the distillation of the sulphur, since none of it appeared at the outlet of the tube. All of the sulphur condensed as liquid or solid before it got to the end of the tube. A temperature of about 600 deg. C. was indicated by the pyrometer.

To be better able to observe the evolution of sulphur and to keep it down to a slow rate, a piece of hard glass tubing was next used, and this was drawn out to a point at one end in order that the flame of sulphur might not strike back into the tube. The end of the tube coming outside of the furnace was heated by means of a Bunsen burner so that no sulphur might condense to liquid or solid. In this way it was possible to watch somewhat more closely the course of the distillation. A temperature of 625 deg. C. was maintained for 25 minutes and during this time there was a continuous evolution of sulphur.

Much of the material was strongly magnetic, but there were a considerable number of unaffected particles. It was thought that this might be due to an unequal treatment of the particles, since those nearest the outside of the tube would be likely to get more heat than those in the middle of the tube. Other points that were noted were a certain amount of gluing together of the particles of ore by the sulphur which had condensed in the ore bed during the cooling Many of the particles were very strongly magnetic and had been converted throughout the grains. The particles seemed to retain their magnetism after the removal of the influence of the magnetic field, a fact which might result in mechanical entanglement in carrying out the magnetic separation.

To insure a more nearly equal treatment of all particles of ore and in order to regulate the distillation still better, all of the succeeding tests were carried out in a small cast-iron drum 5 in. inside diameter and 7 in. long inside. The ends of the drum were closed by cast-iron plates bolted on and removable for filling and emptying the drum. The drum was mounted upon the bearings in such a way that it could be lifted off in order to fill it. A ratchet and pawl arrangement was used to rotate the drum at a rate of one to three revolutions per minute. The drum was surrounded by a sheet-iron insulation lined with asbestos paper, and the upper part of the insulating jacket could be lifted off. Two single and one triple Bunsen burners were found amply sufficient to heat the drum to a bright red which was more than was required at any time.

Pieces of pipe were threaded into the middle of both ends of the drum. One of these was open in order to allow the escape of sulphur vapors and the other extended well into the drum and was closed on the inside end and a Hoskins' couple inside of this served to indicate the temperatures. The drum had two 1-in. angles riveted to the sides in order to promote the tumbling and stirring action within the drum.

In the first test 1060 grams of ore were used. This contained about 3 per cent of moisture. A temperature of about 775 deg. was maintained for 40 minutes, and the weight of the ore after roasting was 860 grams. Much of the ore was found to be decidedly magnetic, but about one-third of the iron particles were practically unconverted. A useful method of determining the percentage of converted particles was that of separating out one size, for example, that between 20 and 40 mesh and examining this under a magnifying glass. If desired this procedure can be carried out on any size using the proper degree of magnification and a fair estimate of the results obtained can be made at once without waiting for the results of analysis.

It seemed possible that the non-uniform roast of the iron particles might be due to insufficient tumbling within the drum. For the next run, therefore, the portion of the pyrometer tube within the drum was removed, so that the inside of the drum was now entirely open and the ore could fall freely. All temperatures after this are approximate, being taken in one shaft, close up to the drum itself. The temperatures at this point were probably about 25 deg. higher than in the drum.

For the next run 1117 grams of ore were taken and the loss of weight was 85 grams. A temperature of 725 deg. C. had been maintained for 17 minutes. Although a burner was placed under the outlet tube, a portion of the sulphur condensed and it was not possible to observe the rate of evolution closely.

In the next run, therefore, a piece of solid shaft was substituted for the pipe and a ⅛-in. hole provided very close to the drum and connected with the interior of the drum, as an outlet for the sulphur vapors. This made it possible to watch the evolution of sulphur very closely. A temperature of 670 deg. C. was maintained for 48 minutes. In this, as in the previous run, the magnetization of the iron particles was not uniform.

With the idea that it might be necessary to drive off more sulphur in order to make all particles magnetic, a temperature of 660 deg. was maintained for three hours; 1119 grams of ore lost 110 grams during this time. The result obtained was not satisfactory.

It was noticed in all of these tests that the sulphur seemed to come off in puffs and jerks whenever one of the angles came near to the top of the drum, and thus caused a handful of ore to drop to the bottom of the drum. Apparently when the ore has closely approached the decomposition temperature, any slight additional influence, such as the falling of the ore just described, will cause an evolution of sulphur. If as slight an effect as this will cause an evolution of sulphur, it is evident that the tendency to evolve sulphur may vary considerably in different parts of the drum where there are bound to be differences of temperature of 20 deg. or more. Furthermore, if some of the particles have this advantage of 20 deg. or more over others, this condition would remain until the end of the distillation, which would not be the case with reactions brought about by a contact of some gas with ore grains. In this latter case the reaction would become much slower as soon as a surface conversion of the grains that had gotten the first start had been affected, and those getting less heat would have some chance to catch up.

This points to the advantage of bringing about the desired reaction by passing over the ore a current of some gas, such as water vapor or products of combustion, instead of attempting to carry out strictly a distillation treatment. In the next run, therefore, a current of steam was passed through the drum while the heat was being applied; 1184 grams of ore were taken and the temperature was held at 550 deg. C. for two hours. The loss of weight was 57 grams. About 500 cc. of water were evaporated during this time. The vapors given off from the drum seemed to contain H_2S, SO_2 and SO_3, besides undecomposed steam. The ore obtained from this run seemed to be much more uniformly magnetized than in any of the previous runs. This method of treatment would probably be applicable only where considerable quantities of exhaust steam were available.

Another method that seemed to offer a means of securing a more nearly uniform magnetization seemed to be to carry the distillation of sulphur very much further, and to drive off practically all of the sulphur that would come off at such temperatures as had been used in the previous experiments; 1140 grams of ore were used and the temperature was held at 700 deg. C. for one hour, at the end of which time the sulphur had practically stopped coming off. The loss of weight was 216 grams. An attempt was made to catch the sulphur in a 1-in. iron pipe which was again used to provide an outlet for the sulphur vapors. Ninety-seven grams of sulphur were caught in a dish in this way, but a large quantity was lost by dripping upon the floor and by burning.

The ore from this run was extremely magnetic, since probably practically all of it had been converted to the magnetic sulphide Fe_7S_8. A magnetic separation was made upon a small

portion of the ore, using the size between 20 and 40 mesh. The non-magnetic portion weighed 30.1 grams and contained 62.0 per cent zinc and 1.4 per cent iron. The magnetic portion weighed 51.4 grams and contained 0.6 per cent zinc, 34.0 per cent sulphur and 55.4 per cent iron. This indicates a good recovery of zinc and a good grade of product. It may be assumed that most of the 55.4 per cent of iron was originally in the form of pyrite. From this an estimate can be made of the amount of sulphur that would be boiled off, and this would either be a salable product by itself, or could be mixed with the magnetic tailings containing 34 per cent of sulphur and in this way bring the total sulphur content well up over the minimum requirement. It will be understood that the magnetic separation would not be as good if mixed sizes were worked upon, nor could as much care be used in a large scale separation as was used in this small test.

While the analysis of the products obtained seemed satisfactory, the physical nature of the iron-sulphur product was not what was desired. The particles were extremely friable and most of them could be rubbed to a powder between the fingers. In working on a commercial scale this would probably result in an excessive amount of fines which might be troublesome both in the magnetic separation and later on in the use of the tailings in acid manufacture. It seemed possible that the friable nature of the iron tailings was due to too rapid a rate of distillation and in order to get evidence on this a small crucible full of ore was subjected to as slow a distillation as possible. The cover of the crucible was sealed on with sodium silicate and asbestos cord and a notch cut in one side of the crucible cover to provide one outlet for the vapors, in such a way that the rate of evolution could be closely observed. The crucible was heated in a small electric muffle furnace, and 2¼ hours were taken to complete the distillation. The maximum temperature in the furnace, outside of the crucible, was 840 deg. C. at the end of the distillation period. Much of the sulphur came off at about 725 deg. C. The physical nature of the iron particles seemed to be about the same as before so that apparently the friability results from a complete conversion to the magnetic sulphide rather than from the rate of distillation used.

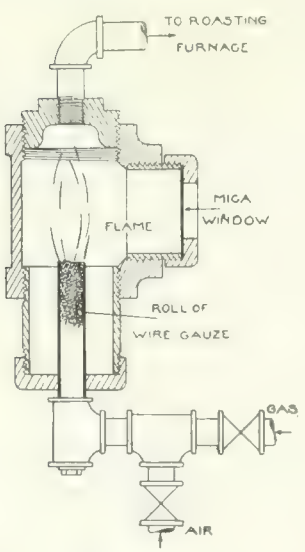

FIG. 1.—COMBUSTION APPARATUS.

It was desired to make some tests using an atmosphere closely analogous to products of combustion as occurring commercially with coal or producer-gas firing. The reason for using these conditions was that there seemed to be a possibility that the roast could be carried out in a furnace of the type of the Wedge, Herreshoff or McDougall, possibly but not necessarily muffle fired, and with a non-oxidizing or at least feebly oxidizing atmospheres in contact with the ore, instead of the strongly oxidizing atmosphere commonly used in the Mathey roasters in Southwestern Wisconsin. The most readily available material was illuminating gas, and in order to get the products of combustion of this and be able to pass them through the small ore drum described an apparatus as shown in Fig. 1 was devised.

The combustion chamber consists of a 2-in. iron tee and the remainder of the apparatus was constructed of suitable iron pipe fittings. A mica window was clamped into the branch of the tee, together with asbestos washers, in order to permit observation of the flame. A roll of wire gauze was tightly packed into the pipe introducing the combustible mixture into the combustion chamber in order to prevent a striking back of the flame. The gas and air were admitted as shown, and were mixed before entering the combustion chamber. The gas was measured by means of a calorimeter gas-meter and the air was measured by means of a gauge as shown in Fig. 2. This kind of a gauge has been found useful in experimental and other work and will therefore be described. It can be used in cases in which the Venturi-meter or Pitot-tube principle cannot be satisfactorily applied. It is not original with the writer. Two glass tees are connected by means of a piece of capillary tubing, the length and diameter of which will depend upon the amount of gas to be measured, the pressure available, and the percentage of accuracy of reading desired. The branches of the glass tees are connected by means of a U tube containing water, mercury, or any suitable liquid.

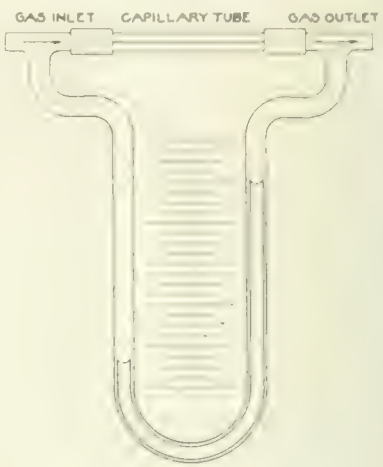

FIG. 2.—GAUGE.

With the apparatus as described, products of combustion of widely varying composition could be obtained. If much air was used the flame would have a pale purple color. As the amount of air is reduced or the gas increased the flame first becomes blue and then turns to a yellowish green color. With a very pale purple flame an analysis showed 8.6 per cent CO_2, indicating a considerable amount of free oxygen. As the air was reduced the percentage of CO_2 went up to a maximum of 15.6 per cent. When the air is reduced still more and the green flame appears, the products of combustion contain CO or other combustibles in sufficient quantities so that the gases leaving the combustion apparatus and ready to enter the roasting drum will burn with a very pale blue flame. If too great an excess is used, either of air or illuminating gas, combustion can no longer take place and the flame blows out.

The gases from this combustion apparatus were introduced into the rotating drum previously described, using an asbestos stuffing box. From one roast that was made the following results were obtained after magneic separation:

Non-magnetic portion:		
Weight obtained	55.8	grams
Per cent of zinc	57.7	per cent
Per cent of iron	3.35	per cent
Magnetic portion:		
Weight obtained	24.6	grams
Per cent of sulphur	42.66	per cent
Per cent of zinc	1.8	per cent

It is evident that the intensity of the magnet was not adjusted quite strong enough, that is, the grade of zinc ore would have been improved by removing a little more material from it which could readily have been done by adjusting the magnet to a greater strength, and this would probably not have resulted in an undue amount of zinc in the non-magnetic portion. The ore used in this test was a different one to that used in the previously described tests and in this instance all sizes through 10 mesh were treated in the separation.

It was desired to get a rough quantitative idea of the relative degree of magnetization of ore roasted by two different methods. The method used may not be one of the highest accuracy, but is found suitable for the purpose.

A large laboratory balance, not enclosed in a glass case, was used. The scale pans, which were of steel, were removed

and the ore put into a shallow cardboard box about 2 in. x 3 in. and ½ in. deep. A strong electro magnet was placed directly beneath and in contact with the two flat pieces of brass upon which the scale pan usually rests.

The cardboard box was filled level with ore and weighed. The current was then turned on the electro magnet and additional weights added up to the point at which the magnet would just hold the box full of ore down, and at which an additional 1/10 gram would pull the box full of ore away from the magnet when the two were in contact.

The following data were obtained:

	Weight of ore taken, grams	Apparent weight with current on magnet	Pull of magnet, grams
Sample No. 1:			
On 10 mesh	107.8	127.4	19.6
10-20 "	105.1	118.4	13.3
20-40 "	115.5	128.1	12.6
Through 40 mesh	115.0	138.7	23.7
Sample No. 2:			
On 10 mesh	133.6	136.9	3.3
10-20 "	119.0	126.2	7.2
20-40 "	110.1	116.1	6.0
Through 40 mesh	104.7	108.9	4.2

This table indicates that sample No. 1 is attracted about three times as strongly as sample No. 2. The variation in the attractability of the different sizes of the same ore is due to a variation in the relative quantities of magnetic and non-magnetic material.

A point noted in all of the tests, even in those in which a satisfactory magnetic separation could be made, was a considerable non-uniformity of the degree of magnetization of the particles. Even with particles of almost the same size, and of apparently uniform composition throughout the grain, that is non-chatty particles, the distance at which some particles would be attracted was usually three or four times that at which others would be attracted, indicating a ratio of attractability of 1 to 9 or 1 to 16.

Conclusion.—These laboratory tests indicate that, after a light roast in any atmosphere which is not strongly oxidizing, there is every probability that a magnetic separation of zinc-iron ore as occurring in southwestern Wisconsin can be satisfactorily carried out without losing so much sulphur that the iron tailings are no longer of value to acid manufacturers.

This work is not complete at this time and it is not desired to attempt to draw conclusions as to the commercial applicability of the results. It is desired merely to point out what has been observed as to the manner of behavior of zinc-iron ores under the various conditions worked with, and to make note of the apparatus that has been found useful for the experimental work.

Northern Chemical Engineering Laboratories, Madison, Wis.

The great bulk of Mexican sulphur is produced from mines near Cerritor, in San Luis Potosi, about 50 miles east of the capital of that state. The production is about 800 metric tons of refined sulphur per month. Tne ore carries from 37 to 90 per cent sulphur, and is refined by the steaming process.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in January, 1912, was sixty-eight. The total tonnage milled during that period was 2,114,394 tons of ore; 10,068 stamps were in operation with an average duty of 7.92 tons per twenty-four hours. Tube mills in commission numbered 257. The yield for the month was 737,060 fine ounces gold. Compared with the report for the corresponding month of 1911, this report shows an increase of 367 stamps and fifty-five tube mills in operation, and 86,000 fine ounces additional gold recovery.

The Camp Bird, Ltd., owning the Camp Bird mine, Colorado, and the Santa Gertrudis, Mexico, both gold mines, has recently entered the copper mining field by taking an interest in the Messina Development Company, Transvaal, South Africa. Three of the directors of the Camp Bird are directors also of the Messina company.

The Electric Zinc Smelting Furnace.

By Charles F. Johnson

It has been well said that zinc is a peculiar metal. Its chief peculiarity consists in the fact that the temperature at which zinc oxide is reduced by carbon is over 100 deg. C. above the temperature at which the metal boils. A second peculiarity is the avidity with which this gas takes hold of oxygen in even weak oxidizers as carbon dioxide and water vapor. For these reasons zinc ores are roasted, mixed with carbonaceous material and charged into small fireclay retorts equipped with condensers. Here the oxide is reduced and the emanating gas passes into the condensers and is condensed into metal more or less perfectly.

There are some 90,000 retorts in this country, each with an average daily production of 17 lb. of metal. The natural result is that a high cost of conversion is charged against each ton of spelter. Including metallurgical losses of zinc, lead, copper, gold and silver, the cost of smelting a ton or zinc ore

FIG. 1. TAPPING SPELTER.

ranges from $20 to $30. As it takes, on average, over 2.5 tons of ore to make 1 ton of metal the conversion cost, with all charges included, is from 2 cents to 4 cents. The obvious reason is the small unit—the 50-lb. retort.

It is a usual saying among metallurgical engineers that zinc metallurgy has made no progress in the last 100 years. While it is true that there has been progress in the way of regenerative furnaces, mechanical roasting kilns, hydraulically pressed retorts, and in ore-dressing, yet the retort of Abbe Dony still holds sway and there is a large percentage of truth in the part-truth that the metallurgy of zinc has stood still for many past years.

In the metallurgy of lead, copper and iron the cost of treatment has been materially cheapened by enlarging the capacity of furnaces and by instituting labor-saving devices. The cost of treating a ton of copper ore has been so reduced that it is now possible to treat copper ores in the blast-furnace so low in copper content as to be regarded in the nineteenth century as good "dump-slags."

What modern industrial conditions demand is a unit capable of such expansion in size that the highest-priced labor can be afforded with the result that the work it performs is highly efficient. In 1893 the average copper furnace smelted 50 tons of ore per day. Now 500-ton furnaces are not considered large, and the celebrated Anaconda furnace smelts some 2500

tons of ore. The same increase has been seen in the metallurgy of lead, iron and steel.

Mr. W. McA. Johnson saw in 1903 very clearly that the electric furnace which put the heat inside firebrick exactly where it is needed and where no air could get at it was in view of the above evolutionary tendency the logical way to meet modern demands.

The economic geological conditions he thought then were equally favorable. For a great many years more zinc has been wasted over the dump in form of slag by the lead and copper smelters than has been used as spelter in the mechanic arts. The amount of these so-called refractory ores with a gross value of $25 to $40 per ton, now valueless, is enormous in the great mining states. Mr. B. B. Thayer, president of the Anaconda Company, is responsible for the statement that Butte will ultimately be as important a factor in the zinc business as it has been in copper business.* It is generally considered by well-informed mining men that there are at least $75,000,000 gross value of these complex sulphides in the upper levels

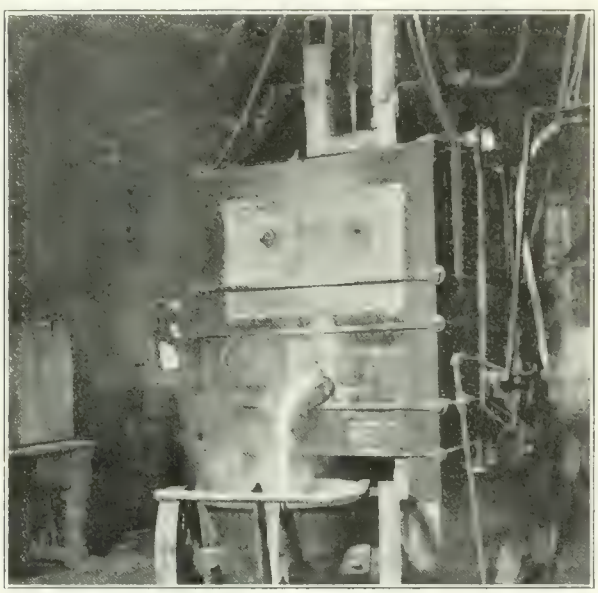

FIG. 2 TAPPING SLAG.

of the Butte Camp. Mr. Johnson's idea has been to make these ores now valueless commercially available by his invention.

Mr. Johnson, as a young man of twenty-six, recognized that the logical solution of the zinc problem was the electric furnace if propertly applied and developed. He had especially suitable training, having studied as an electrical engineer and having done some creditable work in that line. He had also studied physical chemistry under Professor Nernst at the University of Göttingen. Undoubtedly the chief factor in his success was his experience under Col. Robert M. Thompson, president of the Oxford Copper Company, investigating new metallurgical processes in the light of practical economics.

Mr. F. E. Drake, who had been engaged in the electrical business previous to becoming in 1903 president of the Lanyon Zinc Company, was impressed favorably with Mr. Johnson's ideas, and Mr. Johnson was engaged as head of the research department of that concern. He finally was put in charge of the No. 2 Works, where he increased greatly the tonnage and recoveries by the application of the principles of physical chemistry.

Simultaneously he was engaged in experiments in electric zinc smelting. The first work was on a reverberatory resistance type furnace. This was early abandoned as impractical. The next move was a resistance furnace with the charge carrying the current. The idea was simply a glorified and improved retort. The earlier furnaces were intermittent, but finally a continuous type of furnace was invented. Most of this work was done with a dry charge and some very good condensation was effected.

In December, 1904, Mr. Johnson left the Lanyon Zinc Company as it was unwilling to go on with the work in electric smelting. Since then he has been giving all possible time and attention to the work of designing furnaces and testing them out with regard to their commercial future.

One of the first ideas was the use of a condenser with a shower of metallic zinc as the condensing agent. This was perfect from a theoretical standpoint, but tests seemed to show it to be less practical than an earlier idea of using a still surface of metal. As the latter scheme gave very positive results and possessed certain decided practical merits, it was co-ordinated with another early furnace wherein the mineral impurities were eliminated as a fusible slag and wherein lead bullion and a copper matte were produced.

This, of course, gave great commercial promise as the lead, copper, gold and silver were recovered necessarily with the elimination of the zinc and it was not necessary to heat up excess of coal. There were certain difficulties, the chief of which were the formation of CO_2 in the smelting zone. The percentage of CO_2 that can co-exist with zinc vapor varies with the temperatures according to known laws of physical chemistry. Practically speaking, this results in oxidation during the condensation of the zinc vapor with the production of blue-powder in the condenser, in a furnace that uses no excess of carbon. For the superficial film of zinc oxide on the condensing particles prevents them coalescing. To obviate this Mr. Johnson passes these gases through an electrically heated carbon filter whereby the carbon dioxide is reduced to the innocuous carbon monoxide.

Now it is well known that electrical heat is expensive. An electrical hp-year has almost the same number of calories that a ton of good coal has. Coal costs wholesale from $1 to $3 in most well-located centers and in places as high as $7.50 per ton. An electrical hp-year costs from $15 to $40 for a 24-hour load. It will be thus seen that an electrical calorie costs at the cheapest about what twice the most expensive coal calorie costs. Accordingly electrical heat cannot compete with coal heat unless its efficiency is several times greater or unless it has greater convenience and decided metallurgical advantages. Indirect heating by fire gases has at low temperatures a high efficiency (*e. g.*, in boilers, 60 per cent to 70 per cent), but the efficiency decreases rapidly as the temperature increases. To secure a high commercial efficiency it is necessary to utilize the ratio between the dollar and the calorie so that the average commercial usufruct shall be a maximum.

Accordingly the charge in the Johnson process is heated to about 900 deg. C. in a continuous preheater. Then the highly convenient and highly efficient electrical heat completes the work to 1300 deg. C. A heat balance-sheet shows that such an operation under above conditions has thermal requirements of 840,000 calories per 1000 kg of roasted Joplin ore (70 per cent zinc) or 890 kw-hours per short ton of roasted ore. With a low-grade ore (30 per cent zinc) making 25 per cent slag and 16 per cent lead and matte the theoretical net thermal requirements amount to only 436 kw-hours per ton of roasted ore. The Johnson electric zinc furnace will thus probably smelt low-grade zinc ore cheaper than it will high-grade zinc ore. It, therefore, has quite a different bearing on the question of ore concentration methods than has a retort furnace where cost increases as tenor of zinc decreases.

There are several factors, such as losses in busbars, radiation and cost of treating between products such as foul slag, flue dust and blue powder, that increase the power needed. An estimate of the power needed in commercial units for a 30 per cent. ore is 800 kw-hours per short ton roasted 30 per cent.

*This remark [illegible] special [illegible] developments in the [illegible] general metallurgy [illegible]

and 1400 kw hours per short ton 70 per cent roasted ore. The thermal efficiency should be higher in the case of high grade ore because the strongly endothermic reduction of zinc oxide tends to keep the smelting zone at a lower and more equitable temperature, or, in other words, to absorb heat more rapidly and efficiently. This has been found to be actually the case in the work at Hartford.

With care in smelting and operating the condenser, and when these are under firm control the much-dreaded blue-powder causes but little trouble in the Johnson furnace. The best record at this writing at Hartford is 390 lb. of metal and 11 lb. of blue-powder. In commercial practice the amount of blue-powder will be proportioned to secure the best economic results, a maximum of condensing output with a minimum of blue-powder. A certain amount of flue dust is made. This is caught in a chamber and returned to the smelting furnace. By running the furnace slowly and carefully this can be reduced to a low figure, but slow running means lower thermal efficiency. Here also the point of proper commercial balance comes in, as it does in condensing, by separating the heavier zinc gas from the lighter carbon monoxide, and as it does in the question of making slags high or low in zinc.

The Johnson electric zinc furnace metallurgically speaking lies between a lead blast-furnace and an iron blast-furnace. This neat comparison was first made by Prof. H. O. Hofman of the Massachusetts Institute of Technology. It makes a slag too low in iron oxide to be fusible at the temperature of the lead furnace and too high in iron oxide to be a good blast-furnace cinder. A typical slag analysis is SiO_2, 40%; CaO, 22%; MgO, 2%; FeO, 10%; MnO, 1%; Al_2O_3, 10%; ZnO, 2%; Cu, 0.15%; Pb, 0.05%; Ag, 0.30 oz. per short ton.

Slags lower than this in zinc, copper and lead have been made, but the above is low enough for a commercial slag.

As in a lead-furnace, the precious metals find their way largely into the lead bullion. If no lead is present, they concentrate in the matte. The composition of this depends on the relative amounts of copper, iron and sulfur. The ore is roasted usually to 3 to 6%, depending on amount of copper present. The general idea is to make as high-grade matte, as far as is consistent with ease of roasting. As the reduction is so much more intense than in a lead furnace the percentage of lead in the matte is much smaller than in the lead furnace. A typical matte analyses: Fe, 45%; Cu, 25%; S, 29%.

The metal made in the Johnson process varies considerably, somewhat according to the amount of lead in the ores, but principally according to the temperature conditions. Metal as low in lead as 0.15% has been made. The usual average is now when working on an ore containing 8% Pb, 1.30% Pb. The percentage of iron varies from 0.15% to 1.00% as iron is absorbed from the condenser, which is of iron. Speaking generally, there are great commercial possibilities in the manufacture of spelter in electric furnace, suitable for making cartridge brass.

Mr. Johnson and his experts consider that they are now measurably near to the commercial stage. The future problems are those of an engineering nature rather than an inventing nature and his recent results are so consistently good and advance to a present unit of 80 kilowatts from his 40-kilowatt unit accomplished so much that it is thought that advance to a unit of 200 or 300 k.w. will be correspondingly easier.

In the June issue detailed accounts of some of the longer tests, which are now being made, will be given.

Hartford, Conn.

International Electrical Units.

A report to the International Committee on Electrical Units and Standards by a special technical committee appointed to investigate and report on the concrete standards of the international electrical units and to recommend a value for the Weston Normal Cell has been prepared under the supervision of Dr. S. W. Stratton, director of the Bureau of Standards, Department of Commerce and Labor.

The International Technical Committee assembled at Washington under the presidency of Dr. Stratton, who is also treasurer of the International Committee.

The committee unanimously elected as chairman Dr. E. B. Rosa, Physicist of the Bureau of Standards, and secretary of the International Committee. Other members are: Dr. W. Jaeger, Geheimer Regierungsrat, Mitglied der Physikalisch-Technischen Reichsanstalt; Prof. F. Laporte, Sous Directeur du Laboratoire Central d'Electricité; Mr. F. E. Smith, principal assistant, National Physical Laboratory, and Dr. F. A. Wolff, associate physicist, Bureau of Standards. Dr. F. W. Grover was appointed secretary for the preparation of the minutes and records.

The committee conducted experimental work at the Bureau of Standards for a period of two months, and carefully considered the results. The conclusions and recommendations are contained in the following resolutions:

(1) The committee decides to choose as the value of the Weston Normal Cell the mean value of the cells presented by the delegates of the four laboratories. This mean was determined in the following way: There was first determined the mean value of the normal cells presented by each delegate, then the mean was taken of the four numbers thus found.

(2) The committee decides to choose, for the present and until there are other mercury ohms prepared, as the value of the international ohm, to be recommended to all countries for general use, the mean of the values of the units realized at the Physikalisch-Technische Reichsanstalt and at the National Physical Laboratory. Although the international ohm as defined by the London Conference has not yet been strictly realized, the committee believes that its value has been attained in two laboratories independently with a good degree of precision, and that future work is not likely to change it by more than 2 or 3 parts in 100,000.

(3) In view of the fact that the mean of the results with the silver voltameter obtained by this committee will probably not be changed by more than a few parts in 100,000, when the specifications are finally completed, the committee decides to recommend to the International Committee on Electrical Units and Standards the following value for the electromotive force of the Weston normal cell:

$$E = 1.0183 \text{ international volts at } 20 \text{ deg. C.}$$

On the subject of the standard cells, the committee is of the opinion that new experiments are necessary before completing or changing the specifications of the London Conference.

On the subject of the ohm, the committee expresses the hope that new international ohms, fulfilling all the specifications of the London Conference, may be realized soon in different laboratories.

On the subject of silver voltameter, the committee is of the opinion that the specifications for the silver voltameter should not be completed until further experiments shall be made by the members of the committee in their respective laboratories on subjects which are not considered settled at the present time, and that after these experiments the committee shall complete the general specifications.

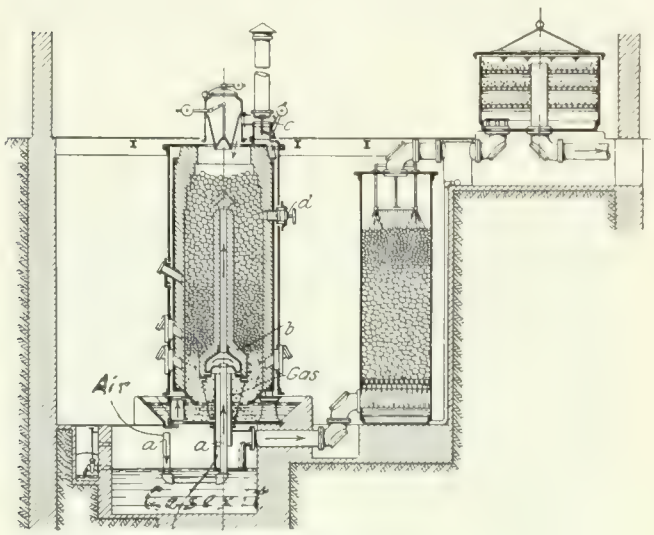
Peat Gas Producer and Peat Gas Engine.

An abstract of a paper of CARL HEINZ giving the following description of a peat gas producer of the Goerlitzer Maschinenbauanstalt and the use of the gas in a peat gas engine, is given in *Stahl und Eisen*, 1911, Aug. 17, p. 1350.

Air and fuel enter the producer at the top and the gas exit is in the center of the bottom so that the air is forced to pass through the center of the producer decomposing the volatile matter into gases of calorific value. The moisture which is

present in the peat fuel in considerable quantities must be taken into consideration. For its decomposition while passing through the hot-fire zone only a certain amount of heat is available. It is, therefore, important that the heat from the gasification be fully utilized.

There are two kinds of heat losses in a gas producer, due to radiation and to the sensible heat of escaping gases. Both these amounts of heat, however, are utilized according to the special design of this producer. The air circulates first through the lower conduit and comes so in contact with the warm scrubber water. A part of the air which has been preheated is carried upwards through the pipe *a* in the center of the producer where



PEAT GAS PRODUCER

it is thoroughly preheated by the hot gases and enters then the air superheater *b* in which the temperature rises to a still higher degree.

The other part of the air passes through the feet of the producer into an air jacket which envelops the whole shell of the producer and enters finally the producer by the reversing valve *c* on top of the producer. In this way the outer surface of the producer is maintained at a temperature hardly higher than that of the surrounding air. The escaping gases are cooled down so far that the gas outlet into the scrubber may be touched by hand. All ordinary heat losses are thus made use of in the gasification process.

If there is a large excess of moisture in peat, the process is somewhat modified by regulating both air supplies in such a way that the gasification in the upper part of the fuel-bed takes place in two directions, one downwards and the other upwards.

It seems that a content of 80 per cent moisture and 20 per cent dry fuel in the peat is about the limit permitting the evaporation of the water, but it is, of course, impossible to obtain in this case a gas of calorific value.

The modification of the process for very wet fuel is as follows:

When the fire on top of the fuel bed appears to disappear, the heater opens the stack and valve *d*. Valve *c* is then closed, to prevent air from entering on top. The preheated air enters by *d* causing a down draft combustion due to the suction of the gas engine and an upward combustion due to the draft in the stack. The moisture is evaporated and escapes through the stack. When the fire has burned through at the top, the valve is switched over. The bad smelling gases rising from the scrubber enter the producer together with air and are there consumed.

In commercial use at last year's exhibition in Posen the whole plant worked continuously day and night and cleaning of the gas engines was necessary only every three months. Slagging of ashes is done during the operation of the producer, without any nuisance from dust.

In the same issue of *Stahl und Eisen* page 1345, there is an illustration of the peat gas engine at the Exhibition just mentioned and some figures are given of the results obtained. The highest percentage of moisture in peat gasified was 50 per cent. The fuel consumption per horsepower hour is 2.2 lb. (1 kg.) of peat. Careful tests made by Prof. Baer, of Breslau, showed that with a cost of peat of $1 per ton the kw-hour at the switchboard costs 0.15 cent. R. J. W.

The Retirement of W. D. Weaver from the Active Editorial Direction of Electrical World.

Announcement has just been made of the retirement of Mr. W. D. Weaver from the active editorial direction of *Electrical World*. He will maintain his connection with *Electrical World*, however, as consulting editor.

As a token of the esteem in which he is held, some of his immediate personal friends and his journalistic associates gathered at the Engineers' Club, New York, at a luncheon served on April 29. Mr. James H. McGraw acted as toastmaster. Among the speakers who expressed their sincere appreciation of the honorable editorial career of Mr. Weaver, his advocacy of the best in technical journalism and his helpful constructive influence in electrical engineering development, were his editorial predecessors: Mr. T. C. Martin, Dr. L. Bell, Dr. Carl Hering, further Mr. B. A. Behrend, Mr. J. J. Carty, Mr. John R. Dunlap, Mr. W. C. Elgin, Mr. Gano Dunn, and Dr. A. S. McAllister. As a memento of the occasion the associates of Mr. Weaver in the McGraw Publishing Company presented him with an appropriately engraved watch, chain, and fob.

Mr. Weaver is a graduate of the U. S. Naval Academy and served in the navy for 12 years. His career as electrical engineering editor began in 1893, when he became editor of the original *Electrical World*. In 1896 he enlisted the aid of Mr. James H. McGraw in the foundation of the *American Electrician*, of which Mr. Weaver was the first editor. In 1899 when the *Electrical World* and *Electrical Engineer* were consolidated, he became editor of the combined paper, which position he has held continuously up to the present time, the name of the paper having been changed to the present one of *Electrical World* after the absorption of the *American Electrician* in 1896. An interruption in his editorial service occurred during the Spanish-American War, when he served as volunteer chief engineer on the U. S. S. Glacer.

Through the retirement of Mr. Kirchhoff from *Iron Age* and of Mr. Weaver from *Electrical World* in such a short succession, technical journalism has lost two of its strongest and most successful editors.

While little can be said here of Mr. Weaver's literary predilections nor of his fondness for bibliography and his collection of books and publications on the French Revolution, yet a word on the hard work which he has done in the interest of electrochemistry should not be omitted at this place. He was one of the organizers of the American Electrochemical Society and during a number of years, in its early life, served on its Board of Directors and did a great deal of active work in the framing of the constitution and the organization of the society.

When it had been suggested to *Electrical World* to start an electrochemical supplement he saw right away that this would be a wrong policy and that when the psychological moment came the thing to do was to start a specific electrochemical journal. Mr. Weaver interested Mr. McGraw and with their co-operation *Electrochemical Industry* came into existence in 1902. Its editor has always found in Mr. Weaver a good friend, who unhesitatingly extended his aid when needed and gave his advice when asked. This journal cordially joins the many admirers of Mr. Weaver in wishing him godspeed and many years of happiness in the circle of his family and of his friends.

Boston Meeting American Electrochemical Society.

The twenty-first general meeting of the American Electrochemical Society held in Boston, Mass., from April 18 to 20, may be looked upon as the celebration of the tenth birthday of the society, which was founded on April 3, 1902, in Philadelphia. The Philadelphia meeting ten years ago was so enthusiastic that no seventh son of a seventh son was needed to predict for the society the glorious career which has since become history.

While the society has grown wonderfully in number of members and fields of activity, the Boston meeting showed that the spirit of youthful enthusiasm has remained exactly the same as in the olden days. While ten years ago good-natured, yet sharp controversy centered informally around the ionic dissociation in solutions, it was in Boston the theory of electrons in gases and metals which was discussed and disputed with equal fervor during two long sessions taking a whole day. The symposium on electric conduction, brilliantly arranged by President W. R. WHITNEY, was indeed the most characteristic feature of the Boston meeting.

And the whole meeting was arranged in an equally excellent style, so that the frightful weather during the first two days could not spoil in the least the enjoyment of the meeting in intellectual Boston. The greatest credit for the success is also due to the never-resting and never-tiring secretary of the society, Dr. J. W. RICHARDS; to the strenuous chairman of the committee on papers, Mr. F. A. LIDBURY, and to the local Boston committee, with its always courteous and active chairman, Dr. WILLIAM H. WALKER.

The number of members and guests who registered was 167, and at all professional sessions the attendance was well above 100 and the interest was never lagging.

W. LASH MILLER, PRESIDENT AMERICAN ELECTROCHEMICAL SOCIETY.

An alphabetical list of those who registered, as well as an account of the social functions and excursions is given at the end of this report.

Business Meeting.

The first session was held on Thursday, April 18, in the Chemical Lecture Room of the Lowell Building of the Massachusetts Institute of Technology. The president, Dr. W. R. Whitney, called the meeting to order at 9:45.

The secretary, Dr. J. W. Richards, presented the annual report of the board of directors. The society is in an excellent condition, both as respects to membership and finances. The number of members is now 1,377, the net increase during last year being 110. The assets of the society in cash and bonds on Jan. 1, 1912, amounted to $5,865.34, as compared with $4,565.74 a year ago.

A special feature of the report was the announcement that at the meeting of the board of directors the night before, the board appropriated the sum of $250 for aid of experimental research. If successful this appropriation is intended to be made annually.

The results of the election of officers was then announced as follows:

Dr. W. Lash Miller, of the University of Toronto, is the new president.

Messrs. F. A. Lidbury, E. R. Taylor and L. H. Baekeland were elected vice-presidents.

Messrs. E. F. Roeber, L. E. Saunders and L. Kahlenberg were elected managers.

Dr. Joseph W. Richards was re-elected secretary, and Mr. P. G. Salom treasurer.

Uniformity and Simplicity in Electrochemical and Electrothermal Calculations.

The first paper in the professional session, which followed the business meeting, was presented by Dr. CARL HERING, of Philadelphia, Pa., on the above subject.

To get uniformity and simplicity in electrochemical calculations, Dr. Hering suggests to use as practical units some decimal multiple of the corresponding absolute unit, following the lead taken by electrical engineers.

His first specific suggestion is to represent all power, no matter in what form it is, in terms of watts or kilowatts and to do away with calories per second, B.t.u.'s per minute, etc.

His second recommendation is to measure all forms of energy in watt-hours, kilowatt-hours, instead of calories, B.t.u.'s, etc. This means that all specific heats, latent heats, "heats" of combination, etc., should be in watt-hours or kilowatt-hours instead of in thermal units, thereby avoiding all conversion factors.

The third recommendation is to adopt as a unit of thermal resistance the "thermal ohm," that is, that resistance which causes 1 watt of heat current to flow when the difference of temperature at its two ends is 1 Centigrade degree. (See the author's paper in our Vol. IX, p. 13, 1911; a table of thermal resistivities of numerous substances in the new unit was given by the author in our January issue of the present Vol. X, p. 43, 1912.)

The author's fourth recommendation is to urge the use of the Centigrade scale to the entire exclusion of the Fahrenheit.

The chief conversion factors to and from the author's simplified system are as follows:

Power:

1 watt = 0.238882 gram calories per second.
1 gram calorie per second = 4.18617 watts.
1 watt = 0.0568776 B.t.u. per minute.
1 B.t.u. per minute = 17.5816 watts.
1 kilowatt = 14.3329 kilogram calories per minute.
1 kilogram calorie per minute = 0.0697695 kilowatt.

Energy:

1 watt-hour = 0.859975 kilogram calorie.
1 kilogram calorie = 1.16282 watt-hours.
1 watt-hour = 3.41266 B.t.u.
1 B.t.u. = 0.293027 watt-hour.

Thermal Resistance:

1 thermal ohm = 4.18617 gram calorie units of resistance.
1 gram calorie unit of resistance = 0.238882 thermal ohm.
1 gram calorie unit of resistance = reciprocal gram calorie unit of conductance.

(A gram calorie unit of conductance is a conductance which permits a flow of 1 gram calorie per second per degree.)

[illegible]

1 thermal ohm, inch cb. unit = 1.8[illegible] gram cal., cm. cb. units.

1 gram calorie cm. cb. unit = 0.238882 thermal ohm, cm. cb unit.

1 thermal ohm, inch cb. unit = 2.54001 thermal ohm, cm. cb. units.

1 gram calorie, inch cb. unit = 2.54001 gram cal., cm. cb. units.

To reduce thermal conductivities given in B.t.u. per hour, per square foot, per inch thickness, per Fahrenheit degree, to thermal ohm, inch cube units, multiply the reciprocal of that number by 273.013.

In the discussion which followed, Messrs. Griffin, Richards, and Whitney participated. Dr. Whitney said that while the metric system was gaining all the time, yet manufacturers could not be expected to throw away what they have and to go over to the metric system right away. In the meantime it will be well to give in papers all values both in the old and new units.

Temperature Variations of Thermal Resistivities.

A second paper, by Dr. Carl Hering, discussed the effects which the variations of thermal resistivities with the temperature have on the calculation of the heat flow through furnace walls. For the purposes of analysis it is necessary to assume some law for this variation. Dr. Hering assumes as an approximate law that the thermal conductivity increases at the rate of 1/273 part for every degree C. above 0 deg. C., or in other words, that the thermal conductivity is proportional to the absolute temperature.

If the two sides of a furnace wall are maintained at certain temperatures, the temperature in the wall drops gradually from the inside to the outside and according to the different temperatures the thermal conductivity varies from point to point. Now Dr. Hering shows analytically that it is correct to assume for the whole wall a certain mean resistivity or mean conductivity over the whole range of temperature in the wall and that "the proper mean value of the thermal resistivity or conductivity for the conductor as a whole, is the value for the mean of the two extreme temperatures. The mean of the two extreme values of the resistivity would give a far too high resistance; but for conductivities this mean is correct.

"This applies not only to conductors of uniform section, but also to those that flare like the parts of cubical or sperical shells."

In an addendum it is stated that Dr. Horace Clark Richards has found the following general rules:

"The correct value of the equivalent constant conductivity to use in calculating the resistance of a conductor is the arithmetical mean of its values at the ends, not only for the cases of uniform section and uniform spherical (or cubical) flare, but for a conductor of any form whatever, provided that the surface, except the ends, is insulated.

"The same law is applicable when the conductivity is any linear function of the temperature as $k = k_0 + at$, and therefore is the correct approximation when the law is not more exactly known.

"In general, when the conductivity varies with the temperature according to any law, the equivalent conductivity of the conductor is the temperature-average of its conductivities, i.e., if a curve is plotted with temperatures as abscissas and conductivities as ordinates, the proper value is the average ordinate of the curve.

"Of course, all this applies equally to electrical conductivity."

In the discussion which followed, Mr. Fitz Gerald pointed out that while a theoretical discussion of this kind is a useful guide in the designing of furnaces, yet it is necessary to be very cautious about accepting mathematical calculations based on theoretical considerations only, without checking the results by experimental work. He referred to a statement of Queneau: "The great value for heat insulation purposes of silica brick when burned at a moderate temperature, 1050 deg. C., is [illegible] the fact that their coefficient of heat conductivity is practically equal to that of kieselguhr brick and only one-half that of clay brick." While some silica brick may be good heat insulators, yet this is not general, as shown in Mr. Fitz Gerald's paper abstracted below.

Mr. Fitz Gerald also mentioned an experiment the result of which could hardly have been expected on theoretical grounds. That is that the heat losses of a certain furnace with walls 63 mm. thick were practically the same as the heat losses from the same furnace with walls 126-mm. thick, as long as the temperature was within certain limits. The conditions of this experiment were complicated. There were three factors; radiation, convection, and conduction. The radiating surface with the double walls was, of course, much greater than with the single wall. The probability of losses by convection currents through joints in the bricks were less with the double wall. The temperature gradients, were, of course, different in the two cases. The conductance was seriously modified in the case of the double wall by the resistance of the surface contact between the inner and outer walls and so forth.

In view of these complicated conditions it is unsafe to depend on calculations based on present data, and it is, therefore, necessary to depend on experimental results.

Dr. J. W. Richards referred to the resistivity figures given in Mr. Randolph's paper (see below) and pointed out that the assumption of the thermal conductivity being proportioned to the absolute temperature was fulfilled in the case of one material only.

Dr. W. Lash Miller sketched a very simple and general method of treating the whole mathematical problem with the aid of calculus.

Dr. Carl Hering emphasized the usefulness of fundamental laws. As to Mr. Fitz Gerald's experiment he said that the peculiar result obtained was a combination of internal resistance and surface resistance, and the latter factor seemed to have been of very great importance; it would be desirable to separate the effects of both factors. In the case of steam boilers the thermal resistance is almost entirely a surface resistance; this is the reason why copper and iron give practically equally good results in spite of their different thermal conductivities. For temperature measurements on the furnace surface Dr. Hering suggested the use of graded waxes with known melting points.

Dr. Thwing, referring to the last suggestion, said that by covering the surface with wax the condition of the surface was changed and this would have an effect on the temperature measurement. Dr. Whitney said that waxes had no definite melting points. Dr. Richards thought that easily fusible alloys would be more practical, but Dr. Thwing said that they had no definite melting points either.

Mr. Duschak pointed out that touching a surface with a thermometer may cool the surface and cause an error.

Dr. Richards stated he had found Thwing's radiation pyrometer method very satisfactory down to 100 deg. C.

Mr. Richardson thought melting wax was cheap and so were alloys, but they were of no use for proving fundamental laws. Dr. Hering replied that at present we have practically no experimental data and that any results, even if not of highest accuracy, must be useful.

In reply to a question of Mr. Sadtler how low temperatures could be measured by the radiation pyrometer, Dr. Thwing said that there was no trouble in going low down, but it was necessary to have a sufficiently large surface. The advantageous range of the use of the radiation pyrometer was, of course, the region of higher temperatures.

Dr. Bray suggested for the measurement of the temperature of furnace surfaces the use of thermo-couples, always properly embedded within the surface.

Experiments on Heat Insulation.

A paper by Mr. F. A. J. Fitz Gerald, of the Fitz Gerald and Bennie Laboratories, of Niagara Falls, N. Y., gave a pre-

liminary account of an experimental investigation of different heat-insulating materials as to their relative suitability for furnace insulation.

In all experiments the insulating material is in form of bricks and a furnace is always built up from the bricks in the same way (the design and dimensions being given in the paper). The furnace is closed and heated electrically from the inside by means of a nichrome resistance wire. By means of a rheostat the current through the resistance wire and therefore the temperature, can be regulated.

Readings are taken when for a given current a definite temperature has been reached in the furnace and remains perfectly constant. The rate of generation of energy in the resistor is then determined and this gives the rate at which heat is escaping through the furnace walls, neglecting what escapes by conduction through the leads going to the resistor and through the wires of the pyrometer thermo-couple.

From the data obtained in this way curves are plotted in which the abscissas are temperatures and the ordinates watts. These are shown in Fig. 1.

Curve 2 in Fig. 1 is a fire brick of moderately good quality, that is to say, it is not of any special make

Curve 4 in Fig. 1, is for a silica brick. In spite of its low heat conductivity this particular silica brick is not a satisfactory

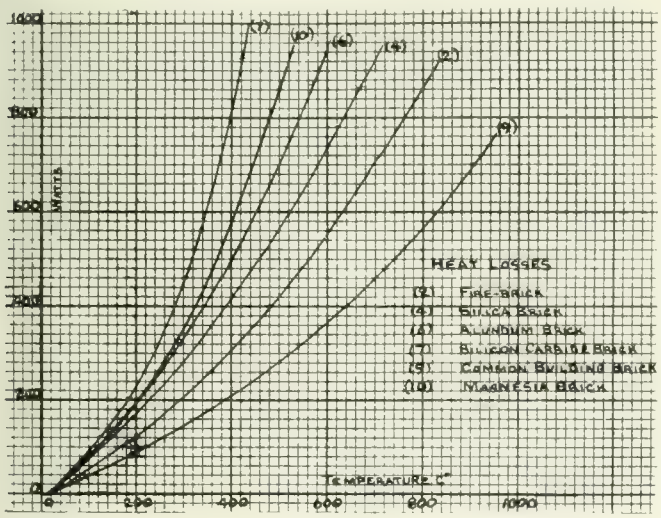


FIG. 1.—HEAT LOSSES WITH DIFFERENT REFRACTORIES.

insulator. The maximum temperature reached with the silica brick was 670 deg. The heat loss here was 36 per cent greater than with the fire brick. It is not very safe to theorize as to the cause of this phenomenon, but it looks as though the radiation from the surface of the silica brick is very much greater than from the ordinary fire brick.

Curve 6 was obtained from an alundum brick, one of the highly refractory ones made by the Norton company. The transmission of heat was so rapid with this brick that the maximum temperature obtained in the furnace was only 570 deg. This illustrates well the value of such alundum refractories as crucibles, muffles, etc., where it is desirable to have as efficient transmission of heat as possible.

Curve 7 relates to a brick made of silicon carbide. The brick is pure silicon carbide, that is, no bond is used in making it. The transmission of heat is extremely good with this brick so that the maximum temperature reached in the furnace was only 420 deg.

Curve 9 is that for an ordinary red building brick of the cheapest kind. It is seen to be the best insulator of any of this lot, the heat losses being as much as 34 per cent less than those for the fire brick (2) at a furnace temperature of 800 deg.

Curve 10 shows the results obtained with a magnesia brick. This was of a standard kind made of brown magnesia.

In another experiment the furnace was built first with the ordinary fire brick (No. 2) and afterwards the same furnace was entirely covered with a 25 mm. (1 inch) thickness of a special heat-insulating material supplied by a well-known manufacturer. This material reduced the heat losses by more than 50 per cent.

Another experiment showed that the use of a special insulating brick instead of ordinary fire brick reduced the heat losses by 68 per cent.

In the discussion which followed, Dr. Hering agreed that empirical data were so much lacking as not to permit furnace design from fundamental laws, but he pointed out that it was necessary to study analytically fundamental laws in order to interpret the results of experimental practice correctly.

Dr. Whitney emphasized that surface resistance was very important and Mr. Fitz Gerald added that heat connection was also very important. Mr. Kohn referred to the effect of packing granular insulating material, for instance, the changes of thermal conductivity when magnesia packs. Mr. Fitz Gerald agreed that the cellular structure was, of course, very important.

Thermal Resistivity of Insulating Materials.

A paper on this subject, by Mr. C. P. RANDOLPH, is an account of an investigation carried out in the research laboratory of the General Electric Company. An apparatus is described in detail which was designed for carrying out a large number of thermal-resistivity measurements on compressible materials, such as lampblack, magnesia-asbestos, etc.

The material is pressed between two copper plates, one heated by electricity to the desired temperature, the other cooled by water. The apparatus is described in great detail in the paper and the special advantages claimed for the apparatus are that the contact resistance is eliminated, that the effect of side losses is eliminated, and that no formula for a special geometrical shape has to be used.

A standard compression for powdered and fibrous materials of low density was adopted, viz., the material was packed as much as possible by tapping the thickness measured, and the material then compressed 25 per cent of the thickness it assumed when tapped. Unless otherwise specified, this is the condition which determines the densities given below.

The values of resistivities are given in Table I (p. 288) in "thermal ohms," calculated per inch cube and per cm. cube.

T = temperature of the side at which the heat enters the insulation.

t = temperature of the side at which the heat leaves the insulation.

A = effective area of cross-section in square inches.

L = length (thickness) of insulation in inches.

W = watts.

D = density in grams per cubic centimeter.

$K' = .1(T - t) \div (W/L)$ = resistivity in "thermal ohms" per cube.

R = resistivity in thermal ohms per centimeter cube.

R'' = resistivity in degrees per calorie per second per centimeter cube.

In the discussion which followed Dr. Hering complimented the author on his research, but thought that heat can be measured more accurately and easily as electrical energy than as heat in water as done by the author. An interesting result is the fact that the resistance becomes greater when pulverized material is compressed; the opinion to the contrary is an inherited fallacy. Mr. Skinner spoke on some similar measurements made by him.

Temperatures on Silicon Carbide Furnace.

Mr. L. E. SAUNDERS, of the Niagara Falls works of the Norton Company, then presented a paper on temperature measurements on the silicon carbide furnace. There is a com-

paratively narrow temperature region within which silicon carbide forms, since below this region it will not form and above it it will decompose.

Experiments on a small laboratory scale have been made before by Tucker and Lampen and on quite an elaborate scale by Gillett. Mr. Saunders' work is particularly interesting as it checks up on a large scale the work done formerly on a small scale. Mr. Saunders' measurements were made on the commercial crystolon furnaces at the Chippawa plant of the Norton Company (crystolon being this company's trade name for silicon carbide).

The only pyrometers available for this purpose are optical and radiation pyrometers, and to determine the temperature of the core of the furnace, where the silicon carbide forms, some means must be adopted to reach that position with fumes or

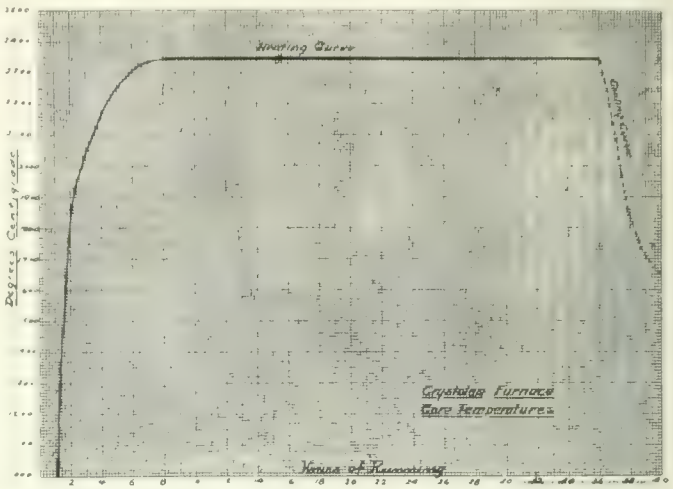

FIG. 2—CURVE OF TEMPERATURES OF SILICON CARBIDE CORE DURING FURNACE RUN

vapors eliminated. A tube at once suggests itself, with some suction appliance for removing or keeping out the fumes with which the interior of this furnace is well supplied (since the fumes would seriously interfere with the temperature readings). Gillett used a tube, made of silicon carbide, with a double wall, one end closed with a graphite disc, this end being placed against the silicon carbide core on the side, the other end projecting through the brick walls of the furnace.

Mr. Saunders, in working on a much larger scale, encountered many difficulties with the tube construction. The greater distances to cover, the settling of the charge, and the longer time of running, necessitate tubes of comparatively great length and strength, and of high resistance to thermal and oxidizing conditions. Mr. Saunders was forced to use amorphous carbon tubes. For taking temperature measurements, he used a Thwing radiation pyrometer.

Turning now to the experiments, readings were first attempted at the graphite disc next the core throughout a furnace run. The curve, Fig. 2, is typical of the results obtained. It will be noted that the temperature increment is rapid, but the readings at the lower points were shown to be low by means of an additional single tube inserted beside the other, with a small hole through which the heating of the core was observed. The difference in temperature between the inside and outside of the graphite disc lessens rapidly as the core heats up and as Gillett has shown the permanent heat lag becomes small at points above 2,000 deg. C., and after the run has continued for some hours.

Changes in core area, or in other words changing the rate of energy developed per square mm. of core area, has had less effect than was expected on the core temperature. With areas varying as much as 5 per cent the variation from the average in the maximum temperature reached has not been more than

50 deg. C., although as was expected the larger core areas gave the lower temperatures.

In addition to reading temperatures at the core, numerous readings have been taken at various distances out through the furnace charge. This was done with a separate graphite disc, slightly smaller than the inner diameter of the tube, which was attached to a thin carbon rod, by means of which it was moved to the desired position. With this appliance the author was able to determine the points at which fire-sand begins to form, at which crystalline silicon carbide forms, and at what temperature it decomposes into its constituent elements.

The results of the measurements of the author together with those of former investigators are given in table II.

TABLE II.—TEMPERATURES IN SILICON CARBIDE FURNACE

	Fire-sand (Limits)		Crystalline Silicon Carbide (Limits)	
Observers	Formation °C.	Decomposition into Crystalline SiC	Formation °C	Decomposition into C and Si
Tucker and Lampen, 1906	1650	1950	1950	2220
Same, corrected by Gillett	1500	1830	1830	2220
Gillett, 1911	1540 ± 30	1820 ± 20	1820 ± 20	2220 ± 20
Saunders, 1912	1000 ± 50	1840 ± 30	1840 ± 30	2240 ± 5

In the discussion which followed, Dr. Bancroft pointed out the identities and differences between large-scale and small-scale working. There is absolute identity with respect to the results of the temperature measurements, while there are necessarily considerable differences in the methods of measurements. Messrs. Amberg, Lidbury, Burgess, Thwing, Whitney and Tucker also participated in the discussion.

Dr. Richards spoke of the way in which carborundrum crystals are formed. They are due to the two vapors of silica and carbon coming together. Dr. Whitney suggested the possibility of silicon vapors instead of silica vapors.

Furnace Electrodes Practically Considered.

A paper on this subject, by Mr. R. TURNBULL, of Electro Metals, Ltd., Welland, Ontario, was read in the author's absence by Mr. Fitz Gerald.

Mr. Turnbull considers amorphous carbon electrodes only. The mixture used in its manufacture is anything but a complicated one, being simply one kind of carbon mixed with certain percentages of pitch and tar. This, after being well mixed together, is moulded in some special apparatus to the desired form and then baked in a furnace in a non-oxidizing atmosphere. Good electrodes were made from the beginning, but the trouble was that not all electrodes made were equally good. "Electrodes made at the same time, under the same conditions, and baked in the same furnace, have shown in actual service as many different characteristics in quality as could well be imagined, some giving excellent service whilst others simply went to pieces after being in operation for a few minutes."

Mr. Turnbull thinks the main cause of failure was the use of the wrong carbon material. In the early stages of electrode manufacture petroleum coke was mostly employed. But it did not work well, as electrodes made from it crumbled to pieces in the furnaces. Better results were then obtained by the use of retort carbon, a kind of coke deposited in the retorts in gas works, being nearly pure carbon. But as the retort carbon had to be collected from gas works all over the world a homogeneous article could not be counted upon, and this made its use dangerous to the manufacturer, so far as reliability was concerned.

It was only when anthracite coal came into use that real progress was made, and the best kind of electrodes in use today are made from this material.

We are indebted today to the Plania Werke for the moulded screw, which enables electrodes to be joined together, thus doing away with the stub and machining of the electrode and the trouble of changing electrodes in the furnace. This screwed electrode applies mainly to furnaces for the manufacture and refining of steel. At the present time nearly all manufacturers are using anthracite coal as the carbon base, and while electrodes made by some manufacturers are superior to those made by others, this is mainly due to the different methods of moulding the electrodes and preparing the coal employed.

So much progress has been made in this industry in the last two or three years that perfectly satisfactory electrodes up to 24 inches (60 cm.) in diameter and 7 feet (2.1 m.) long are now being made, whilst only a few years ago nothing over 12 inches (30 cm.) square and 5 feet (1.5 m.) long was satisfactory. No doubt still larger electrodes can and will be built, as electric furnaces are still growing in size, and the time is not far distant when steel furnaces of 30 tons' capacity, and operating with electrodes 3 feet (0.9 m.) in diameter, will be as common as are our small 5-ton furnaces of today.

As to the use of electrodes in furnaces Mr. Turnbull gives the following hints: In order to avoid all losses to the greatest extent possible the current should enter the electrode at a point as near as possible to the point where it will leave it. It is quite common practice to connect the metallic conductor to the head of the electrode, but this is a grave mistake, as the loss in volts in a long electrode will be from 4 to 6, depending on the current density employed, and in a furnace where the operating voltage is 50 volts, this loss would be equal to from 8 to 12 per cent of the total energy consumed.

Electrodes should be held in the same manner as one would hold a bar vertically in the hand, so that they can be taken at any point on their length, and in smelting furnaces the holder giving contact to the electrode should not be at any time more than 1 foot (30 cm.) above the charge. As the electrode wears away it is slipped through the holder, and the process goes on until it is finally taken by the head, but at no time should the part of the electrode carrying the current project more than 2 to 6 inches (5 to 15 cm.) from the holder itself.

The losses, both of heat and energy, can be decreased by increasing the size of the electrode, but this can be carried too far. Mr. Turnbull recommends a current density of from 30 to 35 amperes to the square inch of section (5 to 6 per sq. cm.) in order to keep the electrode as cool as possible and thereby prevent side oxidation and heat losses. With too large an electrode, quite a good percentage of the total energy supplied to the furnace would be required to keep the electrode warm.

An important point, the value of which is sometimes overlooked when considering the size of electrodes, is that it is often advisable to use electrodes of greater cross-section than electrical necessity demands, but for a totally different reason. In some processes, for instance, the electrode when working is surrounded to a certain depth by charge mixture. At the surface of such charge mixture, and therefore at some distance from the working end of the electrode, inflammable gases are given off, and these burning in air tend to attack and consume the electrode. Thus there is a tendency to reduced cross-section at this point with consequent increased current density, followed by rise of temperature, which further aggravates the condition described. It is, therefore, wise, for convenience sake, to use a larger cross-section so that the burning away does not result in eating the electrode through, letting a large piece of electrode into the charge and disturbing conditions generally. This is one of the exigencies imposed by practice.

In reply to a question of Dr. Hering, Mr. Fitz Gerald described a case in which evidences of the skin effect in an electrode were found.

Gas Circulation in Electric Pig Iron Furnaces.

A paper, by Dr. Jos. W. RICHARDS, of Lehigh University, dealt with "gas circulation in electric reduction furnaces" as practiced at the Joernkontoret's electric pig iron furnace in Trollhättan (see Mr. Leffler's report in our vol. IX., pp. 368 459, 505, also page 631). As described before, this circulation of gases is chiefly employed for the purpose of cooling the roof of the crucible.

Dr. Richards points out that the advantages of this cooling system are offset by serious disadvantages. He recommends that the artificial circulation of the gas should be entirely dispensed with. The arch of the crucible of the furnace should be protected by water cooled plates, as is common in open hearth furnaces.

Among other recommendations made by Dr. Richards on the method of working at the Joernkontoret furnace is one to the effect that the limestone flux should be calcined before putting into the furnace.

Further the shaft of the furnace should be provided with auxiliary heating to maintain its contents at or above 400 deg. C., to permit of reduction of Fe_2O_3 by the slow current of CO gas.

Under these conditions an amount of carbon equal to one-fifth of the weight of iron produced should be sufficient, producing gas containing two volumes of CO_2 to one of CO.

Eliminating the expense of circulating and purifying the gas, and reducing the amount of fuel required for reduction, would both simplify and cheapen the operation of the furnace in Dr. Richards' opinion.

There were several communicated discussions of this paper, one by Mr. Leffler of Sweden, and another by Mr. Noble of the Noble Electric Steel Company of California. Mr. Leffler wrote that if the artificial gas circulation could be dispensed with, nobody would like it better than those who have to run the furnace. Mr. Noble stated that in their electric pig iron furnace in California only calcined limestone is used as flux and no artificial gas circulation.

High-Tension Equipment for Electrochemical Plants.

A paper on this subject was presented by Mr. J. Rattray Wilson, of Niagara Falls, N. Y. The high-tension part of the electrical equipment of electro-chemical plants is now practically standard, the chief requirements being foolproofness and easy accessibility.

In the vicinity of Niagara Falls the primary current is delivered at a tension of 11,000 and 12,000 volts, and until recently it was all brought to the consumer's premises on overhead cables. On the American side this overhead construction is largely being done away with, the conduit system taking its place. This alteration saves a great deal of trouble, as it eliminates to a very large extent the heavy surging from lightning or other external causes. It is more expensive to construct, but no doubt it will pay in the end.

In bringing in the overhead power cables the author has made it a rule to have these about 20 feet (6 m.) above the ground, 18 feet (5.4 m.) being a minimum. The author prefers to build a special intake tower for this purpose, containing all the incoming switches, lightning arrestors, main circuit breakers and necessary meters. This tower can be located where convenient, but it ought to be as central as possible.

The author gives considerable details of wiring and of the protection devices employed. He emphasizes that the main oil circuit-breaker must be a heavy one and the best is none too good.

In connection with the transformer installation the use of a water rheostat, placed between the disconnecting switches and the transformers, is interesting; a special, single-pole, oil circuit-breaker being used to short-circuit. Where transformers have to be started under full load, this rheostat is of great importance.

In the first place, it is impossible to determine which phase the transformer circuit was opened on, and consequently when starting it may be closed on a reversal of magnetism, thus causing a dead-short-circuit, so to speak. Secondly, when closing-in on, or near, the top of a wave, surging is sure to follow, and it is no uncommon thing to find the circuit-breaker coming out four or five times in succession. Thirdly, closing a transformer circuit under full load will cause severe stresses in any case. The transformer builders recognize this, and now build choke-coils in the case, along with the other parts. Although this helps to a large extent, it is not adequate in all cases.

The effect of a long column of water acting as a resistance allows the transformer to pull into step, as it were, without undue stress. In starting a 750 k. w. transformer, with 12,000 volts on the primary, under the most severe working conditions the author could devise, the immediate starting current never exceeded one-sixth of the normal working current. The construction of this rheostat is very simple. Two wooden tanks are made and set up on petticoat insulators, supported on either a wood or a pipe frame. A loop from one of the poles is cut, one end brought through the bottom of one tank, and the other through the bottom of the other. These cables terminate in cast-iron discs. The closing mechanism is a copper rod of suitable cross-section, fixed to but insulated from a wood bar, the wood bar being capable of being raised or lowered, and kept in position by sliding in grooves. To the ends of the copper rod are fixed cast-iron balls to give surface for the current to pass to or from the water, also to act as contact or arcing pieces, in conjunction with the metal discs mentioned above. Both the discs and the balls are screwed onto copper rods so as to be easily replaced if necessary, the rods to the discs passing through stuffing boxes on the under side of the tanks. The movable rod is bent "U" shaped so that the vertical portions are coincident with the vertical axes of the tanks. This rod is raised or lowered by a rope, leading through pulleys to a winch placed in a convenient position in the low-tension room.

The method of operation is as follows: The oil circuit-breaker is closed on one pole, the copper rod is next lowered slowly till it makes contact, then the short-circuiting switch is closed, thus closing the other pole; the rod is then raised to the top of its run ready for another occasion. The rheostat may be used for breaking circuit provided the column of water is long enough, but it is very much better practice to use the oil circuit-breaker, which is designed for this purpose, as the stress which may be set up by the change of frequency due to the arc being maintained on the top of the water may cause troubles of its own.

In a communicated discussion Mr. J. L. Harper explained in detail why at the present time it is believed to represent good judgment, in all except long overhead lines, to consider most protective devices as causing more trouble than they are worth, to make a study of the factory ends of the distributing lines in order to produce a minimum of fluctuations, surges or unbalancing conditions, and to develop and use, both in the central station and at the receiving end of the lines, switches having a capacity commensurate with the whole capacity of the generating plant back of them.

Power Supply to Electric Furnaces.

In a paper on "power supply to electric furnaces for refining iron and steel," Mr. W. Sykes, of the Westinghouse Electric & Mfg. Co., pointed out that while pretty soon a large industrial development is to be expected in the installation of electric furnaces in the steel industry, it will first be necessary to modify certain features of construction.

Arc furnaces of 15-ton capacity are now in operation, using the electrodes. On account of the difficulties of building very large electrodes, the author thinks that in designing furnaces of say 30 to 50 tons capacity two or more sets of electrodes will be adopted. This will complicate to some extent the construction and "considerable development will be undoubtedly necessary to satisfactorily handle the numerous electrodes." A furnace with six electrodes has already been built and is in operation.

The author doubts whether furnaces of more than 30 tons are necessary or desirable. The handling of currents even of 12,000 amperes presents considerable difficulty, not only from the standpoint of conduction, but also on account of the effect of the self-induction of the leads on the power factor of the equipment.

The reactance must be limited as much as possible, and an

examination of existing furnaces shows that considerable trouble has been taken by interlacing the conductors to reduce the self induction. It is probable, however, that before handling larger currents some structural changes will be necessary to avoid running the conductors close to iron supports, etc., and also to reduce their length.

When a large number of furnaces are used at one plant, the effect of the variations in current during operation would not be very great, and it is only when considering small installations that particular attention need be given to this feature.

In the case of a single furnace, provision must be made in the power house to take care of short circuits in the furnace, since they are unavoidable. The frequency of these short circuits is dependent upon the regulating mechanism of the furnaces, which is one of the details that must be given more attention in the future than in the past.

In discussing the induction type of furnace, the author points out the difficulties of getting a reasonably high power factor and the advantages obtained by combining the induction with the resistance type in the Roechling-Rodenhauser furnace.

When considering a new station for the operation of induction furnaces, it would undoubtedly be cheaper to install generators with a large kilo-volt-ampere capacity compared with the size of the prime movers. The cheapest way to take care of the wattless component is undoubtedly to increase the size of the generators. If the generating plant is already installed, it is necessary to provide other means for accomplishing the same purpose, and in general two methods are available; one is to use a motor generator set either with a low-frequency generator, or one of large K.-V.-A. capacity, and the other to use a synchronous condenser which will compensate for the low power-factor of the furnace.

Comparative cost curves given by the author for both arrangements, show that there is a very appreciable saving in the first cost (something like 50 per cent) in the use of the synchronous condenser, for which there is also a saving of 6 or 7 per cent in power. Hence when furnaces are installed on existing power stations and trouble is caused by low power-factor, the proper arrangement is to install a synchronous condenser instead of a motor-generator set. In the case of frequencies higher than 25 cycles this also holds good, although with 60 cycles the saving is somewhat less.

The use of the resistance type of furnace for steel refining has been limited to very small sizes, on account of the difficulty of handling the very large current necessary. The author illustrates this by a numerical example.

The author adds a note on the electric pig iron furnace and he discusses the problem of power generation. Of course, water power would be cheapest, but there are also possibilities of producing power from coal cheaply and gas power is also available. But, after all, the cost of power is by no means the principal item in the expense of electrically refining steel, and quite as much, if not more, can be accomplished in the reduction in the cost of production by reducing the consumption of electrodes, linings, etc., as by reducing the power cost.

Electric Furnaces for Heating Bars and Billets.

Mr. THADDEUS F. BAILY, of the Electric Furnace Company, of Alliance, Ohio, gave an account of further developments of his electric furnace for heating bars and billets, which was described in our vol IX, p. 262 (May, 1911).

A chrome lining in his furnace proved unsatisfactory. Silica brick and Grecian magnesite brick with ground magnesite proved satisfactory and magnesite was even better than silica. Magnesite was, therefore, chosen for the final furnace.

The dimensions of this furnace were 56 in. (140 cm.) wide, 45 in. (113 cm.) front to back and 42 in. (130 cm.) high, and it was designed for 60 kw. current consumption when heating 240 pounds (109 kg.) of metal per hour. The wall loss was calculated at 30 kw. per hour. These figures checked very closely, as the wall loss with a ruling temperature of 2050 deg. F. (1455 deg. C.) was 28 kw. and the metal heated was 280 pounds (127 kg.) with 66 kw. in one hour's time, this giving a figure of 4 pounds (1.73 kg.) of metal per kw. hour. The metal was raised from a temperature of 50 deg. F. (10 deg. C.) to 2350 deg. F. (1288 deg. C.). Under the above conditions the furnace had a thermal efficiency of approximately 50 per cent.

The voltage of this furnace was entirely satisfactory; from a starting voltage of 150 volts the voltage was rapidly reduced to 60 volts, the current flowing at this voltage with a temperature of 2650 deg. F. (1454 deg. C.) was 1,000 amperes, with power factor 0.98. This current and temperature condition was maintained for hours at a time when heating metal. When no metal was being heated, the current was reduced to 46 volts, 600 amperes, with power factor 0.98, and the temperature in the furnace maintained at 2650 deg. F. (1454 deg. C.).

When this furnace had been run for 13 days, the top was removed and the interior inspected, and the following observations noted:

The contact between the resistance body and the electrodes was perfect, there being no arcing or trouble of any kind.

The contact between the electrodes, which were 4 x 4 in. (10 x 10 cm.) carbon, and the standard feeder-cables was made with bronze clamps and Dossert cable-lugs, and gave no trouble whatever.

A tendency of the electrodes to burn at the point of entering the furnace walls was corrected by using two 3-in (7.3 cm.) round electrodes in place of one 4-in (10-cm.) square, and placing a sheet iron sleeve over the outer end of these electrodes to a point at least 8 in. (20 cm.) inside the furnace walls. The clamps were then placed over the sleeve and electric connection made from clamp to electrode, the current going through this protecting sleeve. This arrangement effectually prevented the oxidation of the electrodes at this point.

The electrodes in contact with the resistance material showed no reduction in size whatever—in fact, were of slightly increased size, owing to particles of the carbon resistance material adhering to the electrodes.

The coke or resistance material, composed of ½ to ⅜ in. (0.6 to 0.9 cm.) crushed coke, was completely converted into graphite, and lay in a compact though not hard mass in the core of the furnace.

The Grecian magnesite lining had eroded to a depth of about 1 in. (2.5 cm.) on sides and bottom, where in contact with the coke, but had not fluxed with the coke at all. This lining was then repaired by adding a 2-in. (5-cm.) layer of Grecian magnesite, mixed with water, so that it would hold to place until the resistance material was put in. On heating the furnace to temperature this magnesite cintered into place without trouble. Since this repairing, the furnace has run about 30 days with great regularity, and the linings are apparently in excellent condition.

The cost of the magnesite for such repairing as noted above was about $2, and required about 3 hours' time for one man to do the work. This low cost of repairs was exceedingly gratifying as compared with the high cost of refractory repairs in oil furnaces.

The data given in table III. was taken from a typical test sheet showing the current conditions and metal heated during a given period:

TABLE III.

Temperature of interior at charging	2615° F. (1425° C.)
Temperature of interior at withdrawing	2600° F. (1426° C.)
Voltage of furnace	60
Amperage of furnace	1150
Power factor	0.99
Indicated kilowatts	69
Amount of metal charged, being 8 bars 1 in. (2.5 cm.) square by 18 in. (45 cm.) long	92 pounds (41.7 kg.)
Time in furnace	50 minutes
Temperature of metal, when charged	60° F. (15° C.)
Temperature of metal, when withdrawn	2360° F. (1239° C.)
Kilowatt hours consumed in heating metal	23
Pounds (kg.) of metal per kilowatt hour	4 pounds (1.73 kg.)
Kilowatt hours per ton of metal heated	500
Capacity of furnace, per hour	276 pounds (125 kg.)

In the discussion which followed, Dr. Richards expressed the opinion that by improved design and better insulation the efficiency of the furnace might still be raised quite considerably.

Electric Conduction in Gases.

The special feature of the Boston meeting was the symposium on electric conduction. It consumed the whole day of Friday.

As a preliminary introduction an illustrated experimental lecture was delivered by Prof. CHAS. R. CROSS in the Physics Lecture Room of the Walker Building of the Massachusetts Institute of Technology. The lecture was devoted to demonstrations of electrical discharges in high vacua and the demonstrations were really brilliant. They illustrated the evolution of our knowledge of electric conduction through rarified gases.

Presidential Address.

The presidential address of Dr. W. R. WHITNEY, the director of the Research Laboratory of the General Electric Company, of Schenectady, was intended as an introduction to the symposium on conductance which followed. Dr. Whitney pointed out that we are in the midst of a period of great advance in our conceptions of electric phenomena and that a knowledge gained in any of the separate fields such as, for example, a vacuum tube, is becoming applicable to other fields like open-air arcs or even metals. The ions and electrons are no longer the property of a small group of pure physicists, but are rapidly becoming the alpha and beta of electrochemistry in general.

The object of Dr. Whitney's address was to recall and emphasize some simple general facts of electric conductivity. But he was impressed with the thought that some of the simplest facts are often very interesting, and whatever ideas or theories of conduction are advocated, they must first serve to cover and clothe such simple facts.

The bare fact that electrical conductivity of pure metals increases with falling temperature at approximately the same rate for all the metals must be of the utmost importance to a further understanding of the phenomena of conductivity.

That the temperature coefficient of resistivity of metals is about the same as that for the expansion of gases has undoubtedly led to the attempts to apply gas laws to the conducting ions in metals. Just as we cannot obtain gases of appreciably higher expansion coefficient than 0.0037 by any system of mixing them, so also we fail by alloying the metals to get any alloy having a higher resistance coefficient than this value. Magnetic metals, such as iron and nickel, have a somewhat higher coefficient because of the inductive effect, but this irregularity is, we are told, in turn a support of the ionic theory of conduction.

Dr. Whitney reviewed the researches on metallic conductivity at low temperatures which have led to the conclusion that the electric specific resistance of all pure metals vanishes at the absolute zero of temperature. But this is only true for metals since the resistance of *alloys* in general does not disappear at zero. This in turn is another fundamental fact which new conduction theories must cover.

Another fundamental fact is the apparently general rule that there seem to be no ductile poor conductors. The pure metals or those pure elements which can be obtained in wire form, for example, all possess high conductivities comprised within a rather narrow zone.

While these are interesting scientific facts they have also opened possibilities from an engineering view point. An instance are the schemes for cooling long-distance transmission lines by liquid air.

Dr. Whitney then reviewed the resistivity of alloys, chiefly following the generalizations of Guertler. As a first general approximation, the alloys of metal-pairs may be divided into two classes: those which exhibit conductivity at least approximately calculable from the conductivities of the components. For example, any alloy of lead and tin conducts about as the two quantities of the components would if placed side by side. This applies to alloys between lead, tin, zinc and cadmium.

There is another class of alloys which at certain compositions are simple chemical compounds, such as Cu_2Sb, Cu_3Sn, etc. These have conductivities not apparently to be predicted at all from the conductivities of the components. This corresponds to the cases of melting-points of alloys which latter follow in some case quite simple general rules, but which do not permit of prediction of the melting-point of a compound when one is formed between the two metals.

Between the *compounds* of metals and either of the metals themselves mixtures are possible whose conductivity will be like that of the simple mixtures of lead, tin, etc.; that is, they will be calculable from the volume-concentration of the two components, when the metal compound is considered as one component, and so also when two metals form two different compounds these two may act in turn like the single metals, lead and tin.

There is another feature which involves the crystallization-condition of the alloys on cooling from molten state. In the case of the lead-tin or the simple group, the metals crystallize out pure, just as salt or ice may separate from an aqueous solution, but in other cases the freezing microscopic crystal is itself a mixture and the composition may change with the liquid concentrations, so that the resistance of the final solid is no longer calculable from the resistance of the components. To this class belong those cases in which a very small quantity of an added element causes a very great increase in resistivity. Guertler has pointed out that this electrical difference between the compound and the mixed crystal, lies in the fact that even a very small quantity of foreign element in the mixed crystal very greatly interferes with conductivity, while the pure *compound* of the elements is homogeneous and has a maximum conductivity, just as the pure element has.

The fact that the presence of certain impurities in very small amounts in materials like copper and iron affects their properties to a great extent is of great importance to the engineer. Even so small a quantity of arsenic as one-tenth of 1 per cent reduces the conductivity of the copper by 30 per cent. If traces of foreign matter are of such effect on the conductivity of copper, then it may well be possible that some of our present copper could be still further refined to advantage. It is fairly well known that the present methods of refinement yield copper whose conductivity is nearly 2 per cent higher than the best obtained by Matthiessen in 1861, when he gave us our value for "pure copper."

If electric apparatus were made with 2 per cent poorer copper than at present, the additional loss per ton of copper used would be about $10 per year at 1 cent per kw. hr. (or $100 at the price most of us pay for current) at 50 per cent load factor. As there are about one-quarter million tons of copper used annually in the electrical industry, this 2 per cent difference in the copper resistance constitutes the considerable perpetually-acting conservation of power resources of two and one-half million dollars a year. It seems highly improbable that this refinement of copper has reached the "ne plus ultra" stage, even from an economic standpoint.

In the case of iron, where again high electrical conductivity is frequently of greatest importance, it has been shown that less than 1 per cent of several other elements, such as carbon, silicon, arsenic, etc., reduce the conductivity to about half the value for pure iron. High-resistance iron alloys, being cheap, are commonly used for their high resistance. All electric street cars carry a hundred pounds or more of such iron resistance.

Then there are the changes in conductivity produced by annealing or softening hard metals.

An exceedingly interesting case of conductivity is that which takes place in an arc. Dr. Whitney points out that a theory of the arc in air which postulates only a passage of negative electrons which causes some wasting away of the cathode, would apparently cover the known phenomena of the arc. But

we are not sure that the phenomena of an arc in a confined and partially evacuated space can be considered as similar to those in an arc at atmospheric pressure. It is possible that in a confined and partially evacuated space the positive ions migrate from anode to cathode, where they are neutralized by negative electrons. Dr. Whitney thinks that the positive iron, at least in gaseous conduction is soon going to become as firmly fixed in our vocabulary as it is in the case of electrolytic conduction.

With respect to the conductivity of solutions in water a noteworthy fact is that at ordinary temperatures it never reaches anything like the magnitude of the arc or metallic conduction. While we may by suitable selection of concentrations produce any desired low conductance value, we cannot exceed about one-ten-thousandth of that of metals.

We find also in general a fairly uniform value for the effect of temperature on the electrolytic conductivity, but this is quite different in amount and sign from that of the metals. It usually lies between 5 and 6 times as great for aqueous solutions at ordinary temperatures. In the case of aqueous solutions the evidence of the migration of ponderable material, both in negative and positive direction, is too convincing to be questioned, and the commonly occurring but not necessarily visible decomposition at the terminals of this type of conductor differentiates it from the metallic type.

In conclusion Dr. Whitney expressed the hope that when the theories of conduction are well advanced we will also have obtained some conception of the rationale of temporary and permanent magnetism

Symposium on Electric Conductance.

The presidential address of Dr. Whitney was followed by the symposium on conductance. It is proposed to arrange a symposium on some important subject of live interest for every annual meeting of the Society and the arrangements for this symposium will be in the hands of the president. At such symposium men actively at work on the subject under discusion are to be the principal speakers and a general discussion is to follow. President Whitney had chosen the general subject of "electric conductance" for this year's discussion and his selection proved excellent, the interest centering especially in the application of the electronic theory to gases and solids.

Dr. D. F. COMSTOCK, of the Massachusetts Institute of Technology, was the first speaker. He presented a concise general sketch of the modern theories of the intimate structure of matter in so far as they bear on the phenomena of conduction. Dr. Comstock distinguished three fundamental realities which go to make up the visible structure of matter. These are atoms, electrons, and energy (in general, electromagnetic energy, gravitation only being neglected which is a small force).

Of atoms there are about 100 different kinds, and we have learned in recent years to consider the atom as a far more complicated structure than heretofore.

Electrons are very much smaller than atoms and to emphasize this point Dr. Comstock used the comparison of a pin head with an office building. Electrons are only of the negative kind.

Radiant energy has momentum when it moves. It exercises a pressure on surfaces which reflect or absorb. It may be said in general that energy behaves very much like matter.

Atoms, electrons, and energy are the only three entities needed for building up our model of the visible world.

Positive electricity does not occur in form of electrons. But in every atom is incorporated a certain (very large) amount of positive electricity and the atom is neutral if it is also provided with just such a number of negative electrons as to balance the positive electricity.

Charging an atom positively means to take away a negative electron. Charging an atom negatively means to add a negative electron.

The relative number of electrons which can be added to or taken away from an atom is very small. This number determines the chemical valency. The properties of elements can be explained by this affinity of the atoms for the electrons.

Electrification of a body by conduction is simply the separation of electrons. It is simply a separation within the two bodies in contact. Nothing is added.

Electrons in metals move like ions in electrolytes with this important difference. The positively charged atoms in the metal remain in the same position. What moves is only the negative electrons and they move in a direction opposite to that arbitrarily assumed for the electric current.

Dr. Comstock emphasized that the speed of electrons in metals is of the same order of magnitude as that of ions in electrolytes. This speed is in the order of centimeters per second. It is important that the electrons do not move with anything like the velocity of light as is sometimes assumed. What moves with such enormous velocity is the impulse.

In general the conductivity of every substance depends firstly on the number of electrons or ions; secondly, on their valency (that is the number of free electrons, being one or two, etc.) and thirdly on the frictional resistance which they encounter when they move along. There is not the propagation of a wave motion. There is not the flow of ether. All electric currents are convection currents. All conductance is the bodily movement of the electrons.

The next speaker was Dr. E. WEINTRAUB of the General Electric Company, of Lynn, Mass., who criticised severely the arbitrary and injudicious application of the electron theory to new fields for which it has not yet been proven applicable. He also offered some interesting positive generalizations. One of these is the classification into good and poor conductors which although not exactly sharp was shown to be much more far reaching than is generally supposed.

Dr. Weintraub considered first the conductivity of elements. Metals are good conductors and their conductivity becomes infinite at zero absolute temperature. He asked what explanation the electron theory could offer for this fact. It is true that the temperature coefficient of resistivity of metals is nearly constant and nearly equal to that of the extension of gases but the conditions are very different when we pass over to poor conductors. Dr. Weintraub cited boron as a striking example. The resistivity diminishes here very rapidly with an increase of temperature. While the good conductors generally obey a law of variation of resistivity with temperature such as $1/R_o \, dR/dt$ it is entirely different with poor conductors like boron which obey a law like $\lg R = a + bt$ where R is the resistivity and t is the temperature. Dr. Weintraub asked how the electron theory accounted for this difference in the laws for good and poor conductors.

He then passed over to the discussion of solid solutions. It is a general rule that if another element is added to a good conductor the conductivity decreases, for instance, when a little copper is added to pure silver or where a little silver is added to pure copper. On the other hand if some addition is made to a poor conductor like boron the conductivity increases; this is, for instance, the case if a little iron is added to boron. This is a characteristic feature of all poor conductors.

Dr. Weintraub then took up the conductivity of compounds. As to the agreement between theory and facts with respect to the parallelism between thermal and electric conductivity he said this agreement was much emphasized by the advocates of the electron theory, but was probably overemphasized, since serious deviations do exist, especially at low and at high temperatures. Further the law does not hold at all for poor conductors.

Again with respect to the relation between conductivity and density trouble is experienced with poor conductors. In general it would seem that the relations between conductivity and other properties hold only for good conductors.

Possibly the step to the infinitely small electron has been too big a step. It is perhaps more important for the present to

investigate how metals crystallize, since we know this to have an effect on conductivity. We do not know yet enough of the internal microstructure of solids and solid salts.

Prof. R. A. Millikan, of the University of Chicago, said, first, in reply to Dr. Weintraub, that the electron theory demands lack of parallelism between the behavior of good and poor conductors.

He then gave a fascinating sketch of his further researches on the isolation of electrons in gases by means of his oil drop method, described in our Vol. VIII, p. 638 (November, 1910). Currents are nothing but electric charges in motion and by means of his method he is now able to measure the elementary electric charge, *i. e.*, the charge of an electron, with highest accuracy.

The results of his further more recent researches may be summed up in two statements.

First, Professor Millikan has been able to demonstrate that the process of ionization in gases produced by all kinds of ionizing agents which he employed consists in the detachment of *one* single electron. Hence the phenomenon of valency does not manifest itself so far in gases.

Second, the very careful extension of his fundamental researches on catching electrons with oil drops has led to a result which may be expressed in either of the following ways: His results may be considered either as a complete proof of the absolute identity of gaseous ions and electrolytic ions, or, if this is assumed as having been previously established, then it is a complete quantitative proof of the correctness of the kinetic theory of matter. The research from which this result was obtained had to do with Einstein's theory of the Brownian movements.

Dr. O. W. Richardson, of Princeton University, was the next speaker. He thought that Dr. Weintraub required too much from the electronic theory; electronic conduction and electrolytic conduction cannot be compressed into a single formula. If the electronic theory explains some simple relations only it is valuable.

A case in point is the old law by Wiedemann and Franz that for good conductors the ratio of electric to the thermal conductivity is independent of the nature of the metal. Lorenz found that the temperature coefficient of this ratio is the same for all substances and very close to the temperature coefficient of the expansion of the gases. Now Drude has shown in a very simple way how these laws follow from the electronic theory. The agreement is pretty good and certainly remarkable.

One of the strongest arguments in favor of the electronic theory of the conduction in metals, in Dr. Richardson's opinion, is the fact that electrons are shot off when a metal is heated. There is a close analogy between this emission of electrons and evaporation. One may say that electricity evaporates in form of negative electrons, and may speak of the vapor pressure of negative electricity.

The first speaker of the afternoon session was Dr. M. W. Franklin, of the General Electric Company, Schenectady, N. Y., who gave a concise outline of the experimental researches with vacuum tubes carried out by J. J. Thomson, Wilson, Millikan and others, which have resulted in the measurement of the electric charge and of the ratio of the electric charge to mass of electrons in gases.

Dr. H. M. Goodwin, of the Massachusetts Institute of Technology, then gave a review of the extended researches carried out by him and under his direction on the conductivity of fused salts. Faraday's law holds for fused salts as for aqueous solutions, but when we try to apply the model of migrating ions to fused salts we encounter the difficulty that the velocities of the ions cannot be directly measured, since in a homogeneous material like a fused salt the transference numbers cannot be determined as in solutions.

It is only in indirect ways that we can hope to get the values of the mobilities. The first way is by comparison of the conductivity of a solution and its change with temperature with the viscosity of the same solution and its change with temperature. The second way is based on specific heats and latent heats of fusion; and the third way is based on the measurements of the e.m.f. of cells with fused salts. These three different methods were sketched by Dr. Goodwin.

The indications are that fused salts are highly ionized and that even solid salts below the melting point are highly ionized so that the increased conductivity of a salt in the state of fusion is due rather to the change in viscosity and therefore to greater mobility of the ions than to a larger number of ions.

Dr. P. G. Nutting, of the Bureau of Standards, Washington, D. C., then discussed the characteristic curves of conduction through gases in which the current is plotted as function of the impressed e.m.f., and illustrated various applications of these curves.

Dr. C. J. Davisson, of Princeton University, gave a long account of experimental researches on electric charges given off from heated salts. With alkaline salts and with alkaline earth salts the carriers of the electric charges seem to be the metals in the salt. Calcium seems to be present as an impurity in most of the salts. As far as evidence is available the current is not carried by gas molecules. It might be possible that part of the current is carried by metallic ions and part by gas ions, but no evidence for this has ever been found.

Dr. W. C. Bray, of the Massachusetts Institute of Technology, discussed a general law proposed some years ago by Professor Kraus and himself, in order to give a single formula for inductance which covers all possible solvents and concentrations. This formula is

$$\frac{C\gamma^{m}}{C(1-\gamma)} = K + D(C\gamma)^{m},$$

where C is the concentration, γ the degree of ionization calculated from the conductance ratio Λ/Λ_0, and K, D, m are constants. A more careful study, which is still in progress, has furnished striking confirmation of this law.

While the whole formula has been tested only in a few cases so far, the two terms on the right hand have been tested separately with good success, each term representing a special case.

The evidence that the law of mass action is obeyed in dilute solution is based on the experimental results of Franklin and Kraus in liquid ammonia and of Dutoit and his co-workers in propyl, butyl and amyalcohols and in acetone, sulphur dioxide, pyridine, etc. There is a rough parallelism between the values of K for a typical salt (as NaI) and the dielectric constants of the pure solvents. The deviations from the law of mass action are in general appreciable when the ion concentration is greater than 0.0005 normal.

The values of m usually lie between 0.4 and 0.6 in aqueous solution and between 0.9 and 1.2 in liquid ammonia and are still larger in solvents of lower dielectric constants. Whenever m is greater than 1, the values of the equivalent conductance pass through a minimum as the concentration increases and then increase with increasing conceration. D is the controlling factor in determining γ at high ion concentration, and usually lies between 0.1 and 5.0 for the different solvents. The above law ceases to hold in the neighborhood of normal concentration, and Λ then decreases with increasing concentration. There is evidence that this decrease is connected with the rapidly increasing viscosity of these concentrated solutions.

The next speaker was Prof. Charles A. Kraus who drew attention to an interesting link between metallic and electrolytic conduction proving that, after all, metallic conduction cannot be radically different from electrolytic conduction.

This most interesting link is furnished by the consideration of solutions of metallic sodium in liquid anhydrous ammonia. In general the solution behaves like an electrolyte, but when it becomes very concentrated it behaves like a metal and it also has the appearance of a metal.

The last formal speaker of the symposium was Dr. S. J. Lloyd, who pointed out that, with very few exceptions, pure ordinary salts, oxides, bases, are very poor conductors. But when the temperature is raised the conductivity increases.

It is difficult to apply the electrolytic dissociation theory to this field. The present opinion concerning the mechanism of conduction in solid and fused salts is that not only are pure fused salts highly disassociated, but solid substances are also highly dissociated so that the degree of dissociation in the fused state is not so very different from that in the solid stage. The much greater conductivity in the fused state is then due to the viscosity change which causes greater ionic mobility.

The general discussion which followed was opened by Dr. Whitney.

Dr. Weintraub agreed that some excellent work has been done on electric conduction in gases. Undoubtedly in gases the electrons are the carriers of the electricity. It can be understood that attempts are being made to transfer the electron theory to wider fields. But it should not be forced artificially on solid conductors. Dr. Weintraub considered the agreement between theory and practice with respect to the parallelism between thermal and electric conductivity as more or less accidental.

Dr. Richardson replied explaining why he considered this special agreement as really significant and as a strong support of the electronic theory.

Dr. Comstock pointed out the extraordinary difficulties which are met with in the development of the theory. One has to proceed step by step and it is of greatest importance to get some positive results.

Dr. Millikan agreed with this and told the story how his little nephew came home from school thoroughly disgusted with his teacher because "she has said all week three and four is seven, and now I have learned the darned thing, she says five and two is seven."

Demonstration of New Apparatus.
Determining Carbon in Iron and Steel.

Mr. F. W. Robinson, of the Hanovia Chemical Manufacturing Company of Newark, N. J., then demonstrated some new apparatus placed on the market in this country by Mr. Chas. Engelhard, of New York City.

The first was an electric furnace for the quick determination of carbon in iron and steel. The method is to burn the carbon

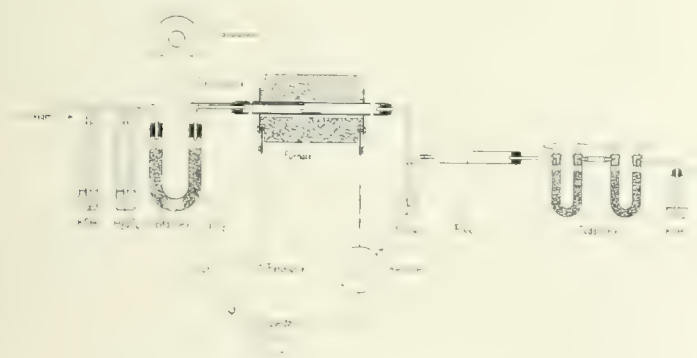

FIG. 3. DETERMINING CARBON IN STEEL

in a stream of oxygen and absorb the carbon dioxide thus produced. The method was not successful until the use of the electric resistance furnace provided a sufficiently uniform temperature for a satisfactory combustion. Mr. G. Mars, of the Boehler Steel Works, in Germany, has shown that with a suitable furnace the method is not only simple and accurate but on account of its rapidity is eminently suitable for use with the open-hearth process, particularly when with varying charges the Eggertz tests are unreliable.

The arrangement is shown in Fig. 3, permitting any number of estimations to be made successively almost without interruptions, so one man working two sets of apparatus can make 20 to 24 determinations a day.

The combustion is carried out as follows: The furnace is first heated up to a temperature of 700°-1000° C. (for cast iron 700°, for ordinary steel 900° and for some special steels 1000°) during which a slow stream of oxygen is passed through the apparatus. The soda lime tubes are then weighed (all weighings are made with the soda lime tube full of oxygen) and connected to the apparatus again. One to two grams of the metal in the form of turnings as there weighed into a porcelain boat and the boat slid into position in the furnace. This is done from the front end so that the thermo-couple and oxygen inlet tube need never be disturbed. The boat should be slid in so far that the back end is flush with the junction of the thermo-couple and during this operation the stream of oxygen should not be interrupted. The rubber stopper is immediately replaced in the combustion tube and the taps of the soda-lime tubes opened.

The temperature of the furnace is then gradually raised, with steel during 15 mins., with cast iron during 20 mins., to a maximum of 1150°-1200° C. The beginning of the reaction can be noticed by a visible reduction in the rate of the gas through the H_2SO_4 washbottle. Provided the turnings used are not too coarse, the heating current may be cut off as soon as the maximum temperature is reached, otherwise this temperature should be maintained for 5 to 10 minutes before cooling down. After completion of the combustion the stream of oxygen is continued for 5 mins. to drive all the CO_2 into the absorption tubes and these are then disconnected and weighed.

To obtain accurate results with difficult combustible materials such as ferro-chromium and ferro-manganese the turnings must be mixed with an oxygen yielding substance such as bismuth oxide and the combustion is then conducted as before.

Pyrometry.

The second demonstration of Mr. Robinson referred to "some recent developments in the field of temperature measurement."

Mr. Robinson first showed a copper-constantan thermo-element, of which not less than 1100 are used on German locomotives for measuring the temperature of superheated steam The copper-constantan element is built into the slide-valve chamber and the indicating galvanometer is fixed onto the boiler casing in the driver's cab. Comparisons with a mercury thermometer showed that the latter was lagging several minutes behind the thermo-element, with serious consequences.

In the construction of resistance thermometers an important advance has been made by Dr. E. Haagn, of the firm of Heraeus, by completely embedding the platinum resistance wire in fused quartz, and at the same time adjusting the resistance to a standard value within 0.04 per cent. This value is usually 50 ohms, but can within limits be increased or decreased at will. The significance of this is obvious, for, embedded in the quartz glass, the resistance cannot change through mechanical or chemical influences and the resistance elements are interchangeable without alteration to the galvanometer scale or any part of the installation.

The process of embedding in quartz has been shown by the Reichsanstalt to alter the physical constants a and b in the expression for the relation of resistance to temperature

$$R_t = R_0 (1 + at + bt^2)$$

This simply means that the temperature scale is slightly different from that for a wire lying free in the air, but the temperature scale for these thermometers has been carefully determined by the Reichsanstalt

These quartz-glass resistance thermometers are also constructed for a number of special uses, e. g., the small volume and mass of the resistance element allows of the exact following of small and rapid temperature changes in physico-chemical investigations. For calorimetric measurements Heraeus has introduced a specially long resistance element (up to 25 cm) combining high resistance and consequent extra sensitiveness with the real temperature mean throughout the length of the calorimeter while for melting point and boiling point determinations an element of only 2 cm length and 25 ohms resistance is used.

For medical and physiological use a special mounting in gilt capsules of a quartz thermometer bent double in the middle to minimize space has been introduced by Siemens & Halske. It is usually advisable to connect it with a recording galvanometer and one sees at once the great advantage of this method over the usual ½ daily measurements with a mercury thermometer. These instruments can be introduced and retained for quite long periods even in the stomach or rectum without undue inconvenience to the patient and no attention is required, as they can be fitted with a signalling device for the critical temperature.

Quartz Mercury-Vapor Lamp.

The third demonstration by Mr. Robinson was that of the quartz mercury-vapor lamp for scientific and medicinal uses. Perhaps its most important quality is its richness in ultraviolet rays, for which the fused quartz, unlike glass, is transparent down to the wave length 185 $\mu\mu$. This lamp is therefore a very rich source of actinic rays for photochemical and botanical research. For medicinal uses two types of the lamp are on the market. The first is the Kromager lamp for the treatment of local surface and allied disorders. The second is the Bach lamp and is known under the name of the "miniature Alpine sun."

Saturday Meeting.

The Saturday morning session was held in Pierce Hall of Harvard University. During the session Dr. Theo. W. Richards welcomed the Society in a felicitous little speech to Harvard and gave an outline of the new buildings of chemistry now under erection at Harvard. He pointed out the advantages which the erection of various buildings has over the standard European system of centralization in a single building. Of course, there are also some disadvantages.

Vacuum Furnace Metallurgy.

The first paper of the Saturday session was presented by Dr. Colin G. Fink, of the General Electric Company, of Harrison, N. J. He described experiments carried out with the idea of ascertaining whether ores, particularly complex or "rebellious" ores, such as smaltite, containing arsenic, sulphur, phosphorus or similar elements, could be more readily and more economically reduced in a vacuum.

Experiments were made with the treatment of smaltite ore from Canada, in a vacuum electric furnace. Simple heating of the ore without any additions was first tried, but without great success. Up to temperatures of about 1500 deg. C., but 40 per cent of the arsenic present in the ore is expelled. It is only after exceeding the melting point of cobalt that a further reduction of the arsenic is brought about. If silver is present in the ore, it distils out at about 1300 deg. and can be collected in a chamber fitted into the cooler portions of the furnace.

Since it proved difficult to reduce the ore by intense heating, Dr. Fink tried the effect of additions. Of all those he tried the most effective was calcium carbide or a mixture of calcium carbonate and carbon.

With a mixture of 20 parts CaO_3 and 6.4 CaC_2 and 30 parts ore, when the charge was heated at 1500 deg. C. for 1½ hours, the percentage of arsenic in the product was 2.1. In this case the calcium oxide and carbide react with each other: 2CaO + CaC[illegible] = 3Ca + 2CO and the metallic [illegible] the arsenic [illegible] = 3Ca + [illegible] calcium arsenide separates from the reduced cobalt as slag and part of the arsenic is volatilized.

The second part of Dr. Fink's paper describes experiments made with Nipissing ore. One lot analyzed 9.65 per cent cobalt, 4.65 nickel, 28.65 arsenic, 18.06 silver, 39 gangue.

The behavior of this ore was very similar to that of the smaltite ore. When heated alone a splendid separation was obtained into crude silver (83 per cent Ag), metal speiss, and slag. Upon cooling, the three layers can be very easily separated mechanically. (U. S. patent 996,479.)

The dividing line between silver and speiss is exceedingly sharp in the vacuum furnace product. A number of comparative runs were made in a carbon resistance furnace of the Moissan type, the gas pressure in the furnace being one atmosphere. Although a separation of the crude silver, speiss, and slag was obtained, it was very incomplete and the volume of arsenic fumes evolved was most annoying.

In the vacuum furnace it was found convenient to make the runs in two stages. During the first stage the temperature was maintained at about 1250 deg. to 1350 deg. for two hours. At the end of this time, instead of cooling down or tapping off the three components, the temperature was still further increased to 1550 deg. to 1600 deg. and the charge kept there for about three hours. At this temperature the silver distilled out, leaving the speiss and slag behind.

The composition of the charge at the end of the first stage was, crude silver (lowest layer) 27 per cent; speiss, 47 per cent; slag, 20 per cent, and arsenic (distillate) 8.5 per cent. The addition of 5 to 10 per cent of coke facilitates this separation of silver, speiss, and slag. Its action is partly chemical, as a reducing agent, and partly physical, in so far as it keeps the charge porous, allowing the gases to escape readily. The crude silver of three runs assayed 81.34 per cent, 82.21 per cent, and 83.7 per cent silver. There was no silver found in the slag, and none in the distillate at the end of the first stage. At the end of the second stage (1600 deg.) all of the silver was in the distillate and none in either speiss or slag.

The third part of Dr. Fink's paper deals with the production of antimony from stibnite. A vacuum-furnace process is suggested by the low vacuum boiling temperature of antimony. Under atmospheric pressure the metal melts at 632 deg. C. (Pelabon) and does not boil until a temperature of 1500 deg. to 1700 deg. is reached. The boiling-point in the vacuum, however, is not more than 100 deg. above the melting-point.

Dr. Fink's experiments show that either iron or, as before a calcium oxide and carbon mixture, may be employed as reducing agent. In the former case, with a temperature of 600 to 700 deg. C., the reaction

$$Sb_2S_3 + 3\,Fe = 3\,FeS + 2\,Sb$$

proceeds almost quantitatively in presence of an excess of iron. If this reaction is first allowed to take place, and the temperature then raised to 900 deg. to 1250 deg., the antimony will readily be distilled away from the sulphide of iron. If calcium oxide and carbon are used, the best results are obtained by using for every 11.3 parts of stibnite (62 per cent Sb), 12 parts limestone, 2½ parts coke, and 6 parts fluorspar.

All ingredients of the charge were finely ground (40 mesh) and thoroughly mixed. The heating was performed in two stages; the temperature was gradually raised to 600 deg. to 700 deg., and maintained at that point for one to one and a half hours, until the following reaction was practically complete:

$$Sb_2S_3 + 3\,CaCO_3 + 6\,C = 2\,Sb + 3\,CaS + 9\,CO$$

Thereupon the current was slowly increased until a temperature of about 1300 deg. was obtained, and after about one hour's heating at this point the charge was allowed to cool in vacuum. The addition of CaF_2 to the charge seems to facilitate the separation (by distillation) of the Sb from the slag in the second stage of the heating. At all events, better results were obtained with than without the addition of this flux.

Dr. Fink concludes that this $CaC_2 + CaCO_3$ or calcium carbide-vacuum method is cheap, and when the conditions are properly chosen the output is over 95 per cent. The product is practically equal in quality to that obtained by the "iron method."

As another application of vacuum-furnace metallurgy Dr. Fink mentions a gold-silver separation process of W. C. Arsem which consists in heating the alloy of these two metals in a vacuum furnace to a temperature of about 1300 deg., to distill off the silver. If platinum is present in the alloy, the temperature is raised, after the silver distillation is complete, to about 1500 deg., and the gold distilled over.

Dr. Fink's paper was discussed by Messrs. Richards, Hering, and Johnson.

Standard of Radio-Activity.

Mr. MERLE RANDALL presented a paper giving an extended account of an investigation carried out at the University of Missouri on "the Boltwood standard of radio-activity."

One of the experimental results is that in general no constant relation exists between the Boltwood emanation standard and the C. G. S. electrostatic standard as ordinarily used.

The maximum ionization current produced in the ordinary electroscopes by the radium emanation and its products from an old mineral containing one gram uranium was calculated as 6.18×10^{-10} amp. or 1.854 C. G. S. units.

For small electroscopes of the same design, the observed ionization current is nearly proportional to the volume of the ionization chamber.

The "ionization efficiency," *i.e.*, the ratio of the observed to the maximum ionization current, was found to vary between 39 and 79 per cent for the electroscopes studied.

Several forms of apparatus for separating the radium emanation from its solutions were studied, and the approximate efficiency of each form determined.

All the forms of apparatus for separating the emanation were successfully improved, so as to avoid all loss of emanation in the transfer of the gas from the collecting bulb to the electroscope.

In standardizing the electroscopes it is necessary to so arrange the standardizing experiments that nearly the same quantity of radium emanation is boiled off as in the later determinations.

A new form of electroscope is described by the author and its merits proven.

An improved method of mounting the plate glass inserts in the brass frames of several types of electroscopes is described, also a new form of cradle mounting for the reading microscope of electroscopes.

It is shown that in the case of some of the electroscopes the potential is proportional to the scale divisions over the range of the reading microscope. In other electroscopes this proportionality did not hold.

Small "flashlight" dry batteries were used and found satisfactory as a source of potential for calibrating and charging electroscopes.

A peculiar "crawl" effect was observed with electroscopes having sulphur insulation. The effect of this effect upon the rate of fall of the leaf is pointed out.

An anomaly in the air-leak was observed in some of the electroscopes used. The rate of leak decreased with the time-interval of charge of the leaf.

Dry Cells.

Prof. C. F. BURGESS then presented a preliminary report of the Committee on Dry Cell Tests (consisting of Messrs. C. F Burgess, J. W. Brown, F. H. Loveridge, and C. H. Thorp) and also read a paper by Mr. CARL HAMBUECHEN on the "performances of dry cells."

The preliminary committee report gave an account of standard methods which are recommended tentatively for the testing of dry cells. In view of the importance of the subject and in view of the fact that a paper on the same subject (emanating from the British National Physical Laboratory) has just been presented before the Faraday Society in London, all the dry cell papers are being reserved for our next issue when the subject will be covered in full.

Diffusion and E. M. F. Produced by Centrifugal Action.

The President-Elect, Dr. W. LASH MILLER, of the University of Toronto, presented a paper on "the influence of diffusion on electromotive force produced in solutions by centrifugal action."

In Tolman's measurements of the electromotive force produced in solutions by centrifugal action (Proc. Amer. Acad. Arts & Sci., vol. 46, p. 109, 1910), the equations for the electromotive force are deduced without allowing for any possible differences in concentration at the two ends of the tube produced by the whirling. As in some of his experiments these differences would become considerable if the rotation were sufficiently prolonged, it seemed possible that even in a few minutes the "concentration cell" effect might become measurable, and that it might perhaps account for the "residual electromotive force" observed by him.

Dr. Miller gives in the present paper the complete mathematical theory of the rate at which diffusion would take place under the influence of centrifugal force. Its application to Tolman's work shows, however, that the polarization produced by concentration changes in short periods of centrifuging is very slight and that the effect is much too small to account for the "residual" voltage observed by Tolman.

Phase Potentials.

A paper by Dr. REINHARD BEUTNER, of the Rockefeller Institute of Medical Research, deals with "potential differences at the junction of immiscible phases."

In the first part the emf's of cells formed of *solid* salts are discussed. For instance, a cell, made up of two solid silver salts, as follows:

$$Ag \quad \text{solid } AgCl \;|\; \text{solid } Ag_2SO_4 \;|\; Ag$$

has an emf exactly equal to zero. The reason is that no change is possible in this system.

It is quite different if a sodium salt is added; for instance,

$$Ag \;|\; \text{solid } AgCl \;|\; \text{solid } NaCl \;|\; \text{solid } Na_2SO_4 \;|\; \text{solid } Ag_2SO_4 \;|\; Ag$$

This cell shows an emf because in it the reaction

$$Ag_2SO_4 + 2\,NaCl = 2\,AgCl + Na_2SO_4$$

is possible. The emf will have such a direction that the current produced by it causes formations of those two salts which are in equilibrium or will not react with each other: these are AgCl and Na_2SO_4. That is, the silver electrode in contact with Ag_2SO_4 must be the positive pole and this is really the case. The emf calculated from thermochemical data is 0.535 volt, in good agreement with the experimental measurements.

Now, cells made up of saturated solutions or molten salts behave in a very different way. Hence the potential difference at the junction of two immiscible phases (or the "phase potential") is very different from the potential difference between aqueous solutions or between fused salts. The "phase potential" behaves very much more like a potential difference at metals. An important analogy between the two is that the potential difference between a metal and a solution of one of its salts varies with the concentration of the solution according to a logarithmic law, and that exactly the same rule holds good for phase potentials.

Phase potentials are of especial importance for electric phenomena in animals and plants. Organic tissues are built up from cells surrounded by membranes. These membranes separate aqueous solutions of various substances (among them salts) from each other. Although the chemical composition is unknown, any membrane may be assumed to have a small electrolytic conductivity (possibly of the order of magnitude of a solid salt). Then phase potentials will exist on both sides of the membrane.

Dr. Beutner gave an account of phase potential measurements on fruit skins and leaves and stated some general results there-

by obtained. Finally discussing the relation of this subject to Nernst's excitation law, he concluded that in the experiments with fruit skins and leaves, just mentioned, they have roughly imitated one of the processes which take place many thousand times in our nerves and muscles, when we move.

Dr. Beutners paper was discussed by Dr. Whitney and Dr. Bray.

Lead Plating.

A paper by Prof. Frank C. Mathers and O. Ralph Overman, of the University of Indiana, on "the effect of addition substances in lead plating baths," was read, in the absence of the authors, by Dr. Schluederberg.

This paper gives the results of experiments to find the best addition substances for use in lead plating and refining baths.

The following classes of compounds were tried: Inorganic, essential oils, resins and gums, sugars and starches, alkaloids and their derivatives, glucosides, proteids and nitrogeneous animal substances, ferments and enzymes, phenols and miscellaneous substances.

Some compound in all organic classes showed marked beneficial action. Most of the compounds were without marked beneficial action.

All effective addition agents contain the hydroxyl group. This is too general a relationship to be of any value.

The addition substances, arranged in the order of their beneficial action, are: Clove oil or eugenol, peptone, phloridzin and gum guaiac.

Clove oil is recommended for use in lead perchlorate plating and refining baths. About one-thrid of a pound is required per ton of lead.

Phloridzin is, perhaps, a slightly more satisfactory addition substance, but its cost is prohibitive for anything but experimental work.

Other satisfactory addition substances may be discovered among the oils and gums. These fields have not been completely covered.

A communicated discussion by Mr. Victor Engelhardt referred to two patents of Siemens & Halske and Nussbaum (German patent 223,152 and an older United States patent 832,024) relating to processes covered in the paper.

Dr. Bancroft criticized some of the authors' conclusions with respect to their applications to the theory of electrolytic deposition. "An effective addition agent forms a dispersed phase, solid or liquid, which is carried to the cathode by the current and is absorbed by the precipitating metal." This definition excludes sodium chloride from the list of addition agents. But there is no more reason to call sodium chloride an addition agent for copper than to call potassium cyanide an addition agent for silver. These substances do not form dispersed phases and are not carried as such to the cathode by the current. They act by cutting down the ion concentration and the hydrolysis, and by changing the corroding action of the solution on the metal or the salts of the metal. It is merely a source of confusion when two foundamentally different phenomena are grouped together.

Electric Endosmose.

Prof. Wilder D. Bancroft, of Cornell University, presented a paper on "electrical endosmose." Perrin has made the generalization that all porous diaphragms become charged positively in a solution which is strongly acid and become charged negatively if the solution is sufficiently strongly alkaline. This is the same as saying that electrical endosmose will carry the acid solution through the diaphragm from cathode to anode and will carry the alkaline solution through the diaphragm from anode to cathode. Without discussing whether this generalization is or is not absolutely accurate for all diaphragms, Professor Bancroft showed in his paper how certain apparent exceptions may be accounted for.

It was emphasized that the relative adsorption of cations and anions by a diaphragm determines the sign of the charge on a diaphragm, being positive if the cation is adsorbed to a greater extent than the anion and negative if the reverse is the case.

Various experimental facts with respect to both the movement of solutions through diaphragms and the analogous movement of colloids in solutions under the influence of the current were described and discussed in their relation to the theory of electroplating.

For instance, Müller and Bahntje found that, in acidified copper sulphate solutions, starch and gum arabic did not move to the cathode and did not cut down the size of the copper crystals when the solution was slightly acid; but did both these things when the solution was made more acid. The movement of the colloid to the anode in a slightly acid solution in a porous-cup experiment described is exactly analogous. Of course, the reversal will come at different degrees of acidity with different colloids. In fact, Müller and Bahntje found that gelatine moved to the cathode in solutions in which starch moved to the anode. The effectiveness of gelatine in cutting down the size of lead crystals in the Betts process is due largely to the fact that the solution is markedly acid.

Aluminium sulphate is often added to zinc baths to improve the quality of the zinc deposit. The explanation for this has been given by Schlötter. "Since aluminium sulphate is dissociated hydrolytically, in aqueous solution, into sulphuric acid and colloidal aluminium hydrozide, the action of aluminium sulphate is clearly that of a colloid. We get a similar result when copper is deposited electrolytically in presence of aluminium sulphate."

The electrolytic precipitation of black, perverulent copper from a dilute copper sulphate solution is also cleared up. This is shown to be due to hydrolysis, with a formation of too much colloidal cupric oxide (too much relatively to copper as ion).

Rotating Cathode.

A paper of Dr. C. W. Bennett, of Cornell University, described details of construction of a rotating cathode, built at the suggestion of Professor Bancroft, in order to obtain samples of metals and alloys by precipitation with high current density for the purpose of studying their physical properties.

The revolving cathode described will operate at speeds up to 6000 r.p.m. It will carry 300 amp, giving a current density of about 3500 amp per square foot when 4 in. of the cathode is receiving a deposit (385 amp per square decimeter on 10 cm). The metal can be removed in nice shape for testing physical properties without subjecting to strain of bending or heating.

Tensile Strength of Electrolytic Copper.

A second paper by Mr. C. W. Bennett related to "the tensile strength of electrolytic copper on a rotating cathode."

After reference to the commercial processes of Elmore and Cowper-Cowles for the electrolytic deposition of copper on rapidly rotating cathodes, the author described his own experimental arrangements.

A few fundamental relations were first emphasized. In general, if a solution is stirred during crystallization the crystals resulting are smaller than those from the same solution without stirring. It is also known that the tensile strength of steel, copper, etc., is increased by rolling. Rolling does nothing more than break down crystal aggregates, giving a more finely crystalline mass. Hence, with the precipitated copper an increase of tensile strength was expected with a decrease of crystal size as the rotation was increased. When this was tried the results showed that the theory was correct.

A solution containing 20 per cent $CuSO_4.5H_2O$ and 12 per cent H_2SO_4 was used. The temperature at starting was 35° C. This was desirable, for trial showed that this was the temperature maintained throughout a run at the current density used, *i.e.*, 500 amp per square foot (55 A. per square decimeter). The deposits were treated alike and every precaution was used to keep all conditions, save speed of rotation, constant.

The results are given in Fig. 4. There are two tensile strength curves given, one in vertical direction, the other in

direction of rotation. If the hypothesis was correct that the particles are drawn out in the direction of rotation and a fibrous interlacing mass is obtained, then the tensile strength would always be greatest in the direction of lamination. As

15 20 25 30 35 40 45 50 55

FIG. 6.—EFFECT OF TEMPERATURES.

the curves show that this is not the case, the above hypothesis is untenable.

The voltage curve in Fig. 4 shows that the voltage drop across the cell undergoes an astonishingly large increase with increase of speed of rotation.

The effect of variation of current density was next studied. Two sets of runs, one for a speed of the cathode 2500 r.p.m. and the other for 5500 revolutions, were made, the results being given in Fig. 5. The point brought out is that the maximum tensile strength is obtained at a higher current density when the rate of rotation and hence the rate of stirring is higher.

A few runs were made to show that the variation of the concentration of the electrolytic makes little difference in the difference in the tensile strength. But variation of temperature has a large effect.

If copper wire be drawn while cold through a die, the effect is a decrease in ductility and an increase in tensile strength. This is caused by the breaking down of the large crystals, giving smaller ones embedded more or less in amorphous material. The distance of shear through the crystal is relatively short and hence the elongation is short, or in other words the ductility is slight. The tensile strength goes up, for the material is worked more or less toward the amorphous end,

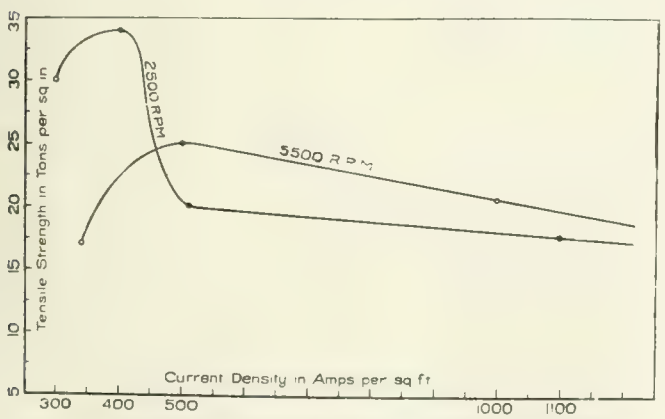

FIG. 5.—EFFECT OF CURRENT DENSITY ON TENSILE STRENGTH.

i.e., the crystals become smaller and under stress show a more even loading. If the hard drawn copper wire be annealed, the tensile strength goes down to about 30,000 lb. per square inch (21.0 kg. per square millimeter) as a limit, and the ductility is increased. The crystals become larger, the distance of shear before they break is longer and hence the ductility is increased.

By depositing copper on a rotating cathode, from a solution at room temperature, it is possible to duplicate the cold worked copper, getting a hard compact sample with very slight difficulty and a high tensile strength. Now by raising the temperature of the solution and hence that of the uncrystallized copper deposited, it ought to be possible to anneal the metal while it is being precipitated. Or looked at from the other point of view, crystallization from a hotter solution should give larger crystals, other things being equal.

That this is indeed so is admirably shown by the test results of Fig. 6. The chief results of the investigation are summed up as follows:

"Copper has been deposited electrolytically at a current density of 4000 amp per square foot or about 430 amp per square decimeter.

"In the electrolytic precipitation of a metal the crystal size decreases as the cathode is rotated more rapidly, other things being equal.

"The crystal size decreases as the current density increases and increases as the temperature rises.

"The concentration of the electrolyte can be varied quite a little without changing the character of the deposit.

"If the precipitation is carried on at a high temperature an

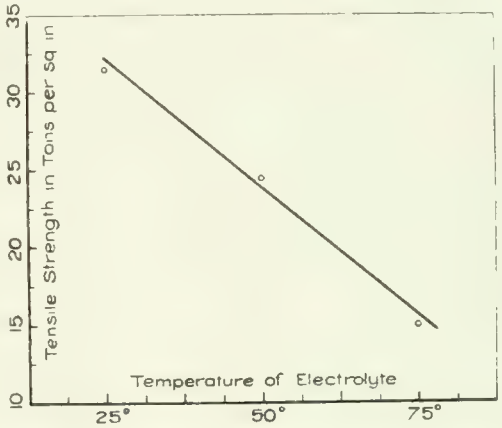

FIG. 4.—EFFECT OF SPEED ON TENSILE STRENGTH AND VOLTAGE.

effect similar to annealing is accomplished during the electrolysis.

"The tensile strength of metals varies inversely as the crystal size, and hence any factor tending to decrease the crystal size tends to increase the tensile strength.

"The effect of rapidly rotating the cathode and of increasing the current density is to increase the tensile strength, the crystal size being decreased.

"A good deposit of copper could apparently be obtained at an infinite current density if the stirring were efficient enough to prevent impoverishment.

"The current efficiency at a high current density with rapid rate of rotation is high, it being 99.6 per cent.

"'Hard drawn' copper can be deposited on a rotating cathode at almost any current density, if the temperature be kept down; and likewise annealed copper if the temperature be kept at about 75° C.

"Electrolytic copper has been obtained having a tensile strength of 68,000 lb. per square inch (47.6 kg. per square millimeter).

"A deposit as good as the best can be obtained with a current density of 2400 amp or more per square foot (264 A. per square decimeter) with the rate of stirring used.

"With the alloys, the trouble is most likely a question of colloidal material.

"Acid solutions, with readily soluble salts, and no possibility

for the formation of colloids should be sought for as electrolytes in alloy precipitation."

The two papers of Mr. Bennett were discussed by Dr. Hering (who suggested that as the surface velocity was the decisive element the speed could be reduced if the diameter of the cathode was made larger), by Mr. Hibbard and Dr. Bancroft.

Smee's Theory of Electrolytic Deposits.

In a paper by Prof. Wilder D. Bancroft with this title it is pointed out that in Smee's Elements of Electrometallurgy, published in 1842, there are some observations on the relation between current density and size of crystals, which appear to have been entirely overlooked or forgotten. Smee saw the analogy between crystallization and electrolytic precipitation and he knew that high current density and low concentration cause a decrease in the size of the crystals while a higher temperature gives rise to coarser crystals.

Regeneration of Sulphated Storage Cells.

In a paper by Messrs C. W. Bennett and D. S. Cole, of Cornell University, it is shown that badly sulphated cells can be economically regenerated by electrolysis in sodium sulphate solution. The cost need not be greater than 20 cents per cell. Allowing 5 cents per kilowatt-hour for power, the increase in the efficiency of the cell will pay for the regeneration in about 90 charges and discharges or in about three months' daily use.

The concentration of sodium sulphate recommended, which can be varied within wide limits, is 200 gr. of the crystallized salt ($Na_2SO_4.10H_2O$) per liter. The sodium sulphate should be chemically pure.

Volatility of Zinc Oxide.

A paper by Prof. O. L. Kowalke, of the University of Wisconsin, deals with the question as to the volatility of zinc oxide which is of importance for electric zinc smelting.

The author's experiments show that zinc oxide can be completely volatilized at temperatures from 1370 to 1400 deg. C.

The loss of zinc oxide increases rapidly with temperature rising above 1300 deg. C., as shown in these tests. The loss seems, however, to be of a nature similar to the slow evaporation of water below the boiling point, but at temperatures above 1400 deg. C. it appears reasonable to say that the volatilization proceeds rapidly.

Electrolytic Reduction of Blue Powder.

A paper by Mr. Warren F. Bleeker, of the Standard Chemical Company, of Canonsburg, Pa., describes an electrolytic method for the reduction of blue powder. Blue powder is essentially metallic zinc in a very finely divided condition, each particle coated with a film of microscopic thinness, and this film is the direct cause of the powder remaining as such, even at a temperature far above the melting point of zinc. It is well known that in various electric zinc furnace processes the condensation of zinc in liquid form has caused difficulties, blue powder having been obtained chiefly instead. Mr. Bleeker's process solves the problem how to treat the blue powder in a simple way.

The experiments were carried out in an iron pot which served as cathode, while an Acheson graphite rod was used as anode. Zinc chloride (previously dehydrated) was introduced into the pot and melted and electrolysis started. Blue powder was then added to the bath at regular intervals and stirred into the bath. It is reduced and the spelter deposits at once and accumulates rapidly in the bottom of the pot. The power consumption was one-tenth kilowatt-hour per pound of spelter. The process is not patented.

The paper was discussed by Dr. Hering and Mr. Sang.

Sherardizing.

A paper by Dr. Arden R. Johnson and Mr. Willis R. Woolrich, of De Paul University, "on the nature of zinc cementizing or sherardizing" was presented by Prof. Burgess.

The authors discuss the fundamental factors in the sherardizing process and describe results of tests made with pure zinc dust. These experiments refer to the relation of duration of heating to thickness of deposit, to the evolution of hydrogen from zinc dust, to the effect of temperature upon the rate of deposition of zinc, to the effect of the state of division of the zinc, and to the effect of mixing inert powders to the zinc dust.

From the results of their experiments the authors have evolved the following theory of the process of sherardizing. In the light of the phase-rule we may regard the iron, zinc and vapor as forming a closed system, all parts of which are practically at the same temperature. Zinc, compared with iron and most other metals, has a relatively high vapor tension. Zinc alloys fairly readily with many of the common metals like iron, nickel and copper. When the process is ready to be started, the iron, for instance, is surrounded and in intimate contact with many particles of zinc. Under the influence of heat these particles, carrying their slight atmospheres of zinc vapor, form a superficial alloy with iron. This superficial alloy on the iron would very likely be a solid solution of zinc very rich in iron. Now we may look upon the iron with its insignificant vapor pressure as greatly lowering the very appreciable vapor pressure of the zinc which is forming a solid solution with it, and we should expect the zinc vapor to distil from the points of higher tension to the place of low vapor tension at the surface of the iron-zinc alloy. As the iron alloy grows richer and richer in zinc under the process of sublimation or distillation, its vapor tension will gradually approach the tension of the vapor of pure zinc particles, and hence the process gradually ceases.

The experimental facts presented show that the nature of the metal to be "sherardized," having reference to its alloying properties with zinc, has a great influence on the temperature at which "sherardizing" will start and its rapidity after starting. That the authors did not succeed after several trials in depositing zinc on a pure zinc rod buried in zinc-dust is also in accord with our theory. Also pieces of iron which had once received a coat of zinc of considerable thickness refused to "sherardize" at any such rate as fresh iron at temperatures below the melting point of zinc. However, if the coat of zinc already present is thin the deposition will start again, though more or less tardily.

New lines for experimentation are suggested by this theory which should at the same time test its validity. One should expect zinc cementizing to be greatly retarded if the finely divided zinc used were a solid solution with some metal of low vapor tension, as iron, nickel or copper. If the vapor tension of the metal to be deposited is lowered until about equal to that of the most saturated solution possible on the surface of the metal being "sherardized," the process should not take place, or only to a slight extent. Furthermore, any substance which would impair or change the initial alloying tendencies of the metals should also greatly influence the process. It is along these lines that the authors are now proceeding in their experimentation.

In the discussion which followed Dr. Jos. W. Richards gave a theoretical curve for the vapor tension of zinc at low temperatures, derived by analogy from the vapor tension of mercury. From this curve and the author's determinations it seems that the rate at which sherardizing goes on at different temperatures is roughly proportional to the square root of the vapor tension. But the process of sherardizing depends not only on the vapor tension of the zinc, but also on the tendency of the other metal to absorb the zinc vapor.

The paper was further discussed by Messrs. Arthur, Miller, Bancroft and Duschak.

Corrosion of Iron by Sulphuric Acid.

The last paper of the meeting deals with "the effect of various substances on the rate of corrosion of iron by sulphuric acid," the author being Dr. Oliver P. Watts, of the

University of Wisconsin. The author refers to the fact that arsenic precipitates itself upon iron from solution and yet protects the iron almost completely from powerful corrosive agents. He offers the hypothesis that the explanation lies in the high overvoltage of hydrogen on arsenic. To test this hypothesis he has carried out an extended experimental investigation. The results confirm the hypothesis in a general way. Other metals of high overvoltage have a protective influence, while all metals of low overvoltage which deposit on iron are accelerators of its corrosion. So far as overvoltages are known, bismuth alone fails to conform to the hypothesis. Theoretically it should retard corrosion; actually it is an accelerator. Unless redeterminations of the overvoltage of bismuth and the single potential of iron shall reconcile theory with fact, the author's hypothesis fails. The overvoltage of bismuth was presumably measured on a solid electrode. Bismuth deposited as a powder. If there is the same difference in overvoltage for bismuth as between smooth and spongy platinum, this correction would put bismuth in the list of accelerators.

The statements which follow are intended to apply only to the corrosion of iron by sulphuric acid.

Tin, chromium and mercury retard corrosion; of these tin alone is as effective as arsenic. The protective action of mercury is very slight.

In studying the effect of different reagents on corrosion it is necessary to consider both the metal and the non-metal or acid radical, since each may have an effect of its own.

The binary salts and acids of the halogens are very good protective agents when used in considerable amounts. To combine most effectively the protective effects of a metal and a halogen, *e.g.*, tin and chlorine, much stannous chloride should not be added, for a large amount of the salt of any metal which precipitates on iron in an acid solution is likely to act as a corrosive agent; only a small amount of stannous chloride should be added, and the extra chlorine added as sodium chloride.

Oxidizing agents are in themselves accelerators of corrosion by acids, although in dilute solution this may be masked by a protective action which supervenes when the oxygen has been used up, as might happen with chromates.

Reducing agents should show more or less protective action, but this fact remains to be confirmed by further experiment.

The paper was discussed by Messrs. Hering, Cushman and Walker.

After a vote of thanks to all who had made the Boston meeting so successful and enjoyable the meeting adjourned.

Excursions and Social Functions.

The afternoon of Thursday was devoted to two alternative excursions. One was to the works of the General Electric Company at Lynn, Mass., where both the River Works and the West Lynn Works were visited. The other excursion was made to Worcester, where the 15-ton Heroult electric steel furnace at the plant of the American Steel & Wire Company was seen while being tapped and charged again and a visit was paid to the works of the Norton company, where the manufacture of alundum abrasives and refractories was shown. The management of the Norton company must be congratulated on the admirable way in which the visit was arranged.

On Thursday evening, after the lecture by Professor Cross, a smoker at the Tech Union was greatly enjoyed.

Here are two samples of electrochemical poetry. From a poem on "Les Immortels" (Dr. Baekeland, Dr. Whitney, Dr. Walker and Section Q) we quote the Whitney verse: "Where all the volts and args and watts and joules and ohms and dynes—Are concentrated into one with integration signs—You add one hundred million amps and calories galore—And make a man who works all day, and then he works some more; —It's Dr. Whitney—Our Dr. Whitney,—He lights the nights as tho' 'twere perfect day.—With much reluctance—He talks conductance,—And what is more, he makes the damn thing pay."

From F. E. G.'s electrochemical love song at least the first verse should be given: "Sue, dear, turn off the tungstens, why fear the night?—At ten centimes a kilowatt, let's save the light. —My love shines luminescent,—Your lamps are glowing blue incandescent,—Love loves the dark,—We two need no watt-candles, my flaming arc."

On Friday evening an informal subscription dinner was held at the Hotel Vendome. Dr. Walker was an admirable toast master and speeches were made by Dr. Whitney, Dr. Miller, Dr. Richards, Dr. Bancroft, Dr. Millikan and Dr. Richardson.

In the following we give a complete list of the names of members and guests who registered:

Paul O. Abbe, New York, N. Y.; C. L. Allen, Worcester, Mass.; Richard Amberg, East Orange, N. J.; W. C. Arsem, Schenectady, N. Y.; Walter Arthur, Schenectady, N. Y.; T. F. Baily, Alliance, O.; Wilder D. Bancroft, Ithaca, N. Y.; A. N. Barron, Cleveland, O.; Mr. and Mrs. Fred M. Becket, Niagara Falls, N. Y.; E. H. Bedell, New York City; C. W. Bennett, Ithaca, N. Y.; S. R. Bergman, Lynn, Mass.; E. R. Berry, Malden, Mass.; Reinhard Beutner, New York; Arthur A. Blanchard, Boston, Mass.; Warren F. Bleecker, Canonsburg, Pa.; P. A. Borck, Worcester, Mass.; John C. Bradley, Waterbury, Conn.; Wm. C. Bray, Boston, Mass.; J. W. Brown, Cleveland, O.; L. C. Brown, Lynn, Mass.; C. F. Burgess, Madison, Wis.; J. H. Byrne, Cleveland, O.; M. J. Callahan, Pittsfield, Mass.; W. A. Carter, Lynn, Mass.; C. R. Cary, Philadelphia, Pa.; A. L. Chesley, Boston, Mass.; R. T. Childs, New York, N. Y.; F. M. Claflin, Lynn, Mass.; Jesse Coates, Coatesville, Pa.; F. Parkman Cobn, Schenectady, N. Y.; T. E. Crossman, New York, N. Y.; R. W. Davis, Jr., Wyandotte, Mich.; Mr. C. Davisson, Pittsburgh, Pa.; Carl F. Dietz, Worcester, Mass.; Chas. A. Doremus, New York, N. Y.; Boyd Dudley, Jr., Rolla, Mo.; L. H. Duschak, Corning, N. Y.; James H. Ellis, Covington, Ky.; C. G. Fink, Harrison, N. J.; Mr. and Mrs. F. A. J. Fitz Gerald, Niagara Falls, N. Y.; Wm. R. Fleming, Newport, Ky.; Karl Georg Frank, New York, N. Y.; Milton W. Franklin, Schenectady, N. Y.; F. E. Gallagher, Boston, Mass.; Jos. J. Geretz, Philadelphia, Pa.; A. E. Gibbs, Wyandotte, Mich.; Miss M. E. Gibbs, Wyandotte, Mich.; A. McK. Gifford, Pittsfield, Mass.; Miss P. L. Gifford, Schenectady, N. Y.; John B. Glaze, Boston, Mass.; J. S. Goldbaum, Philadelphia, Pa.; Luis R. Gonzalez, Boston, Mass.; H. M. Goodwin, Boston, Mass.; J. S. Gravely, Wytherville, Va.; M. L. Griffin, Rumford, Me.; J. R. Griffith, Niagara Falls, N. Y.; E. J. Guay, Lynn, Mass.; C. A. Hansen, Schenectady, N. Y.; L. O. Hart, Harrison, N. J.; I. S Hartman, New York, N Y.; M. W. Hedden, Boston, Mass.; Carl Hering, Philadelphia, Pa.; Mr. and Mrs. Henry D. Hibbard, Plainfield, N. J.; Aldus C. Higgins, Worcester, Mass.; A. T. Hinkley, Niagara Falls, N. Y.; A. Hirsh, New York, N. Y.; C. Vey Holman, Bangor, Me.; A. H. Hooker, Niagara Falls, N. Y.; Henry Howard, Brookline, Mass.; L. E. Howard, Lockport, N. Y.; O. T. Hunzerford, Belleville, N. J.; Mr. and Mrs. Alvois von Isakovics, Monticello, N. Y.; Miss Marie von Isakovics, Monticello, N. Y.; Dugald C. Jackson, Boston, Mass.; W. McA. Johnson, Hartford, Conn.; H. T. Kalmus, Kingston, Ont.; R. M. Keeney, Somerville, Conn.; M. M. Kahn, New York; A. Laib, Philadelphia, Pa.; M. O. Lamar, Schenectady, N. Y.; F. C. Lanzenberg, Athens, O.; S. H. Lawton, Boston, Mass.; F. A. Lidbury, Niagara Falls, N. Y.; Stewart I. Lloyd, University, Ala.; D. A. Lyon, Cambridge, Mass.; R. P. MacPherson, Pittsfield, Mass.; J. P. Maffield, Cambridge, Mass.; R. D. Mailey, Boston, Mass.; Paul R. Manahan, Walpole, Mass.; C. W. Marsh, New York, N. Y.; Arthur C. Melcher, Boston, Mass.; L. M. Miller, Schenectady, N. Y.; W. Lash Miller, Toronto, Ont.; R. A. Millikan, Chicago, Ill.; J. P. Minton, Peoria, Ill.; Thomas A. Mitchell, North Waburn, Mass.; Edward Mueller, Boston, Mass.; I. M. Muir, New York, N. Y.; Geo. J. Niebuhr, Newark, N. J.; P. G. Nutting, Washington, D. C.; L. G Odell, Newtonville, Mass.; Mr. and Mrs. G. S. Page, Pittsburgh, Pa.; Walter O. Patrick, Boston, Mass.; H. D. Pease, New York, N. Y.; John C. Pennie, New York, N. Y.; N. Petinot, Niagara Falls, N. Y.; W. B. Pritz, Cleveland, O.; Mr. and Mrs. E. Quintard, Schenectady, N. Y.; Merle Randall, Poplar Bluff, Mo.; Jos. W. Richards, South Bethlehem, Pa.; F. W. Robinson, Newark, N. J.; E. F. Roeber, New York, N. Y.; Mr. and Mrs. W. E. Ruder, Schenectady, N. Y.; S. P. Sadtler, Philadelphia, Pa.; Pedro G. Salom, Philadelphia, Pa.; R. N. Sargent, Perth Amboy, N. J.; L. E. Saunders, Niagara Falls, N. Y.; Walter H. Sawyer, Lewiston, Me.; Carl G. Schluederberg, Pittsburgh, Pa.; Mr. and Mrs. J. A. Seede, Schenectady, N. Y.; S. Sharples, Cambridge, Mass.; C. E. Skinner, Pittsburgh, Pa.; W. C. Slade, Pittsfield, Mass.; Acheson Smith, Niagara Falls, N. Y.; H. Clyde Snook, Philadelphia, Pa.; E. C. Sprague, Niagara Falls, N. Pattray Wilson, Niagara Falls, N. Y.; E. Weintraub, Lynn, Mass.; A. Berv Werby, State College, Pa.; W. R. Whitney, Schenectady, N. Y.; W. J. Wooldridge, Pittsfield, Mass.; E. P. Young, Boston, Mass.; Jno. A. Yunck, South Orange, N. J.

Gold in bituminous coal is reported by the Geological Survey in connection with a treatise on Wyoming coal. It appears that the coal from the mines about Cambria, Wyo., has been found to carry gold to the value of $2 per ton. When coke made at Cambria was selling at $3.50 per ton, samples were assayed for gold and silver and found to contain $2.46 in gold and $0.28 in silver per ton.

Notes on Chemistry and Metallurgy in Great Britain.

(From our Special Correspondent.)

Sequels of the Coal Strike.

Some consequences of the colliers' strike which in all probability were quite unanticipated by the miners and their blind-guide "leaders" promise to form the initial chapter of the lesson of which both the strikers and the agitators stand so greatly in need, namely, that—as Sir William Ramsay indicated in a recent speech—the coal miners are not altogether indispensable, at all events in their present numbers.

A dispassionate, careful and detailed consideration of Sir William's suggestion for converting the coal into gas *in situ* and drawing off the gas for utilization at the surface in the production and distribution of electrical energy, and in other obvious ways, is not likely to flush even the most ardent advocate of the conversion of our coal mines into gas-wells with great hopes of success; but a small mine has been placed at Sir William's disposal, and it is understood that the practical experiment will be tried in the coming summer; so let those who are inclined to hasty judgment remember that the promise of rapid steam locomotion was at first received with incredulity and derision, and that this is far from being a solitary instance of projects which even men of science regarded as unrealizable having been achieved and having passed into the category of everyday commonplaces.

In the region of fact there are clear indications that our manufacturers who can dispense wholly or in part with the use of coal do not intend to be so completely dependent on its supply as they have been hitherto. Many small and moderate consumers of power have placed orders for electric motors; and there is every prospect of their example being extensively followed by larger firms as soon as the foundries can supply castings. Inquiries for oil engines promise to increase very considerably, and steam raising by liquid fuel is advancing. The power-house of the Liverpool Corporation is being equipped by a well-known liquid fuel apparatus company, as is also Messrs. Harland and Wolff's power house at Belfast, while several factories are being supplied with the same or similar plant. Compressed oil fuel is passing favorably through the experimental stage; and its low cost and superior calorific value are practically certain to ensure an immediate and growing demand.

Finally, several mines in which the remaining coal would only suffice for a year's working or so, together with a larger number of pits where the nature of the seams entails high working costs are, or will be, permanently closed, with the result that some thousands of men who were earning very good wages will, until they can find other employment, have leisure to reflect on their want of foresight.

The Volatility of Metals of the Platinum Group.

At the meeting of the Royal Society early in March a paper on this subject was read by Sir William Crookes, who said he had noticed that the coil of platinum foil in a small electric resistance furnace became thinner with use until it fused at the weakest spot. He then discovered on the porcelain tube a fine deposit of well-formed brilliant metallic crystals which were analysed and found to be platinum. The loss of weight on a platinum crucible heated to 1300 deg. C. for 30 hours in an electric furnace was then determined and found to be 0.245 per cent.; palladium heated to the same temperature for the same time lost 0.745 per cent; and an iridium crucible heated to 1300 deg. C. for 22 hours lost more than 0.7 per cent, while at higher temperatures the loss was greater and proportional to the temperature. The surface of the iridium crucible had assumed a crystalline appearance at the beginning of the latter series of tests, and at the conclusion the edges exhibited incipient disintegration and crumbled when handled with forceps. Rhodium showed a loss of 0.13 per cent in 30 hours at 1300 deg. C.—about half that of platinum.

At 900 deg. C. in the flame of a Méker burner, platinum and rhodium suffered no loss after 20 hours; but palladium and iridium lost in 10 hours 0.0919 per cent, and 0.091 per cent respectively.

The volatilization of iridium at high temperatures *in vacuo* was effected by placing a weighed quantity of the pure clean metal in a fused silica bulb-tube which was then exhausted and heated nearly to redness until moisture and occuluded gases were entirely eliminated; the drawn out end was sealed off, and the tube was placed in a suitable position in an electric furnace where the bulb was heated to 1300 deg. C. for 30 hours. When cold the bulb and the neighboring parts of the tube were observed to have become devitrified and opalescent; and on the less heated portion there was a black deposit which was found on examination to be metallic iridium.

There is little, if any thing, of new discovery in these results. The unsuitability of the platinum and platinum-iridium thermocouple for temperatures over 1000 deg. C. has for years been suspected to be due to volatilization of the iridium; and in at least one not very recent paper dealing with pyrometry the volatility of this metal has been definitely asserted.

It is fairly well known, too, that platinum loses weight by prolonged exposure to the highest temperatures obtainable in a muffle.

Dielectric Resistance with Alternating Currents.

At the meeting of the Institution of Electrical Engineers on the 28th of March, a paper by Professor J. A. Fleming and G. B. Dyke "On the Power Factor and Conductivity of Dielectrics When Tested With Alternating Electric Currents of Telephonic Frequency at Various Temperatures" was read.

It was a noteworthy contribution to electrical knowledge, and deserves the attention of all who have to deal with insulation problems, particularly in relation to alternating emf of low voltage of pure sine-wave form, with frequencies from 900 to 5000. The summary states that the alternating-current dielectric constants of crown glass, celluloid, dry Manila paper, paraffin, ebonite, and mica are of the same order as those obtained with unidirectional electric force; but pure and vulcanized rubber and gutta percha give lower values. The general agreement of the constants found by the authors' methods with those obtained by other methods indicate that their measurements are accurate. It is shown that whereas the power factor of vulcanized rubber at ordinary temperatures is only one-tenth of that possessed by gutta percha yet its alternating-current resistivity is ten times as great as that of gutta percha; and, therefore, the ratio of conductivity to capacity (S/C) is ten times smaller at about 18 deg. C. The figures given in the textbooks for the dielectric resistance of gutta percha as used on cables at 75 deg. F. and for pure rubber at 15 deg. C., per cubic centimeter, after one minute, are nearly 100,000 times greater than the real alternating-current resistivity for the telephonic standard frequency of 800 p.p.s.

The following conclusions are among those arrived at by the authors: (1) All the dielectrics so far tested prove to possess a true dielectric conductivity for alternating currents considerably greater than for steady unidirectional currents. (2) This increased conductivity implies greater power dissipation for the same terminal potential difference or voltage. (3) The alternating-current conductivity increases with the temperature except in the case of vulcanized india rubber rather below 20 deg C., and gutta percha rather above 15 deg. C., in both of which cases it decreases with rise of temperature. In the case of mica and very dry paper it is not affected to any sensible extent by rise of temperature over a range between 0 deg. C. and 60 deg. C. (4) The alternating-current conductivity is in most cases a linear function of the frequency and may be expressed in the form $a + b\,n$, where a and b are coefficients which are functions of the temperature and n is the frequency. (5) The

alternating current conductivity, especially that part of it denoted by a, is greatly increased by the presence of moisture in the dielectric. This part is probably identical with the true direct-current conductivity. (6) The part of the conductivity denoted by the coefficient a is possibly electrolytic in nature, while the part proportional to the frequency is a consequence of an energy loss which is possibly analogous to the hysteresis loss in iron.

The National Physical Laboratory.

At the meeting of the General Board, in the middle of March, the report for 1911 was presented; but it has not yet been issued. In the department of metallurgy the researches on aluminium-zinc alloys and aluminium-zinc-copper alloys were continued, and investigations were carried out on the melting point of iron; the effect of stress at high temperatures; the microstructure of steel at high temperatures; and the causes of brittleness in steel. Experiments on the spontaneous combustion of charcoal yielded very interesting results. With an air supply ranging from 5 to 62 cubic feet per minute to 1 cubic foot of flaked charcoal spontaneous combustion took place at temperatures varying with the rate of air supply from 96 deg. C. to 110 deg. C.; but below 96 deg. C. no rise of temperature was observed in the charcoal. With air containing 5 per cent of sulphur dioxide, spontaneous ignition of charcoal resulted at the temperature of the air, about 18 deg. C.; but samples of decayed wood were far less readily acted on.

Ferrosilicon Explosions.

A. von Gumberz (*Stahl und Eisen*, 1912, 32, p. 267) has investigated two cases of explosions which followed the addition of ferrosilicon to molten steel. In both cases fully 25 minutes elapsed after the ferrosilicon was added before explosion occurred in the ladle. In one case the precautions included the previous raising of the ferrosilicon to a red heat and the thorough heating of the ladle; consequently the presence of residual paraffin on the surface of the ferrosilicon or of gases and moisture could not be suggested as a probable cause. Research established the fact that at a red heat ferrosilicon and copper oxide react exothermically with production of metallic copper and silica. The heat evolved is described as "considerable"; and the suggestion is made that a possible cause of the explosions may be a reaction of the same nature between the ferrosilicon and the iron oxides existing in the slag; but this point remains to be determined.

English Petroleum.

The *Electrical Review* of the 29th of March, announces, in a communication from Mr. W. H. Booth, that petroleum has been found in two spots in England. Near Woking, the lower greensand was reached at a depth of 1571 ft., closely approximating to the mean of the limits Mr. Booth estimated. At present no information has been vouchsafed as to the yield; but, as the discovery is now some weeks old, it is not probable that any great flow has been tapped.

Estimation of Manganese in Ferro-Tungsten.

P. Slawick (*Chem. Zeit*, 1912, 36, 106) heats a mixture of one gramme of the finely divided sample with ten grammes of sodium peroxide for about 3 minutes in a porcelain crucible at a dull red heat; after cooling, extraction with water, and cautious audification with hydrochloric acid, the liquid is boiled for 15 or 20 minutes with a large excess of hydrochloric acid, a slight excess of zinc oxide added, and the whole boiled up and titrated with permanganate. The method has the advantage of rapidity, and the error indicated by a check analysis by another method amounts to 0.02 per cent on an alloy having a manganese content of 0.47 per cent.

Engineering Imports and Exports.

The returns issued by the Board of Trade for January and February compare very favorably with those for the corresponding period of last year, and show substantial increases all around except in imports of new ships, which decreased. The month of February taken alone exhibits a similar improvement. For the two months the imports of iron and steel, including manufactures, are valued at £2,021,532, and exports at £7,907,437 and the respective increases are £332,020 and £711,027. Imports of other metals, including manufactures, reached £5,037,991, an increase of £719,357, with exports £1,877,272, an increase of £169,086. Electrical goods were imported to the value of £274,991, an increase of £43,442; while exports amounted to £528,080 showing an improvement of £99,356. In machinery the imports touched £1,024,516, and the exports are put at £5,013,298, the respective increases being £139,604 and £298,852. Imports of new ships amounted to only £507, a fall of £36,585; but the exports, valued at £711,714, increased by £90,867.

Market Prices.
March, 1912.

Copper has risen considerably throughout the month. Starting at £64.10.0 it was at £65.5.0 by the 5th, then fell away to £64.5.0 by the 11th, recovered 13th, and lost slightly on the 18th. Since then the rise has been rapid, and it now stands at £68.5.0.

Tin has been credited with a "boom," which does not seem an altogether accurate description, the highest price this year being £202, and the lowest £191. Opening at £199 it closes at £198.

Lead has shown a decided upward tendency. Starting at £16.4.0 it was much the same on the 13th, but has since risen steadily to £16.10.0.

Haematite has risen, iron generally being affected by the limited production. Opening 64/6 it closes at 66/-.

Scotch Pig has risen smartly from 55/6 to 56/8 by the 14th and 57/- on the 18th, closing at 58/-.

Cleveland follows much the same course as Scotch Pig, starting 49/6 and reaching 51/8 on the 18th, it closes at 51/3.

India-Rubber has been higher, and with some tendency to harden. Opened 4/8, closes 5/-.

A general rise in metals is evidenced, consequent on limited production throwing the market back on stock.

Recent Metallurgical and Chemical Patents

Iron and Steel.

Titanium Treatment of Steel.—Mr. AUGUSTE J. ROSSI, the untiring worker on titanium, suggests that the usual universal use of ferrosilicon and ferromanganese in connection with the Bessemer converter, open hearth, and crucible processes can be dispensed with, if a treatment with ferrotitanium is substituted for it. For instance, in the case of the Bessemer converter process, after the metal has been blown, it is recarbonized either in the converter or intermediate ladle by any of the well-known recarburizing methods other than by ferromanganese or spiegeleisen. To the metal thus recarburized he then adds, preferably in the intermediate ladle, such an amount of ferrotitanium as to satisfy the affinity of titanium for all undesired elements and compounds present. He then pauses in the operation for a time determined to insure all the reactions possible with the titanium, after which the metal may be poured and cast into ingots as usual. The absence of manganese and silicon is stated not to impair the tensile strength. From ordinary steel the product of this process is distinguished as it contains some titanium (less than 2 per cent being claimed), but much less manganese and much less silicon, if any more than traces, and less carbon. "Notwithstanding it may contain only a moderate percentage of carbon, say for example not to exceed 0.5 per cent, its tensile strength is as great or greater than though it had contained the heretofore usual percentages of manganese and silicon required, for instance, in steel used for rails." (1,017,807, Feb. 20, 1912.)

Hot-Blast Stove.—A patent of Prof. WALTER MATHESIUS, of Charlottenburg, Germany, relates to the construction of a hot-blast stove in which the combustion chamber is arranged centrally, so as to reduce the loss due to heat radiation, and is surrounded by concentric annular flues through which the gases pass in a zigzag course, an inner cupola or dome being provided within the usual outer cupola. Heretofore, the practical utility of such a construction has been frustrated owing to the fact that the inner cupola was not held rigidly in position independently of the walls of the flues, but was carried by the latter, so that the flue walls were subjected to too great a load, which resulted in leakages and in a diminished efficiency of the stove. In the construction of Mathesius one or more of the flues are continued upwardly through the outer or larger cupola, and a smaller cupola is fitted on the top of the elongated flues, a tight stuffing-joint being formed between the elongated flues and cupolas. The latter are moreover carried by the outer iron shell of the stove so that the flue walls only require to support their own weight. In order to create as long a flame as possible in the combustion chamber, the furnace gases and the air for combustion are admitted not radially, but tangentially and parallel to one another so that the flame takes a spirally upward course. In Fig. 1 the furnace gases and the air are admitted through the conduits 3 and 4 respectively. Surrounding the combustion chamber 1 are annular flue walls 5 and 6, forming flue spaces 7 and 8, and around the outer flue wall 6 is provided checkered brickwork 9 between the wall 6 and the outer wall 10, which is surrounded by the iron shell 11. Below the checkered brickwork 9 is a flue space 12 communicating through a conduit 13 with the chimney 21 is the cold air-blast inlet. The smaller cupola 17 is only about half the diameter of the cupola 14 so that the radiation of heat from 17 is only about one-fourth that of the cupolas of the Cowper stove now in general use. Further on account of the large space of the combustion chamber, and the spiral path of the gases and air moving in it upwards, the combustion is retarded and local heating is obviated. The temperature of the gases in cupola 14 is said to seldom exceed 800 deg. C. (1,018,331, Feb. 20, 1912.)

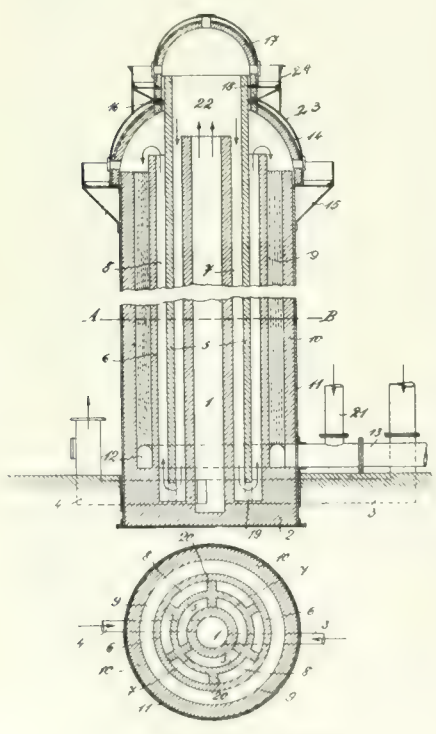

FIG. 1.—HOT BLAST STOVE.

Melting Steel Scrap.—In connection with a former American Electrochemical Society paper of Mr. ALBERT E. GREENE of Chicago, Ill., on his "electric converter, (our Vol. IX., p. 275) a recent patent of Mr. Greene is interesting. The object is to melt steel rich in manganese, silicon or other alloys with pig iron and convert the mixture into steel, without substantial loss of the alloys. The molten pig iron is charged into an electric furnace provided with twyers for blowing the bath. The manganese-steel scrap or other alloy-steel scrap is then added, and while maintaining the bath molten, the bath is blown with a gas which will decarbonize the metal without substantial loss of alloys, thereby converting the charge into steel. The gas should have a component of a reducing nature with respect to the oxides of the alloying metals and a component of an oxidizing nature with respect to carbon. For this purpose a mixture of CO and CO_2 in suitable proportions should be used. When the scrap consists of metals like manganese, nickel, chromium, etc., a basic furnace may be used. But when the scrap contains acid-forming metals like silicon, tungsten, titanium, vanadium and the like, it is desirable to carry out the process in an acid-lined electric furnace, starting with pig iron suitably free from phosphorus and sulphur. If the pig iron contains too much phosphorus and sulphur, these elements are first removed by charging the pig iron into a basic-lined electric furnace and, after adding lime and fluorspar, blowing it with gas of about the composition of blast-furnace gas, containing 20 to 25 per cent CO and 10 to 15 per cent CO_2, maintaining the temperature at about 1300° C. At this temperature the phosphorus comes out more readily than carbon. The sulphur may be removed at the same time as calcium sulphide. Mr. Greene has found that the carbon can be removed from a bath of pig iron and manganese-steel scrap with a loss of less than 2.5 per cent of the original content of manganese and that at the same time nearly all the silicon can be retained if desired. (1,018,418, Feb. 27, 1912.)

Purifying Molten Metal.—Superheated steam has been used heretofore for the purpose of partly refining and purifying metals by forcing the steam through a molten mass. Mr. WILLIAM H. KELLY, of Los Angeles, Cal., proposes to substitute dissociated steam for superheated steam and treat molten metal with the dissociated gases, hydrogen and oxygen. He generates steam in a boiler and passes the steam through a suitably heated retort where the steam is dissociated. It is then conducted through a suitable tube and nozzle into the molten mass of metal. The inventor claims improvement in purifying by his method. (1,019,065, March 12, 1912.)

Fire Brick Lining for Furnaces.—An improved form of furnace brick has been patented by Mr. ALLAN N. H. STRALE, of Chicago. In the ordinary manner of lining furnaces with the brick commonly provided for that purpose, the vertical joints are broken, but the horizontal joints between successive courses of brick are continuous and comparatively open, so that leaks of gas may occur more easily along those lines. The inventor has designed special forms of brick which, when properly laid, will result in broken and bonded horizontal joints, as well as similarly formed vertical joints. In Fig. 1 is shown the manner of laying the bricks in order to attain this end. (1,021,851, April 2, 1912.)

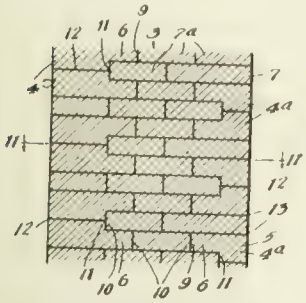

FIG. 2.—FURNACE LINING.

Furnace Charging Apparatus.—In that type of furnace charging apparatus in which a skip or car is periodically loaded, elevated and dumped into a receiving bell hopper, Mr. DAVID BAKER, of Philadelphia, has patented a combination whereby the operation of the upper and lower bells is effected automatically in harmony with the elevation of the skip. By a system of valves and pistons, the upper, or receiving, bell is actuated by the travel of the skip, so that it regularly discharges its contents into the lower bell at each trip of the skip. Control of the lower bell is arranged whereby after a certain number of trips by the skip the former will discharge its contents into the furnace. These operations are controlled by a regulator connected with the hoisting engine. (1,016,539, Feb. 6, 1912.)

Gold and Silver.

Oxidizing Leaching Solution.—Interesting claims are made for a new combination of chemicals used in the treatment of gold and silver ores in the form of sulphides, tellurides, selenides, arsenides and antimonides. JOSÉ B. DE ALZUGARAY, of New York, is the patentee, and has assigned his invention to the International Metallurgical Company, New York. The chief object of the invention is to produce a combination of chemicals which will be strongly oxidizing in their action, and at the same time act as good solvents for the precious metals. The inventor uses hypobromites, bromates and perbromites as strong oxidizers, in combination with alkali cyanides as solvents for gold and silver. In order to overcome the slow action of cyanide solvents on silver the inventor proposes to add a suitable amount of alkali or alkali-earth chloride, which acts as a silver solvent, forming silver chloride, which is easily soluble in cyanide solutions. As an example of the composition of his leaching solution, the inventor gives the following:

Potassium cyanide	0.6
Ferrocyanide	0.3
Calcium hypobromite, bromate or perbromite	0.1
Sodium or calcium chloride	3.0

The same apparatus used in the ordinary cyanide process may be used in applying the above solution. (1,018,955, Feb. 27, 1912.)

Precipitation by Atomized Lead and Zinc.—For many years the standard method of precipitating cyanide solutions of gold and silver has consisted in percolating the solution through masses of zinc shavings. More recently, zinc dust, a by-product of zinc smelting, has been used and found generally more efficient than shavings. Still more recently, however, Mr. JAMES M. NEIL, of Toronto, Canada, has proposed the use of finely divided or atomized lead and zinc, prepared artificially. The method of atomizing these metals was described in our issue for March, 1912, page 180. The metals, lead or zinc, are melted and then atomized by a jet of steam or air, and recovered in the form of metallic dust, free from oxide and in prime condition for precipitation of cyanide solutions.

Mr. Neil states that he has found atomized lead to be a more active precipitant than zinc shavings or zinc dust. The atomized metal may be added to the solution in the usual manner, and the quantity used may be varied according to the richness of the solution. The inventor states, also, that a combination of atomized lead and atomized zinc is still more efficient than either metal alone. The best proportion is one part of lead to two or more parts of zinc. When these metals are mixed and agitated with the cyanide solution an electrogalvanic action is set up, which rapidly precipitates the dissolved gold and silver. The zinc goes into solution, but the lead forms part of the precipitate and is of value in the later process of refining by cupellation. (1,018,438, Feb. 27, 1912.)

Zinc-dust Precipitating Apparatus.—In Fig. 2 is shown an improved device for accurately proportioning the charge of zinc dust to a definite volume of cyanide solution, and giving the exact time of contact desired before the precipitated solution is delivered to the filtering medium. It is the invention of DANIEL BOSQUI, of Gold Road, Ariz., and has been assigned to the Merrill Metallurgical Company, San Francisco, Cal.

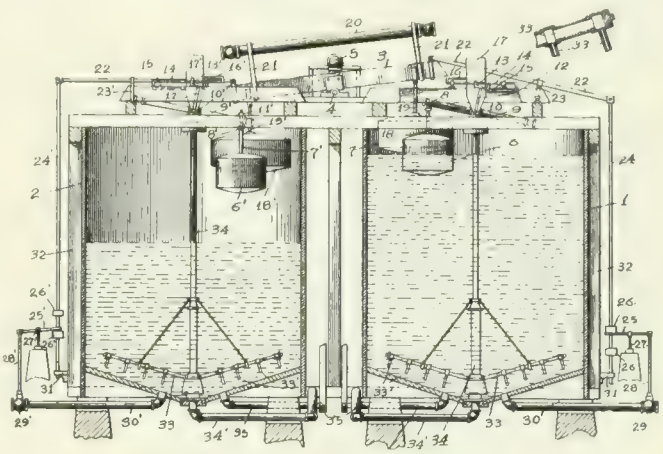

FIG. 3.—ZINC DUST PRECIPITATING APPARATUS.

The apparatus comprises two tanks into which the cyanide solution can be diverted alternately, feed means for delivering a predetermined quantity of zinc dust to the tanks alternately, and means for agitating the mixture of solution and dust. The several steps in the cycle of the process are controlled automatically, as will be seen from the following description. As the operation of the two tanks is identical, only one will be described.

The cyanide solution enters by way of the pipe 5 and the tilting launder 3. As one of the tanks becomes filled to a predetermined point, according to the time of contact desired, the solution raises the float 6. The float is connected by stem 7 with the tilting lever 9, which is a tube partly filled with mercury. As the inner end of the lever is raised the mercury flows to the opposite end and causes the forked arm 12 to be thrown sharply to one side. This forked arm engages a pin 13 which is attached to the slide arm 14, which in turn carries cutter blades 15 and 16 which move within the zinc dust hopper 17, and periodically discharge therefrom a definite quantity of zinc dust into the solution in the tank.

After the discharge of the zinc dust into the solution the latter continues to run into the tank until it acts on the second float 18, which is connected by the rod 19 with the tilting launder 3. Attached to and placed above the launder is a pipe 20 containing mercury which, in flowing to the lower end of the tube, causes the tilting launder to move and discharge the inflowing solution into the other tank. At the same time the rising end of the launder acts through the lever 22, which is pivoted at 23, and lowers the rod 24 which is connected by

lever 28 and rod 27 with the valve 29 which controls the out flow of solution to the filter. Hence the rising launder diverts the flow of solution to the other tank and automatically opens the valve 29 so that the precipitated solution can flow from the tank to the filter.

An agitator consisting of a vertical support 34, radial arms 33 and nozzles 33′ is located in each tank. A centrifugal pump 35 has a suction pipe 35′ and discharge pipe 34′, the latter entering the agitator as shown. When the pump is in operation it forces the solution into the arms and out of the nozzles of the agitator, causing the latter to revolve in the tank and keep the solution and zinc dust well mixed during the definite period which elapses between the addition of the zinc and the discharge of the precipitated solution.

One of the tanks is filling while the other is being emptied, and the action of the mechanism of one is complementary to that of the other. There is no contact of air and solution except at the surface, and yet there is a thorough mixture of solution and zinc in definite quantities and during a definite period of time. (1,018,604, Feb. 27, 1912.)

Agitator.—A combination of the features of air-lift and mechanical agitation has been invented by Mr. CHARLES C. HAFER, of Phoenix, Ariz. It consists of a rotatable hollow vertical shaft supported at the bottom of a tank in a step bearing and at the top by a beam extending across the tank. Near the top and bottom of the vertical shaft are radial arms which support several vertical air-lift pipes, those on opposite sides of the shaft having their discharge ends curved horizontally in opposite directions. The arms and pipes revolve with the vertical hollow shaft. Extending from the bottom of the latter are air pipes which communicate with the vertical air-lift pipes. In operation air is sent down the vertical hollow shaft and through the lower air pipes into the air lifts. The solution is raised and discharged, the reaction of the discharge causing the agitator to rotate in the tank, thus bringing about air and mechanical agitation. (1,020,694, March 19, 1912.)

Copper and Zinc.

Fusing Cathode Copper.—In order to fuse cathode copper and obtain a pure product, free from contaminating gaseous substances, Messrs. WALTER S. ROCKEY and HILLIARY ELDRIDGE, of New York, propose to carry on the operation in a furnace with two compartments. Both of these compartments are provided with oil jets. The copper is fused by the oil jet in the first compartment. The molten metal accumulates in a depression in the bottom which serves as a trap and flows by a conduit into the second compartment where it is received in a crucible provided with a conical perforated cover. The lower part of this crucible is in the form of another trap which prevents the ingress of combustion gases from the chamber in which the crucible rests. By keeping the copper molten in the second compartment at a high temperature the gaseous contaminations are removed by volatilization; and as the trap effectually prevents the ingress of any further gaseous compounds, the copper can be collected in a very pure condition. The object of the process is to prevent the very pure cathode copper from being contaminated in remelting. (1,018,681, Feb. 27, 1912.)

Refining Scrap Copper Alloy.—A method of obtaining a higher degree of purity in remelted copper alloy than has been possible by former methods is proposed by WALTER S. ROCKEY and HILLIARY ELDRIDGE, of New York. They first fuse a flux of boron trioxide, or one containing that substance, and then introduce the copper scrap. The latter melts beneath the flux and its impurities are dissolved therein. A reducing substance, such as carbon, is then added to the flux for the purpose of further reducing the impurities which may have been dissolved, after which the purified alloy may be separated in any desirable manner. (1,019,524, March 5, 1912.)

Roasting Copper Pyrites.—In roasting copper sulphide ores for the purpose of subsequently obtaining the copper by a wet process, it is desirable to carry on the roasting operation so that the maximum amount of copper shall be present in a soluble form. CHARLES GABRIELLI, of Paris, France, has proposed a method of roasting in which the gases can be used for the manufacture of acid and the residue be left in good condition for wet extraction. This process consists in adding to the dead-roasted pyrites a certain quantity of green pyrites at that part of the furnace hearth where the temperature is higher than that at which the sulphate of iron will decompose, but lower than that at which copper sulphate would decompose. A soluble sulphate of the copper is thus formed, while the iron is left in an insoluble form. The inventor claims that this method of roasting will give a higher yield of copper than is obtained by present methods, while at the same time the process does not interfere with the recovery of sulphuric acid. (1,018,609, Feb. 27, 1912.)

Treatment of Copper Ores.—The use of a wet process as an adjunct to ordinary concentration of ores is proposed by Dr. RUDOLF GAHL, of Morenci, Ariz. The inventor cites the well-known losses suffered in concentration, and suggests the use of a wet process to recover metal which now is lost. In carrying his invention into effect he crushes the ore finely enough to liberate all the mineral from gangue, and makes no particular effort to prevent the formation of slime. The coarse sand tailing resulting from concentration is usually clean enough to be discarded at once, but the slime tailing is treated by the proposed wet process. This consists in leeching the tailing with ferric sulphate, which can be prepared cheaply according to several methods indicated by the inventor. Some mine waters carry ferric sulphate in solution; ferruginous smelter slags can be treated with the sulphurous and sulphuric acids contained in the waste gases; scrap iron can be treated with sulphuric acid; iron oxide ore can be mixed with the charge and leached with sulphuric acid, or the iron oxide ore can be treated with the acid first and the resulting solution used for leaching.

Where the iron sulphate is already in the ferric condition it can be used directly, but it must be oxidized if in the ferrous condition. The oxidation can be carried on in several ways. The ferrous solution can be evaporated in reservoirs in the open air, yielding a dry salt in a more or less oxidized state which, when exposed to heat at the proper temperature, will yield basic ferric sulphate. Or the ferrous salt can be precipitated by lime, and the precipitate oxidized by blowing air through the mixture. Or, finally, the ferrous salt obtained by evaporation can be heated above the point of decomposition of basic ferric sulphate, yielding iron oxide and sulphuric acid anhydride, the latter being dissolved and used to leach the iron oxide.

Modifications may be introduced in the process, such as using salt, bleaching powder, nitre, manganese peroxide or the like, for facilitating the solution of the copper. In leaching low-grade slime containing about 1 per cent of copper, the concentration of ferric iron in the solution will be less than 1 per cent, and the quantity of sulphuric acid may attain or exceed 1 per cent.

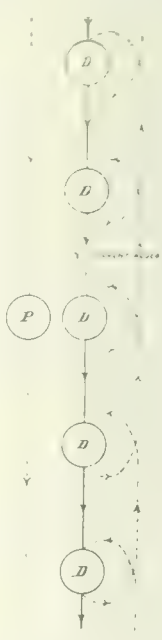

FIG. 3.—DIAGRAM OF PROCESS OF TREATING ORES.

The process described above, or other processes in which solutions are used to dissolve the metal to be recovered, may be carried out to advantage in the following manner, as illustrated in Fig. 3. This is an adaptation of the decantation system, in which, however, provision is made to have the solvent flow counter to the ore. In the figure the solid line indicates the line of flow of the ore and the dotted line shows the flow of solution. The letter *D* indicates tanks in which solution takes

place and *P* represents some form of precipitating apparatus. By this system, in which the solvent is added at some point intermediate the head and tail of the system, nearly exhausted pulp is treated with fresh leaching liquor, and fresh pulp is brought in contact with partly exhausted leaching liquor. At the same time the liquor flowing from the precipitating plant is used for finally washing the pulp in the last tank in the series. In this system, also, heat may be applied to the solu-

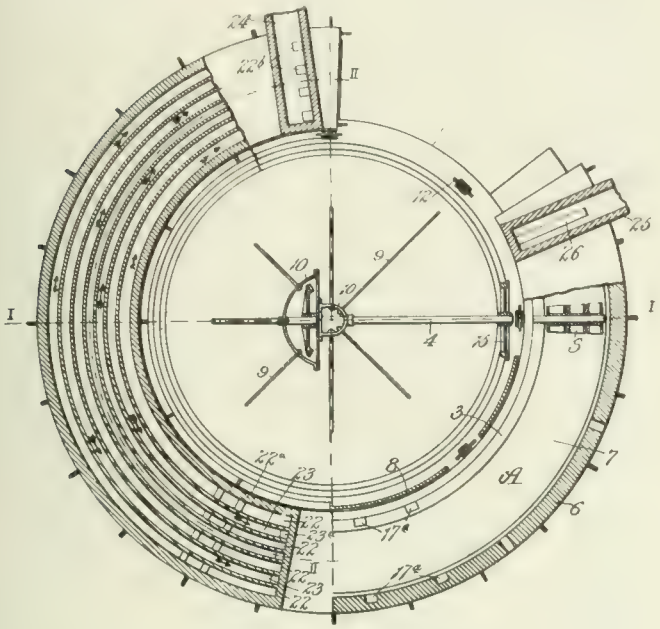

FIG. 5.—RECUPERATIVE ZINC ORE ROASTER.

tions at one point, for example, where the solvent is added, and be distributed throughout the entire plant, heating the incoming ore. Thus the loss of heat will be as small as possible. (1,021,768-9, April 2, 1912.)

Recuperative Zinc Ore Roaster.—According to letters patent recently granted to Mr. JOHN ZELLWEGER, of St. Louis, Mo., the inventor has designed a furnace for roasting zinc sulphide ores, in which a large percentage of the sulphur dioxide will be separated from the fire gases in the kiln and delivered in concentrated condition for acid manufacture. The design further provides a recuperator in which the outflowing gases of combustion are caused to give up heat to inflowing air used in roasting. The roasting furnace is circular in shape, except that the circle is broken between the charging and discharging ends. As shown in Fig. 5, the furnace is divided, roughly, in two parts, lying one on each side of the vertical line drawn through the figure. The annular hearth is shown at *A*, and the traveling rabble, which is constructed of several sections mounted on a shaft, is shown at *S*. The front or feed end of the furnace is the right half of the figure, and the discharge or back end is on the left. Burners are used only in the back end, where extraneous heat is necessary to finish the desulphurization. The ore in the front half burns due to its own fuel which is oxidized by heated air drawn in through the recuperator above the back end of the furnace where the fuel burners are placed. The recuperator is shown in the left half of the drawing as a series of flues through which the furnace gases and air flow in opposite directions, as shown by the arrows.

At the discharge end of the furnace is a stack 24 through which the gases of combustion from the burners pass, being drawn into the stack through flues at *22a* and flowing to *22b*, where they enter the stack. Thus the products of combustion of the fuel is removed from the furnace without mingling with the sulphurous acid fumes which are coming off at the front end of the furnace.

At the front end of the furnace is another stack 25 and fan 26. The fan draws air through the air ducts in the recuperator, the outer ends of which are open to the atmosphere and the inner ends open to the furnace kiln at 23. Thus heated air is provided for the combustion of the sulphur in the ore, forming sulphur dioxide, which is drawn by the fan through the front half of the furnace and up the stack 25, whence it can be delivered to acid chambers.

It will be seen that this arrangement provides for the removal of most of the sulphur from the ore while it is in the front half of the furnace, where it is not in contact with products of fuel combustion, while the back half of the furnace provides for the final removal of the sulphur content of the ore, and the elimination of this small quantity of sulphurous gas with the products of combustion through the ducts 22 in the recuperator and stack 24. This design results in a sort of neutral zone in the furnace between the points *22a*, where the outflowing gases enter the recuperator, and *23a*, where the incoming air is discharged from the recuperator in to the front of the furnace. The gases in this neutral zone can be made to flow one way or the other by varying the quantity of air entering through the recuperator. (1,017,839, Feb. 20, 1912.)

Tin.

Detinning Process.—The recovery of tin from tin scrap and old tin cans has been accomplished successively by electrolysis and by chlorine. Electrolysis was the first successful process, yielding metallic tin and steel suitable for open-hearth refining. The chlorine process succeeded the electrolytic and gave as products tin tetrachloride (anhydrous) and steel scrap. Both of these processes have been used extensively at the Goldschmidt works in Essen, Germany, and were described in detail in our issue for February, 1909, page 79.

A new method of detinning has been patented by Dr. JOSEF WEBER, of Essen, Germany, and assigned to the firm of Th. Goldschmidt. The process consists in treating tin scrap with an alkaline solution containing an oxidizing agent, as saltpeter. The sodium stannate thus formed is decomposed into tin oxide and sodium carbonate by the addition of sodium bicarbonate to the sodium stannate solution. The sodium carbonate is rendered caustic by treatment with lime, and is suitable for use in dissolving more tin.

The process is carried out as follows: The material, after having been subjected to suitable cleansing processes, is brought into a solution containing, say, 20 per cent by weight of sodium hydroxide and 10 per cent by weight of saltpeter. The solution is boiled for about three hours, after which the metal is removed and given a similar treatment in a second bath. Following the second solution the material is given to separate water washes. The detinning baths are used until crystals of sodium stannate begin to form in the first bath, whereupon the second bath is then used as first bath, and a fresh solution is substituted as second bath. The solution which has been saturated with sodium stannate is then concentrated to a sp. gr. of 1.4, when nearly all the sodium stannate will crystallize out. These are removed, treated centrifugally, and subjected to further action for the precipitation of tin oxide. The mother liquor is then made up to proper strength and used as solvent again.

The crystals of sodium stannate are dissolved in water, and sodium bicarbonate is added in order to precipitate tin oxide. The solution of soda which results is then made caustic by treatment with lime, and after being made up to proper strength is again ready for use. The saltpeter is not lost as it remains in the solution. Thus a pure oxide of tin is produced and the chemicals required for its production are recovered. (1,018,734, Feb. 27, 1912.)

Tungsten and Vanadium.

Tungsten Lamp Filaments.—In the production of hydrogeneous and nitrogeneous tungsten, uranium, etc., by means of strongly reducing metals, such as magnesium or aluminium, explosions occur which may be dangerous. It is the object of

an invention of Mr. HERMANN ZERNING, of Halensee, near Berlin, Germany, to so reduce tungsten and other metals without encountering the danger from explosions. His method consists in, first, using a reducing metal which has a lower affinity for oxygen than is exhibited by magnesium or aluminium. Zinc is such a metal. The partly reduced compound obtained by this reduction can then be submitted to the action of magnesium or aluminium for final reduction. The metals thus reduced, which form a hydrogeneous or nitrogeneous compound, can be freed from admixture of metallic oxides as well as from zinc and aluminium by the use of acids, and the resulting product is claimed by the inventor to be in a very suitable condition for the manufacture of electric lamp filaments by first mixing with a plastic substance and then pressing into filament form. (1,019,581, March 5, 1912.)

Recovery of Vanadium as Vanadic Acid.—A process for treating any of the vanadium ores has been patented by BYRAMJI D. SAKLATWALLA, of Bridgeville, Pa., and assigned to the American Vanadium Company, of Pittsburgh. The process consists in grinding the ore to a suitable degree of fineness, say, to 60 or 80 mesh, and treating the pulp with 1:1 sulphuric acid. The extraction is made with the application of heat and the use of steam agitation. The resulting solution is separated from the gangue and treated with oxidizing precipitants to throw out hydrated vanadic acid. The precipitants mentioned by the inventor are sodium or potassium chlorate or the gas generated when hydrochloric acid acts on sodium chlorate, or ammonium persulphate. The red precipitate is separated and calcined for the production of V_2O_5. The liquor remaining after the precipitation can be used again for solution of vanadium, and such use continued until the solution is nearly saturated with other metallic compounds. The latter may then be recovered as by-products. (1,020,224-1,020,312, March 12, 1912.)

Alloys.

An anti-corrosive alloy suitable for use in the manufacture of tanks, pipes, valves, ropes, pumps and similar mining machinery has been patented by Mr. GASTON JACQUIER, of Belgravia, near Johannesburg, Transvaal, South Africa. The alloy can be used as the sole material of which the aforementioned machines are made, or it can be used as a coating only. The alloy is made of the following substances: Aluminium, 92 per cent; bismuth, 2 per cent; copper, 5 per cent; silicon, 1 per cent; or the composition may be as follows: Aluminium, 91 per cent; bismuth, 2 per cent; copper, 5 per cent; magnesium, 2 per cent. (1,019,963, March 12, 1912.)

Iron-Nickel-Copper Alloy.—An alloy containing from 25 to 50 per cent nickel, from 5 to 20 copper, and from 30 to 70 iron, is patented by Mr. G. H. CLAMER, of Philadelphia, Pa. The amount of carbon must not be so high as to cause the copper to separate out in form of nodules; but the strength of the alloy is regulated by the amount of carbon present; "two-tenths of one per cent of carbon is not too much." An alloy containing 65 per cent iron, 25 nickel, 10 copper, and 0.2 carbon has the following properties: "On a test bar ½ in. in diameter and 2 in. between shoulders, strain per square inch in pounds 96,100; limit of elasticity per square inch in pounds, 51,750; elongation per cent of original length 42; reduction of area per cent of original section 53.7." The alloy may be made directly from appropriate ore (compare our Vol. VIII, p. 527 and 546) or by mixing the ingredients and melting. (1,016,549, Feb. 6, 1912.)

Titanium.

Quite a number of patents, relating to the production of titanium alloys and the uses of titanium as purifier in the metallurgy of iron and steel as well as of the non-ferrous metals, have recently been issued to Mr. AUGUSTE J. ROSSI, of Niagara Falls, N. Y. All of them are assigned to the Titanium Alloy Mfg. Co.

Ferrotitanium.—To reduce the losses by volatilization, oxidation, etc., in the manufacture of ferrotitanium, Mr. Rossi now proceeds as follows: Onto the surface of a molten bath of iron in an electric furnace he charges lime CaO so as to form a complete molten cover, and onto this he charges a mixture of titanic acid and carbon, comminuted or agglomerated in briquets. The quantity of carbon must be sufficient for the reduction of both the titanic acid and the lime. Where the temperature is raised, this reduction occurs according to the formulas $CaO + C_3 = CaC_2 + CO$ and $TiO_2 + C_3 = Ti + 2\ CO$. The reduced metallic titanium sinks down and alloys with the iron, while the cover of lime changes into one of calcium carbide, which acts as a reducing agent and protects the metal bath below. Toward the close of the operation an additional covering of carbon may be added to the surface to insure a reducing atmosphere throughout the furnace. (1,019,528, March 5, 1912.)

Zinc-Titanium, Tin-Titanium, Lead-Titanium.—Quite the analogous process to the one just described for ferrotitanium, may be employed for the production of zinc-titanium (1,019,527, March 5, 1912), tin-titanium (1,019,530, March 5, 1912), and lead-titanium (1,019,529, March 5, 1912). However, for the production of lead-titanium Mr. Rossi also describes a second different method. He charges into a graphite crucible a quantity of molten lead and adds to it litharge or other lead oxide and also titanic acid and as much aluminium in shots as is required for reduction. By heating the mixture, reduction is brought about according to the equations $3\ PbO_2 + 4\ Al = 2\ Al_2O_3 + 3\ Pb$ and $3\ TiO_2 + 4\ Al = 3\ Pb + 2\ Al_2O_3 + 3\ Ti$. Carbon may be used instead of aluminium as a reducing agent, but in this case an electric furnace must be employed to attain the required high temperature. (1,020,516, March 19, 1912.)

Silico-Titanium.—In cases in which ferrosilicon and ferrotitanium are employed together, a silico-titanium alloy may be directly used instead. An alloy containing 70 per cent silicon and 30 per cent titanium is produced by Mr. Rossi as follows: 150 lb. of silica, 50 lb. titanic acid and 75 lb. carbon are heated together in an electric furnace, to produce the reactions $SiO_2 + 2C = 2CO + Si$ and $TiO_2 + 2C = 2CO + Ti$. Thereby 100 lb. of the desired alloy are produced. If 20 lb. of iron scrap are added to the above mixture, 120 lb. of an alloy containing 16.7 per cent Fe, 58.3 per cent Si, and 25 per cent Ti, are obtained. (1,019,526, March 5, 1912.)

Aluminium-Titanium.—To produce an aluminium-titanium alloy from aluminium and titanium oxide alone, Mr. Rossi proceeds as follows: To a bath of molten aluminium he adds a mixture of titanium oxide and solid aluminium in shots. The titanium oxide is reduced by the aluminium, but the heat thereby set free is used up in melting the solid aluminium shots. Such additions of mixtures of titanium oxide and solid aluminium are made from time to time. The process is carried out in an electric furnace, in order to have exact temperature control, the current being switched on or off whenever required. (1,020,517, March 19, 1912.)

The Use of Titanium in Non-Ferrous Metallurgy.—The high affinity of titanium for oxygen and nitrogen and the great usefulness of titanium as a deoxidizer and in general as a purifier of metals is well known. The process is in all cases the same. To the bath of molten metal to be purified a little titanium is added, just enough to take care of the undesired elements oxygen, nitrogen, etc., including drosses and slags. In general the quantity of titanium is so chosen that practically all of it acts for purification and therefore passes in the slag, so that the purified metal does not contain more than 1 per cent titanium. The titanium is usually added in form of an alloy, for instance, a zinc-titanium alloy, if zinc is to be purified, or an aluminium-titanium alloy, if aluminium is to be purified, etc. The process is described in detail for the purification of zinc (1,020,512, March 19, 1912), aluminium (1,019,531, March 5, 1912), lead (1,020,514, March 19, 1912), tin (1,020,515, March 19, 1912), and nickel (1,020,513, March 19, 1912).

Boron.

In connection with the very important paper on boron, presented a few years ago before the American Electrochemical Society by Dr. E. WEINTRAUB of the General Electric Co. of Lynn, Mass. (our Vol. VII, p. 509), several recent patents of Dr. Weintraub are of interest.

Reduction of Boric Chloride.—A mixture of a volatile reducible compound of boron, as, for instance, a halide, is mixed with a reducing gas, such as hydrogen, and brought into contact with a thin refractory tube heated electrically to the temperature of reduction. Boron is thereby reduced and deposited on the refractory tube. When the boron layer has reached sufficient thickness, the original tube of refractory material is removed by mechanical means, leaving a tube of pure boron. (The process may also be employed for the reduction of other difficultly reducible metals, such as titanium, in a state of high purity.) The reduction chamber comprises a gas-tight vessel of glass and in its centre a thin-walled heater tube of carbon or graphite prepared either by carbonizing tubes of paper or by turning down carbon or graphite tubes to the desired thickness in the lathe. A mixture of boric chloride and hydrogen gases is then introduced into the vessel, displacing the gas in the vessel, which may conveniently consist of hydrogen. Current is then turned on, bringing about the chemical reaction between boric chloride and hydrogen, whereby boron is deposited upon the surface of the tube and hydrochloric acid gas is formed which is removed. (1,019,394, March 5, 1912.)

Purification of Boron.—To purify boron and reduce suboxide of boron (such as obtained, for instance, by treating a mixture of boric anhydride and magnesium, containing boron anhydride in excess, at a temperature of 1300 to 1600° C. or more), the boron material is pressed into sticks or rods which are heated to 1000° C. to render them slightly conductive and are then mounted as electrodes in a high-tension arc furnace. This consists of a gas-tight vessel of glass or copper with two terminal connections in form of water-cooled copper tubes. To the ends of these copper tubes the boron-material sticks are fastened by means of copper clamps. If the electrodes are initially separated by a distance of one-fourth of an inch and are surrounded by hydrogen at a pressure of not more than 5 in. of mercury, the voltage necessary to cause the current to jump the gap and start an arc is from 15,000 to 30,000 volts. Under these conditions the impure boron electrodes need be but slightly conductive. The hydrogen atmosphere keeps the arc concentrated on the extreme ends of the boron sticks. The impure boron sticks progressively heat up and fuse, the boron loses its oxygen or magnesium, as the case may be, and becomes very pure and dense. (1,019,392, March 5, 1912.)

Manufacture of Boron and Boron-Carbon Alloys.—Pure fused boron is a fair conductor of electricity and has an enormous negative temperature resistance coefficient. The addition of a small amount of carbon increases the initial conductivity of the boron and lowers its extreme negative temperature resistance coefficient to an extent depending upon the amount of carbon added. For example, a few tenths of a percentage of carbon may vary the resistance tenfold. In certain cases this effect is desirable. In a similar manner the presence of a small amount of carbon modifies the wear-resisting qualities of the boron when used as a bearing or die. Boron containing a small percentage of carbon may be produced as follows: A carbon-filament is heated to incandescence in a mixture of vaporized boron chloride and hydrogen, thereby depositing pure carbon on the surface of the filament. During this process, especially if the temperature is raised considerably, the carbon diffuses through the mass of boron. If a perfectly homogeneous product is desired, the mass is fused down in an arc. As the carbon filament has a very small mass and the deposit of carbon can be made quite thick if desired, the percentage of carbon in the final product may be made practically as small as desired. If it is desired to produce thick rods with a higher percentage of carbon, the carbon is deposited simultaneously with the boron by adding to the mixture of boron chloride and hydrogen a vaporized carbon compound, such as gasoline or carbon tetrachloride. Boron chloride and gasoline are completely mixable and, therefore, can be mixed in liquid form and vaporized at the desired rate either by dropping into a vessel which is somewhat heated, carrying the vapor off with a stream of hydrogen or by merely passing the hydrogen gas over the liquid mixture. (1,019,569, March 5, 1912.)

Another method is to first produce pure boron by passing a mixture of boron chloride and hydrogen through a high-voltage alternating-current arc maintained between water-cooled copper electrodes. The reduced boron is driven out of the arc by the action of the arc blast, and some of it fused on the ends of the electrodes, and the rest of it is thrown out as a powder on the walls of an arc chamber. The boron in powdered form is mixed with the desired amount of carbon in the form of powdered graphite, or is mixed with powdered silicon, magnesium or aluminum (if such alloys are to be produced), is then compressed into sticks, and is then fused in a high-potential arc operating in hydrogen, using the sticks as electrodes.

According to another process, an excess of boric anhydride is reduced with magnesium at a temperature of at least 1300 degrees C., but preferably higher. The resulting product is a brownish powder containing boron and oxygen, and is probably a suboxide of boron. It is pressed into stick form and is heated to fusion in a vacuum furnace of the Arsem type containing a graphite heater. As it is necessary to run the heater at a temperature of about 2500 deg. C., a small amount of carbon is introduced into the fused boron, as carbon vapor exists at this temperature in the furnace. If it is desired to introduce a larger amount of carbon than is obtainable by this fusion, the desired additional amount can be mixed with the powdered suboxide of boron before introducing it into the furnace.

If it is desired to produce as a final product fused boron containing a small amount of magnesium, the reaction between boric anhydride B_2O_3 and magnesium is carried on under such conditions that boron combined with magnesium is produced, as by using anhydride and magnesium in theoretical amounts and carrying out the reaction at a relatively low temperature, that is, below 300 deg. C. The product is then fused in a vacuum furnace. A very small amount of magnesium remains in the product. (1,019,393, March 5, 1912.)

Aluminium.

Aluminium Solder.—GEZA HARTMANN, of San Francisco, and R. J. BUSCH, of Los Angeles, Cal., have compounded a new alloy which they claim is superior as a solder for aluminium The ingredients and proportions are as follows: Aluminium, 15.5 per cent; antimony, 7 per cent; bismuth, 9 per cent; vanadium, 0.25 per cent; magnesium, 2.25 per cent; tin, 66 per cent. In preparing the alloy place the vanadium in a covered graphite crucible. When it is melted, add the correct amounts of bismuth, aluminium, antimony and magnesium in the order given and cover with charcoal powder to exclude the air. Stir thoroughly as each metal is added, and when this mixture is molten and mixed add the tin. When all metals are thoroughly melted and mixed, skim and pour into suitable molds. (1,020,757, March 19, 1912.)

Miscellaneous.

Brick for Metallurgic Furnaces.—A brick which shall have for its body-portion a refractory material which will not yield to pressure or lose form at high temperatures, and a surface portion which will likewise resist high temperatures and at the same time offer greater resistance to the chemical action of molten metals, slags, gases, etc., is the invention of W. M. MCNIGHT and R. H. YOUNGMAN, of Pittsburgh, Pa. The patent has been assigned to Harbison-Walker Refractories Company, of Pittsburgh.

The chemically refractory surface which is added to the

brick is not less than ¼ in. in thickness and is placed on that surface of the brick which will be exposed in the furnace. The main portion of the brick may be silica or fireclay such as is used in bricks of that nature; and this main body portion may be burned before the application of the refractory facing, or the facing may be applied to the unburned brick. The refractory facing is of chrome ore, burned magnesite, aluminous clays or aluminous products. A suitable binding medium of relatively low fusing point is placed between the body portion and the refractory facing so that in burning the completed brick, the facing will be fused to the main body. In cases

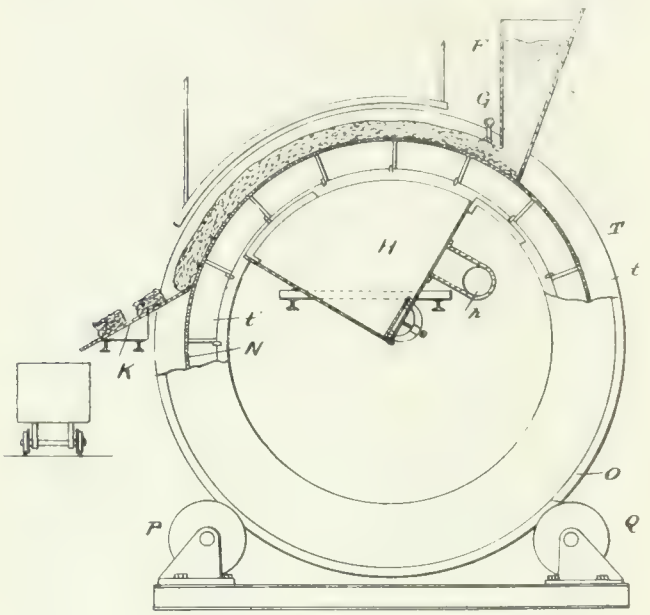

FIG. 6.—ORE SINTERING MACHINE.

where magnesite is used in connection with a silica brick portion, the fusible binder may be omitted, as a fusion can be obtained directly between the magnesite and silica at suitably high temperatures. (1,016,350, Feb. 6, 1912.)

Sintered Ore Product.

The Dwight-Lloyd System of desulphurizing and sintering fine ore into a mass suitable for charging directly into a blast furnace has been described in our issues for February and March, 1912, pages 87 and 162 respectively. In a patent recently granted to A. S. DWIGHT and R. L. LLOYD, of New York, the drum form of sintering machine is described and the merits of its sinter cake set forth. The sinter produced by the Dwight-Lloyd machines is uniformly porous and hard throughout its entire body in contradistinction to the cakes formed by other processes in which there is variable permeability to gases and increasing hardness from top to bottom of cake.

The drum form of machine for producing this cake is shown in Fig. 6, and differs only in form from the straight-line machines described in one of the articles referred to above. In Fig. 6 the drum has a sectional perforated grate on which the mixture to be sintered is discharged from a feed hopper *F*. Ignition is effected by a gas burner *G*, and combustion is continued by suction through the mass into the wind box *H*. By the time the mixture on any part of the drum has traveled over the arc above the wind box it is formed into a sinter cake, which is discharged as shown at *K*. (1,020,345, March 12, 1912.)

Electric Furnaces.

Combined Open-Hearth and Electric Furnace for Steel Refining.—In our last December issue (Vol. IX, p. 650) a patent of Mr. WM. R. WALKER and Mr. JAMES H. GRAY, of the U. S. Steel Corporation, for a combined open-hearth and electric furnace process was mentioned. While that patent related to the process, another patent has now been granted to the same inventors for the furnace. They first employ the furnace as an open-hearth, the electrodes being removed, and reduce silicon, carbon and phosphorus. When the phosphorus and silicon have been nearly eliminated and the carbon largely reduced, they remove the slag, furnish a new basic slag, introduce the electrodes from the top and operate the furnace as an electric furnace, removing sulphur and oxygen from the bath. The first claim refers to "a combined electric and gas-fired open-hearth furnace for the manufacture of steel, having a hearth for the molten bath, regenerators and flues leading therefrom to the bath, means for venting the gases located between the hearth and the regenerators, and electrodes." (1,018,644, Feb. 27, 1912.)

Electric Pig Iron Furnace.—Mr. RICHARD FLEMING, of Westfield, N. J., points out that "the shape and operation of the blast furnace have been adopted after centuries of experience and represent necessities in the reduction of the oxides of iron by carbon which are independent of the particular method of heating employed, whether this method of heating be electrical or by combustion." For electric iron ore reduction he, therefore, adheres as much as possible to the original design of the blast furnace. The "electrical heating must be applied at the point or zone where the maximum development of heat occurs in the ordinary blast furnace so that the thermal reactions may go on in the usual manner. This involves heating at the narrowest part of the boshes." At that point water-cooled electrodes, symmetrically arranged around the furnace circumference, are provided. The iron is reduced and melted and slag is formed and the molten iron and slag drop below the bosh lines into the hearth. The electrodes are so placed that a substantial portion of them is outside the inner surface of the furnace wall. Since they are water-cooled they will build up by the formation of false electrodes or ends from the material reduced in the furnace. Twyers are provided, since the use of a small air blast is convenient in regulating the amount of carbon in the iron produced and to obviate the effects of any excess of carbon due to careless charging. The furnace is stated to be applicable also to the smelting of other metals. (1,020,546, March 19, 1912.)

Shaft Furnace for Electric Ore Reduction.—Fig. 7 shows a shaft furnace patented by Mr. ALBERT E. GREENE. A masonry shaft 1 is supported on plates 15 carried by a series of columns 9. Converging downwardly from the bottom of the shaft 1 is a bosh, with water-jacketed walls 2 of refractory material. Directly beneath the bosh is the smelting chamber 4 whose roof extends outwardly as a flange about the lower end of the bosh. In this way free space is provided on the exterior sides of the wall 2 for access to the roof of the smelting chamber. Extending downwardly through the roof are the electrodes F. Embedded in the bottom of the hearth is another annular electrode 6. The metal tap hole is at 8, the slag tap hole at 10. The bottom of the hearth is upwardly inclined toward the center so that the outer peripheral portion of the

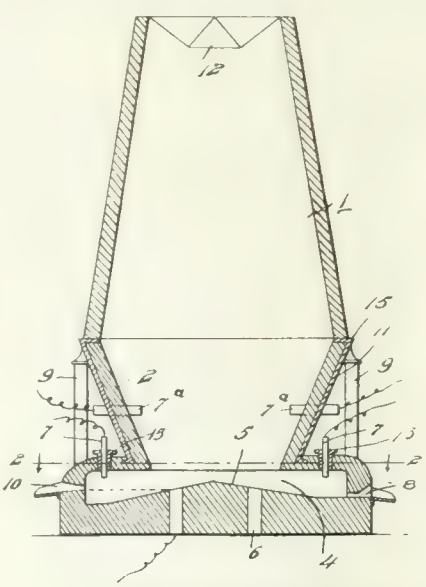

FIG. 7.—ELECTRIC SHAFT FURNACE.

hearth forms an annular conduit, the size of which is so proportioned as to determine the intensity of the current carried by the molten metal below the slag. If additional heat is required, it may be supplied through the auxiliary electrodes 7*a*. (In a modified design also described, these are omitted as well as the bottom electrode 6.) The charge is fed from the top and while it descends it is heated and reduced by the ascending gas. At the lower end of the shaft its passage into the smelting chamber is restricted by the bosh. The charge, resting partly upon the bosh and partly upon the hearth, is held in close proximity to the slag bath, into which the electrodes project, the layer of slag acting as a resistor. The molten metal flows downward through the slag into the hearth. By the construction of the bosh the charge is prevented from falling into the smelting zone and thus displacing the slag bath. The carbon electrodes do not come into contact either with the unreduced charge or with the decarbonized iron. (1,021,187, March 26, 1912.)

Self-Regulating Induction Furnace.—In order to make an induction furnace self-regulating, Mr. RICHARD FLEMING of the General Electric Co., Lynn, Mass., makes the primary coil movable, as shown in Fig. 8. The crucible 1 is circular, 2

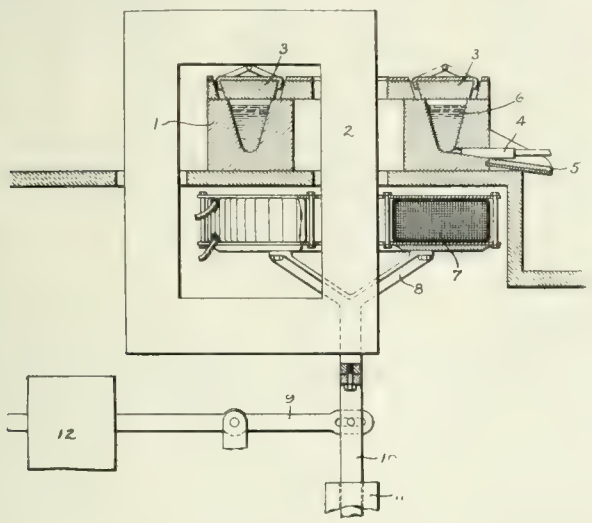

FIG. 8.—SELF-REGULATING INDUCTION FURNACE.

is the magnetic iron core, and 7 is the primary coil, which is so mounted on a frame 8, supported by a lever 9 with a counterweight 12, that it can move toward the furnace 1 or away from it. When the resistance of the charge in the crucible is large, the primary coil will be pressed (by the action of the counterweight 12) against the crucible 1. When the resistance of the charge decreases the increased current will cause the primary coil to be repelled away from the crucible to such a point that the current will decrease to the normal value. (1,020,688, March 19, 1912.)

Carbon Electrode with Graphite Tip.—With amorphous carbon electrodes the difficulty is often experienced that the working end cracks and slivers off and pieces of the electrode fall into the charge. To overcome this dfficulty without going to the expense of graphitizing the whole electrode, Mr. CHARLES A. HANSEN, of the General Electric Co., Schenectady, N. Y., graphitizes the amorphous carbon electrodes at the tip, or working end only. This is done by placing the electrodes in contact end to end and covering the point of contact with powdered coke. When a current is passed through the electrodes thus in contact, the point of contact is graphitized on account of the high temperature due to the transition resistance. The coke serves to protect the heated carbon from oxidation. The heating is continued in this manner for about 15 minutes. When such electrodes are used and the tip is consumed, the adjacent zone of carbon is progressively graphitized by the heat until the entire electrode is consumed. (1,019,463, March 5, 1912.)

Water-Jackets for Electrodes.—A patent of Mr. MARCUS RUTHENBURG, of London, England, refers to the protection of the carbon electrodes against unduly high consumption. It refers especially to furnaces with a stationary casing and a removable hearth, with vertical carbon electrodes suspended from above. If the carbon electrodes are not protected on their sides, they are burnt away by the action of the hot gases rising upwards. Water-jacketing of such electrodes has the disadvantage that the electrodes frequently break and arcs are formed between the broken portions of the electrodes which burn the jackets and allow the cooling liquid to enter the furnace. Mr. Ruthenburg, therefore, provides the electrodes not only with water-jackets, but provides a refractory lining of fire clay or a mixture of fire clay and asbestos between electrode and jacket (1,018,727, Feb. 27, 1912.)

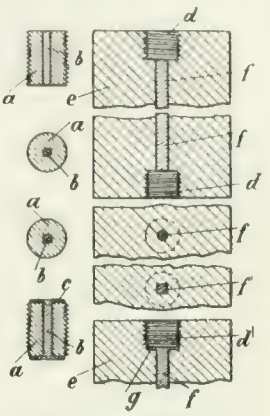

FIG. 9.—CONNECTION OF CARBON ELECTRODES.

Connection of Carbon Electrodes.—The expense for the electrodes is a large item in electric-furnace operations. It is, therefore, important to utilize the electrodes as completely as possible. This is done by connecting a new electrode to the piece left of a partially consumed electrode so that any waste is avoided. The connection between the old and the new electrode must be strong. If metallic connections are employed, they are liable to fuse and evaporate in the furnace. In a patent of Mr. BERTHOLD REDLICH, of Ratibor, Germany (assigned to the Plania Werke) it is proposed to use connecting pieces of carbon reinforced by embedded metal pieces, as shown in Fig. 9. On the left hand of the diagram various forms of connecting pieces are shown, on the right hand the electrodes in connection with which they are to be used. In the connecting pieces on the left *a* is carbon and *b* metal. As shown in the electrodes on the right, metal bars *f* may be provided in the carbon electrodes *e* themselves to form contact with the metal bars in the connecting pieces. Better connection between the metal bars *b* in the connecting pieces and the metal bars *f* in the electrodes can be obtained by adding to the ends of the metal bars metallic plates *c* and *g* respectively as shown in the two lowest diagrams. These then also act as clamps. The electric transition resistance between the old and the new electrode is thereby materially decreased. (1,018,003, Feb. 20, 1912.)

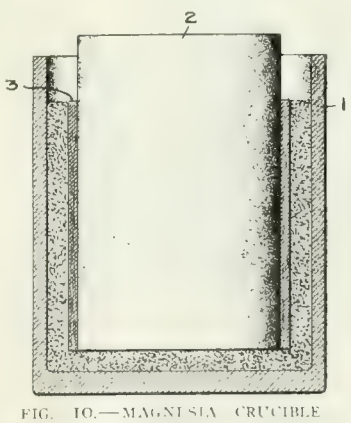

FIG. 10.—MAGNESIA CRUCIBLE

Fused Magnesia Article.—Mr. GEORGE WEINTRAUB, of the General Electric Company, of Schenectady, N. Y., makes refractory articles of magnesia, alumina, thoria, etc., without the use of a binder, as follows: The magnesium oxide is first heated in an electric furnace to a high temperature in order to let it assume a stable condition. This firing causes the magnesia to cake together so that regrinding is necessary. It is ground to the fineness of flour in a tube mill. A mold is then made for the article to be produced, say a crucible. This mold 1 is made of carbon or graphite and a layer of the powdered magnesia is placed on the bottom of 1. A carbon or graphite plug 2 is now placed centrally in the crucible upon this magnesia layer. It is sur-

rounded by a layer 3 of paper which permits the magnesia to shrink when heated. When molding a crucible of 2½ inches inside diameter, a thickness of paper from 1/16 to ⅛ in. is suitable. The space between the walls of the mold 1 and the paper-covered core 2 is then filled with magnesia powder and packed to a certain degree by shaking and bumping. The mold is now placed in an electric furnace and heated to about 1500 deg. C. When finished, and the mold is cooled, the walls of the magnesia crucible contract upon the layer of loose paper-carbon, so that cracking is avoided. The finished crucibles are smooth, homogeneous, and strong, may be safely handled and may even be worked on the lathe. Tubes may be made in the same way. (1,022,011, April 2, 1912.)

Decarburized Silicon—A Resistor Material.—Commercial cast silicon, such as is available in the open market, is made by reduction of silica with carbon in an electric furnace. It runs relatively high in carbon, the carbon contents being sometimes 3 per cent. Cast resistor sticks made from this commercial silicon, eight inches long and one-quarter of an inch in diameter, have a resistance of about 3 ohms. Mr. JOHN T. H. DEMPSTER, of the General Electric Co., Schenectady, N. Y., has found that by decarburizing silicon completely the electric resistivity may be raised two or three times. The decarburizing process is carried out as follows: Calcium carbonate in the form of lumps, to the extent of 10 per cent by weight of the silicon to be decarburized, is charged into a crucible and then the silicon on top of it. The crucible is then placed into an oil furnace and heated to a temperature of 1400° or 1500° C, so that the silicon melts, while the upper surface of the silicon is changed into a layer of silica. The calcium carbonate then breaks up with the formation of calcium oxide and carbon dioxide. The carbon dioxide bubbles up through the molten silicon and reacts with its carbon content to form carbon monoxide. The calcium oxide also rises to the surface, where it combines, in part at least, with the silica layer and forms a protective slag of calcium silicate. The fused and decarburized silicon has a resistivity of 0.172 ohm per inch cube. (1,019,431, March 5, 1912.)

Electrolytic Furnace Processes.

Sodium Cyanide from Sodium Chloride.—In a patent, assigned to the Nitrogen Company, Mr. CHARLES E. ACKER, of Ossining, N. Y., proposes a new method for making sodium from molten sodium chloride by electrolysis. A double-compartment cell is used, as shown in Fig. 11. The anode compartment 2, containing the anodes 9 and molten sodium chloride as electrolyte, and the cathode compartment 3 containing the cathode 10 and molten sodium cyanide as electrolyte, are in communication with each other at the bottom through a layer 6 of molten lead, which reaches above the lower end of the dividing wall so that the molten sodium chloride in 2 cannot mix with the molten cyanide in 3. This molten lead layer acts as an intermediate electrode, being cathode in compartment 2 and anode in compartment 3. The results of electrolysis in compartment 2 are evolution of chlorine at the anodes 9 and liberation of metallic sodium at the surface of contact with the molten lead with which the sodium alloys at once. This reaction is essentially the same as in the old Acker process (where caustic soda was produced from the sodium-lead alloy by reaction with steam). Now this molten sodium-lead alloy is circulated by means of a pump and is thus carried over into compartment 3. The reaction in this chamber is that sodium from the molten alloy enters into the molten electrolyte of sodium cyanide, while pure metallic sodium is set free at the cathode 10. Now if this cathode 10 is made hollow and ammonia is blown through the hole so as to react with the metallic sodium "in *statu nascendi*," then the sodium reacts with the ammonia and with carbon from the cathode, forming directly sodium cyanide, while the hydrogen of the ammonia escapes and carries with it practically no uncombined nitrogen or unused ammonia. Instead of using up the carbon cathode as source for the carbon in the cyanide, another source of carbon may be provided in the form of finely divided carbon suspended in the electrolyte or as carbon in lump form or in the form of a hydrocarbon gas or oil charged into the cyanide. Instead of ammonia, hydrocarbon bodies containing nitrogen may be charged through the hollow electrode into the electrolyte, such as those obtained from the distillation of "vinasses" of the beet sugar refineries, such as methylamin, di- and trimethylamin, etc. In methylamin both nitrogen and carbon are present in the exact proportion required in the cyanide. The cathode 10 is axially apertured, as stated before, and the lower extended horizontal face of the cathode is provided with a long spiral groove which starts from the openings in the center, so that when a gaseous reagent is introduced through the hollow shank of the cathode, it is forced to follow the course of the spiral groove and thus be made to travel a distance of several feet in contact with the alkali metal, the electrolyte, and the suspended or dissolved material in the electrolyte. This method insures completeness of the reaction (1,018,802, Feb. 27, 1912.)

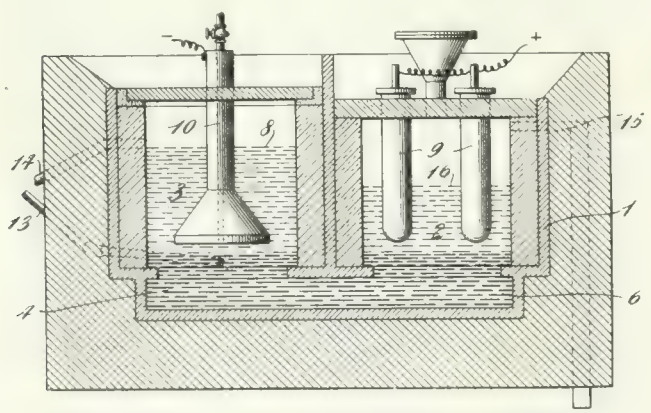

FIG. 11.—SODIUM CYANIDE FROM SODIUM CHLORIDE.

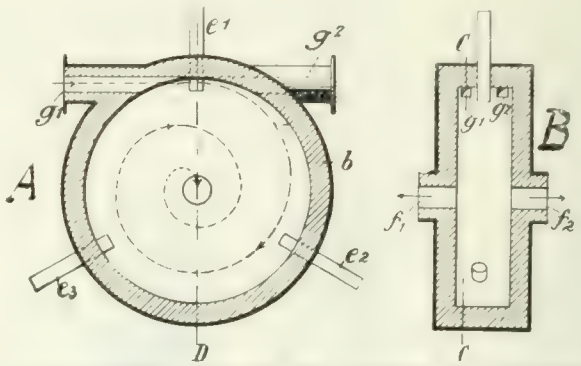

FIG. 12.—FLAME-DISK FURNACE FOR FIXATION OF ATMOSPHERIC NITROGEN.

Gas Reactions.

Flame-Disk Furnace for Fixation of Atmospheric Nitrogen.—A patent assigned to the Elektrochemische Werke, of Berlin, and granted to Mr. FRITZ ROTHE, of Dessau, Germany, relates to a new method of spreading out an arc. In the fixation of atmospheric nitrogen it is well known that short fat arcs are much less effective than arcs which are drawn out so as to have a large surface. Birkeland and Eyde draw the arc out by magnetic means, Pauling simply relies on the tendency of the air, heated by the arc, to rise and take the arc along and thus draw it out. Both processes have been described many times in this journal. In the method of Rothe one or more flaming arcs are spread out into disklike flame discharge by the enforced movement of the air under treatment alone. The furnace is shown in Fig. 12, in which diagram *A* is a cross-section through the furnace and *B* a longitudinal

section on the line *DD* of *A*. The furnace is of moderate width with respect to its diameter so that the air or other gases under treatment shall be in the form of thin sheets, the movement of the air being in the form of a spiral path. With three-phase currents the three electrodes, e_1, e_2, e_3 are arranged at equal distances apart. At the opposite sides of the plane of the electrodes, the air inlets g_1 and g_2 are arranged tangentially to the interior periphery of the furnace lining, while the gas outlets f_1 and f_2 are located on the central line. In diagram *A* the air inlets g_1 and g_2 are shown facing in opposite directions to each other on opposite sides of the flame zone, whereas in diagram *B* g_1 and g_2 are shown facing in the same direction. In the former case the air currents will move in opposite directions to each other on opposite sides of the flame zone. In the latter case they will move in the same direction. In any case the air currents move uniformly in spiral paths to the outlet passages f_1 and f_2, while the arcs are drawn out and reformed into a disk-like single flame discharge. (1,018,990, Feb. 27, 1912.)

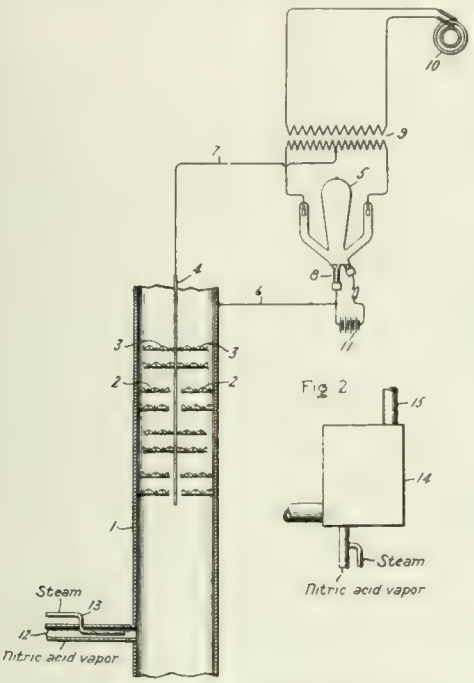

FIG. 13.—PURIFICATION OF SMELTER FUMES

Purification of Smelter Fumes; Removal of Sulphur Dioxide.—Solid or liquid particles suspended in smelter fumes may be precipitated by passing the fumes between plates charged to great differences of electric potential, as in the now well-known Cottrell process (our March issue, p. 172), but sulphur dioxide gas is not thus removed. Dr. WILLIS R. WHITNEY, of the General Electric Company, of Schenectady, N. Y., first mixes the smelter fumes with oxidizing agents so as to convert the sulphur dioxide into sulphuric acid, which is precipitated by electrostatic actions. In Fig. 13 1 is the flue through which the smelter fumes are passed. 2 and 3 are two sets of electrodes charged to opposite direct-current potentials, in form of wire mesh covered with asbestos. Alternating current from the alternator 10 is transformed to high-potential alternating current in the transformer 9 and then converted into direct current by means of the mercury vapor rectifier 5 (the battery 11 serving to maintain an exciting side branch arc in the rectifier). This direct current is used to charge the sets of electrodes 2 and 3. Before the smelter fumes are passed in a zigzag path between these sets of electrodes, they are mixed with steam and nitric acid vapors (or with nitric oxide vapors and spray of water) introduced through the pipes 12 and 13, by means of the well known "lead-chamber process" reaction the sulphur dioxide is charged into sulphuric acid and other liquid or solid products such as nitrosyl, sulphuric acid and the like. These liquids or solid products are deposited or precipitated when passing between the high-tension poles. As indicated in diagram II it may be desirable to mix the nitric acid or nitric oxide fumes and aqueous vapors with the flue gases in a reaction chamber 14 to get a more thorough mixture and to allow the reaction to complete itself before the gases are conducted by pipe 15 to the electric precipitating device. Any surplus watery vapor containing dissolved acid is removed by condensation in any suitable manner. (1,022,012, April 2, 1912.)

Electrical Purification of Gases.—The application of a high-potential electric discharge for the removal of noxious substances from blast-furnace gases was described in our issue for March, 1912, page 172. This process, which is the invention of Dr. FREDERICK G. COTTRELL, of Berkeley, Cal., has been applied also to the purification of sulphurous gases prior to the manufacture of sulphuric acid. Gases generated by the burning of the commercial forms of sulphur or sulphide ores contain impurities such as selenium, tellurium, arsenic, etc., which destroy the activity of the platinum catalyzer used in the contact process. Various means have been adopted to remove these substances by filtration, agitation with water or steam, etc. Dr. Cottrell proposes, however, to remove them by causing them to collect on particles of mist, produced artificially, and then to remove this mist by an electric discharge. This process of forming a mist may be repeated several times successively, and the purification thereby made perfect. The inventor prefers to form the mist of sulphur trioxide and water according to the following description, in which reference is made to Fig. 14, which is given below.

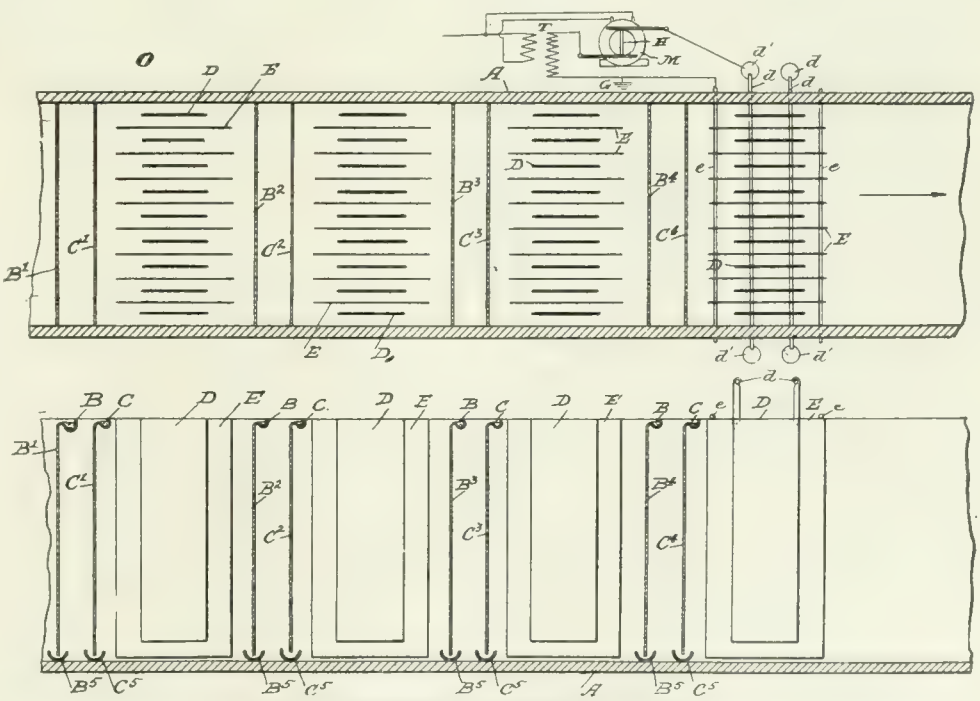

FIG. 14.—ELECTRICAL PURIFICATION OF GASES.

The figure represents a flue in horizontal and vertical longitudinal cross-section, in which the gases flow to the contact chambers in the direction of the arrow. Within the flue are screens B^1, B^2, B^3, B^4, etc. Above the screens is a trough *B* from which water or weak sulphuric acid flows down over the

screen, the excess fluid being removed by troughs B at the bottom. The water thus trickling down over the screen gives off aqueous vapor.

Following each of the water-bearing screens is a second screen C^1, C^2, C^3, C^4. Each of these screens is supplied with fuming sulphuric acid from a trough C above, acid in trickling down over the screen gives off SO_3. The excess acid is received and removed by a trough C^5.

Within the flue, and following the fuming acid-bearing screens, are mounted the electrodes D and E, one set being of opposite polarity to that of the other. These receive their electric charges from the high-potential side of the step-up transformer T through the intermittently contacting hub H driven by the synchronous motor M in such a manner as to make contact at or near the peak of the voltage wave of the high-potential winding of the transformer T, as more fully set forth in the inventor's United States patent No. 859,729, Aug. 11, 1908. These electrodes D and E, by their discharges, precipitate the mist which is formed as follows: By bringing the gases in contact with the screen B^1 aqueous vapor is supplied to them, and on further contact with the screen C^1 sulphur trioxide is added. The gaseous water and acid combine with each other to form a mist of particles of sulphuric acid, and this mist is then precipitated in the chamber provided for the purpose, carrying with it particles of impurities which are undesirable in the acid-making process. This manner of purification is repeated as many times as desired in the succeeding chambers of the flue. (1,016,476, Feb. 6, 1912.)

Electroplating.

Zinc Platings.—Mr. A. A. LEMÊTRE, of Paris, France, uses for zinc plating a cold solution (not over 30 deg. C.) of 12 kg zinc sulphate, 3 kg ammonium chloride, 2 kg sodium sulphate, 1 kg sulphuric acid in 100 liters of water. Bisulphate of soda may be employed to replace either in whole or in part the sodium sulphate or sulphuric acid, since the latter materials are in time formed in the bath. (1,017,981, Feb. 20, 1912.)

"Leading" Molds.—In preparing an electrotype, a mold or case is usually made in a plastic material and covered with graphite or "black lead" to render it conductive. In order to increase the conductivity of the coat and overcome the tendency in the graphite to produce pin holes, Mr. FRANCIS J. MCELHONE subjects the graphite to a preliminary treatment as follows: A solution of 200 grains of pyrogallic acid in a gallon of water (tannic, gallotannic or gallic acid may also be used) is mixed with 8 lb. of graphite and the mixture is stirred until the graphite becomes thoroughly wet and pasty. He then pours in large quantities of water and stirs thoroughly to wash the acid from the graphite. The graphite is collected by decanting and filtration and thoroughly dried and is put on the face of the mold in a dry condition by means of a brush or blast. (1,018,332, Feb. 20, 1912.)

Recovery of Copper and Nickel from the Wash Water from Plating Operations.—To make nickel films or flakes for use in his alkaline battery, Mr. THOMAS A. EDISON plates alternately exceedingly fine films or layers of copper and nickel. The composite copper-nickel sheet thus obtained is then cut into small portions and the copper is leached out to leave the nickel flakes. In this process the sheet is alternately placed into a nickel salt solution and a copper salt solution to receive a coating, but after each removal from a bath, it is necessary to remove the adhering liquid film by wash water. The wash water containing soluble copper and nickel salts has formerly been wasted, but now the metallic values are recovered, the copper by concentration on iron, and the nickel by precipitation by means of sodium hydroxide or sodium carbonate. (1,016,875, Feb. 6, 1912.)

Electroplating Apparatus.—Mr. T. R. CANNING of Birmingham, England, patents details of an electroplating apparatus for dealing with small quantities of work at one time. The articles are placed in a perforated earthenware receptacle which is revolved in the plating bath by means of an inclined spindle rotating in the bearing of a bracket fixed to the wall of the vat. (1,020,262, March 12, 1912.)

Synopsis of Metallurgical and Chemical Literature.

Zinc and Lead.

The Horwood Process for Mixed Sulphides.—For the separation of galena from blende by flotation, Mr. E. J. HORWOOD proposes to give the mixed sulphides a sulphatizing roast whereby the lead is rendered inactive in flotation and the blende remains unaffected. He describes his process in the *Proceedings* of the Australasian Institute of Mining Engineers (Melbourne), New Series, No. 2.

By roasting blende and galena which have been previously ground sufficiently fine to separate the mineral particles from each other and from the gangue, the lead will be sulphatized and its floatability destroyed if the temperature does not exceed 300 to 400 deg. C. The blende will not be appreciably affected, and it can be separated by flotation with an oil-acid mixture by any of the usual methods. The degree to which sulphatization must be carried can be determined only by experiment for each ore; and once determined, there is no difficulty in obtaining the desired results. The method is applicable to raw ore, or to the mixed minerals obtained by previous flotation or concentration on tables. If pyrites be present in addition to galena and blende it is found that sulphatization of the galena will not proceed until the pyrites has been oxidized.

The results of tests given by the author show recoveries of zinc in zinc concentrates ranging from 80.8 to 95.6 per cent: and of lead in lead concentrates from 81.3 to 91.3 per cent. The concentrates are quite free from contaminating metals which should have been separated. The author states that it is possible to conduct the operation of roasting in such a manner as to determine the recovery of the major part of the silver in either the galena or blende, although he is not certain just what the contributing causes are. Comparatively little work has been on copper-zinc ores. The author states that the leady residues present no difficulty in ordinary smelting, and suggests that they can be briquetted or sintered in any of the usual methods.

Gold and Silver.

Absorption of Gold by Amalgamated Copper Plates.—Such different ideas prevail regarding the possibility of absorption of gold in amalgamated copper plates that the definite work done on this subject by Prof. G. H. STANLEY and Mr. M. THORNTON MURRAY will be welcomed. Their conclusions are published in the December, 1911, *Journal* of the Chem. Met. & Min. Soc. of S. Africa.

A plate 0.14 in. thick, which had been in service for twelve years, was used for the investigation. The plate had been sweated and scraped, but not scaled. One portion on assay showed 1.69 per cent gold and 1.31 per cent mercury. The under surface also was amalgamated. In order to ascertain the distribution of this quantity of gold, successive layers 0.02 in. thick were taken for assay. The results obtained are shown in the following table. Layer No. 1 is the sample from the amalgamated surface:

Layer No.	Gold %	Mercury %	Lead %	Ratio of Gold to Mercury
1	10.48	9.39	0.085	1.12
2	.0166	present in all	.084	...
3	.00505	cases but in	.080	...
4	.0084	amounts too	.053	...
5	.0041	small for	.089	...
6	.0145	determination	.089	...
7	.0018	1.89	.104	.00105

It will be seen that over 99 per cent of the gold was contained in the first layer of .02 in. thick, the remainder being distributed irregularly throughout the plate. It is unlikely that any gold originally in the plate would be present in such

quantity or in such uneven distribution. The lead is probably an original constituent, and being liable to segregation, its uneven distribution is not remarkable. A slight but undoubted concentration of this element is shown in the lower half of the plate, which would seem to support the idea of actual filtration through it.

Cross-sections of the plate examined microscopically showed plainly a gray surface scale of amalgam lying on the corroded surface of the plate. Many circular or elliptical spots, bluish gray in color, and some empty pores or blow holes also appeared. Some of the spots on incomplete polishing showed smears of mercury. The section was then exposed to heat to volatilize the mercury and again examined. The former scale of amalgam on the edge of the plate now appeared as gold, and some of the depressions seemed coated with a film of yellow substance which was in all probability gold. Microscope examination of an unused plate showed similar structure, but no evidence of the presence of gold.

The explanation of the so-called absorption of gold seems to lie in the fact that the copper plates used are more or less porous, and contain minute blow holes, some of which at least communicate with one another. Through these passages the mercury has percolated, carrying gold in solution or suspension till the plate has become saturated. The whole examination supports the view that not enough gold is absorbed to influence percentage recovery. It is quite possible, though, for a hard scale to form which will be very rich in gold and which can be removed by scaling.

The authors also investigated gold absorption in iron retorts and amalgam pans, finding appreciable absorption in the inner layers. In these cases the gold seems to fill crevices and cavities formed when the graphite is burned out of the iron. The suggestion is made that perhaps special grades of iron should be used for retorts and amalgam pans.

Pebble Loads in a Tube Mill.—In the *Journal* of the Chem. Met. & Min. Soc. of South Africa for January, 1912, Mr. R. W. DOWLING gives the following valuable data on pebble loads of different depths in a tube mill 22 ft. long and 5 ft. internal diameter:

Depth of Pebble Load	Cubic Feet of Pebbles in Load	Weight in Tons of Pebble Load (105 lb. per cu. ft.)	Relative Volume and Weight of Pebble Load as percentage of total internal capacity of mill
12 in above axis of mill	323.0	16.96	74.8

Measuring Small Quantities of Low Pressure Air.—It is frequently desirable to measure the quantity of air used in metallurgical operations, as in air agitation. In order to accomplish this easily, and without resort to expensive apparatus, Mr. G. S. WEYMOUTH, of the Great Fingall Mine, has designed the apparatus shown in Fig. 1. The original article appears in the *Monthly Journal* of the Chamber of Mines of Western Australia, January, 1912.

The method consists in substituting temporarily an equal flow of air under conditions which allow of easy measurement. The only disadvantage is that the flow of air must be diverted from the point of application for half a minute, while the measurement is being made. In the figure *a* is a valve regulating the air to the required pressure; *b* is a mercury gauge; *c* and *d* are stop-cocks; *e* the apparatus under test; *f* a small tin receiver connected by rubber hose to *d*; *g* is a round orifice in a tin plate for air outlet, and *h* is a water gauge with a range of about 12 in. to allow for occasional rushes of air while manipulating the cock *d*.

A low-pressure supply being required at *e*, say, 5 lb. per square foot, and the cock *c* being open and *d* closed, the regulating valve *a* is opened until the gauge *b* indicates the required pressure. The valve *a* should not be touched again during the test. The height of mercury on *b* is marked; and to measure the quantity of air flowing at this instant, the cock *d* is opened and *c* closed; *d* is then gradually closed until the gauge *b* reads the same as before. In this way the total substituted resistance to the free flow of air is equal to that of the apparatus being tested, the pipe *a* to *i* in both cases acting as an intermediate receiver with constant in and out-flow as provided by the gauges. The height of the water gauge is now taken, and the area of the outlet orifice noted; the cock *c* is opened and *d* closed, the gauge *b* reading the same as before. This is a check on the constancy of flow during the testing period. The velocity through the orifice *g* is that due to a

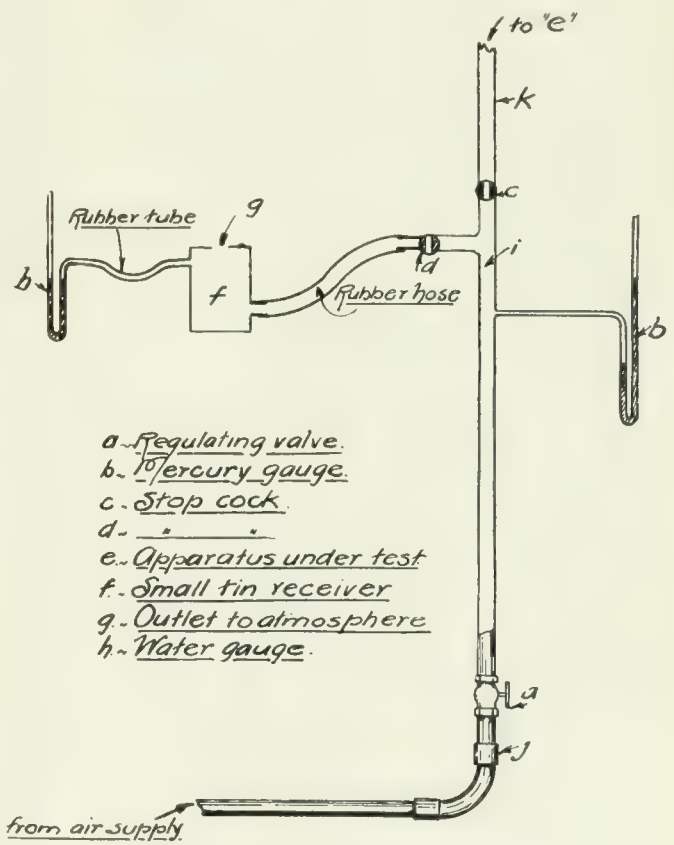

FIG. 1.—MEASURING SMALL QUANTITIES OF AIR.

head of air equivalent to the pressure on the water gauge, and is $\sqrt{2gh}$ = feet per second, h being the height of the motive column (head) in feet. Reducing to inches of water, and simplifying, this becomes $\sqrt{\text{in. water}} \times 66.1$ = feet per second. The coefficient of flow for such an orifice being 0.64 owing to the contraction of the flow near the edges, the actual mean velocity over the full size of the orifice becomes $\sqrt{\text{in. water}} \times 42.3$ = feet per second.

In the author's experiments the effective velocities for an orifice of 1 in. sq. area, at pressures up to 4 in. water gauge, were tabulated, with the corresponding discharges of cubic feet of free air per minute. All subsequent readings for different sizes of orifice were simply referred to this table. Removable

screwed caps were used on the receiver, with orifices of 0.125, 0.25 and 0.5 sq. in. area, these being simple fractions of 1 sq. in.

These different orifice sizes were used to keep the water gauge readings within reasonable limits, and covered all measurements up to 7 cu. ft. per minute with ⅜-in. pipe fittings. Pipe sizes do not come into the calculations, provided they are large enough to carry the quantity of air. The receiver *f* need be only of sufficient size to reduce the kinetic action of the air to a negligible quantity and give a true reading on the water gauge.

In the author's actual experiments the receiver *f* was a tin of about 1 qt. capacity. For air lifts consuming about 50 cu. ft. per minute a 5 gal. can was used, with orifices of 0.5, 1, 2 and 4 sq. in. area. The pipe fittings in this case were 1 in. No difficulty was found in measuring quantities between 0.5 and 60 cu. ft. per minute. By substituting a high-pressure gauge at *b* readings can be taken at any pressure. A little experience soon gives the proper size of orifice to use.

Tin.

Tin Concentration in Bolivia.—In the *Australian Mining Standard* for Feb. 8, 15 and 22, 1912, Mr. O. Gore Adams gives detailed account of tin mining and dressing operations in several Bolivian mines and mills.

At the Llallagua mill the ore is treated in jigs and on tables in the usual manner, with intervening stage crushing. The final recovery is made on stationary canvas tables. Complete costs and details of operation are given, as follows: During one month the mill treated 3338 tons of ore of an average grade of 7.15 per cent tin. The concentrate contained 65.1 per cent tin. The recovery was 96.08 per cent. (These costs are calculated from "Bolivianos" and "pence" given by the author.)

The detailed cost of mining and milling is given as follows, per ton of ore treated: Exploitation, $6.38; development, $3.18; milling, $3.35; total cost to produce concentrate in store at the property, $14.20 per ton of ore treated. To this must be added the cost of freighting and exportation, which amount to $2.45 and $1.95 respectively, per ton of ore treated. The costs calculated per ton of concentrate produced are, exploitation, $58.25; development, $29.55; milling, $31; total cost to produce concentrate in store at the property, $132.25. Add to this the cost of freight, $23, and duties, $18.75. The total cost of marketing the concentrate, including every expense incurred, comes to $190 per ton of concentrate.

The system of treatment at the Socavon de Oruro mill is quite complicated owing to the complex nature of the ore. It contains tin, lead, copper, silver, gold, antimony, arsenic, sulphur, etc. An effort is made to save the first five. The ore is crushed dry in ball mills having screens of diagonal slots 1 millimeter wide. The ore is then roasted in hand-rabbled reverberatories, having three hearths in line, each 4 inches below the preceding. There is sufficient fuel in the ore to maintain combustion. About 4 per cent of salt is added to the charge on the last hearth, and the discharged mixture is sent to the cooling floor where it is moistened. It is then leached with water for 24 hours, to dissolve the soluble copper and silver which are later precipitated on scrap iron. The precipitate contains about 50 per cent copper and 250 oz. silver per ton. The ore is then subjected to the leaching action of a solution of $Na_2S_2O_3$, 0.5 per cest strength, for two or three days.

The resulting solution then contains from 300 to 600 grams silver per litre, and is precipitated by calcium sulphide. The precipitate is filtered, dried, roasted and shipped to Europe. It assays 35 per cent silver, 23 per cent lead, 2 per cent copper and 4 oz gold per ton. The residue from this leach is classified and concentrated on jigs, tables and buddles. Natural deposits of salt, lime and sulphur are found in the vicinity, so that the cost of these minerals is not high.

Pumping by Compressed Air.

Applications of Compressed Air in Chemical and Metallurgical Engineering Practice.

The use of compressed air for the transfer and agitation of liquids has become of such importance in modern chemical and metallurgical engineering practice that a recent lecture by Mr. Herbert T. Abrams on this subject should prove exceedingly interesting. Mr. Abrams is connected as engineer with the Ingersoll-Rand Company and his lecture was delivered last year before the Department of Mechanical Engineering of Columbia University. It is published in the April, 1912, issue of the *School of Mines Quarterly*. In view of its great interest to our readers we reproduce the lecture here almost in full.

The field in which compressed air can be used for lifting and forcing water is divided by Mr. Abrams into four distinct methods:

1. Pumps of the ordinary direct- acting type driven by compressed air;
2. Pneumatic displacement pumps;
3. The "return-air" system;
4. The "air-lift" system.

Direct Acting Pumps.

Mr. Abrams passes briefly over the use of air in place of steam for operating ordinary mechanical pumps. High economy must not be expected in a combination of this kind for the reason that pumps of this type, of themselves, are wasteful of power, and, generally speaking, no consideration is given as to whether they are to be run by steam or by air, no attention is paid to proper ratio of cylinders, and seldom is there any attempt to re-heat the air either before using it in a simplex or duplex pump, or between stages in a compound pump.

"Compressed air should be used in a great many instances where steam is now being wasted, but we are so inclined to listent to talk about 'compressed air efficiencies,' meaning always 'compressed air losses,' that we frequently lose sight of the more important final analysis, which is to define whether a saving in fuel is an actual credit or whether such apparent balance is not over-balanced in the item of extra labor or upkeep or general utility."

As compressed air is found driving steam pumps in mines, quarries, and wherever there is an available supply of air, Mr. Abrams briefly gives the simple rules used for proportioning pumps and the volume and pressure of air needed to run them.

The simplest way to find the quantity of free air and the pressure required is first to determine at what speed and under what air pressures the pump is to be run, and calculate the cubic feet displaced per minute at the pressure necessary to do the work. This may readily be converted into terms of free air at sea level or the greater quantity at any altitude. To this must be added a percentage, say 10 per cent, for the loss due to leakage.

With a given air pressure and head of water, the diameter of the air cylinder may be found by the rule: Determine the pounds pressure of resistance by taking one-half the elevation in feet, as representing the equivalent pressure in pounds, add one-third excess for pumps over 7-in. stroke. Divide this result by the pounds pressure of air at the pump, and the result will be the proper ratio.

Knowing the dimensions of the air cylinder and pressure, the free air requirements can be calculated by means of the simple formula,

$$V = 1.1 \frac{ASP}{144\,P_a}$$

where

V = volume of free air per cubic feet per minute,
S = Piston speed of pump in feet per minute,
P = absolute air pressure at pump.
A = area of air cylinder.

P_a = atmospheric pressure at any elevation.

Problem. Pump assumed over 7-in. stroke; head, 360 ft.; air pressure, 60 lb.

To find area of air cylinder, add one-third to the head (360 plus ⅓ = 480 ft.). Take one-half of this head as the equivalent pressure (240 lb.). Dividing 240 lb. by 60 lb. pressure gives a ratio of 4, or, in other words, the air cylinder should have four times the area of the water cylinder.

Having decided on a pump to handle 50 gal. of water per minute at a piston speed of 100 ft. as the proper size, we find, either by calculation or by manufacturers' tables, that the water end is represented by 3½ × 7-in. cylinder. Our ratio having been established at 4 to 1, the diameter of the air cylinder will be 7 in. and its area 38.5 sq. in.

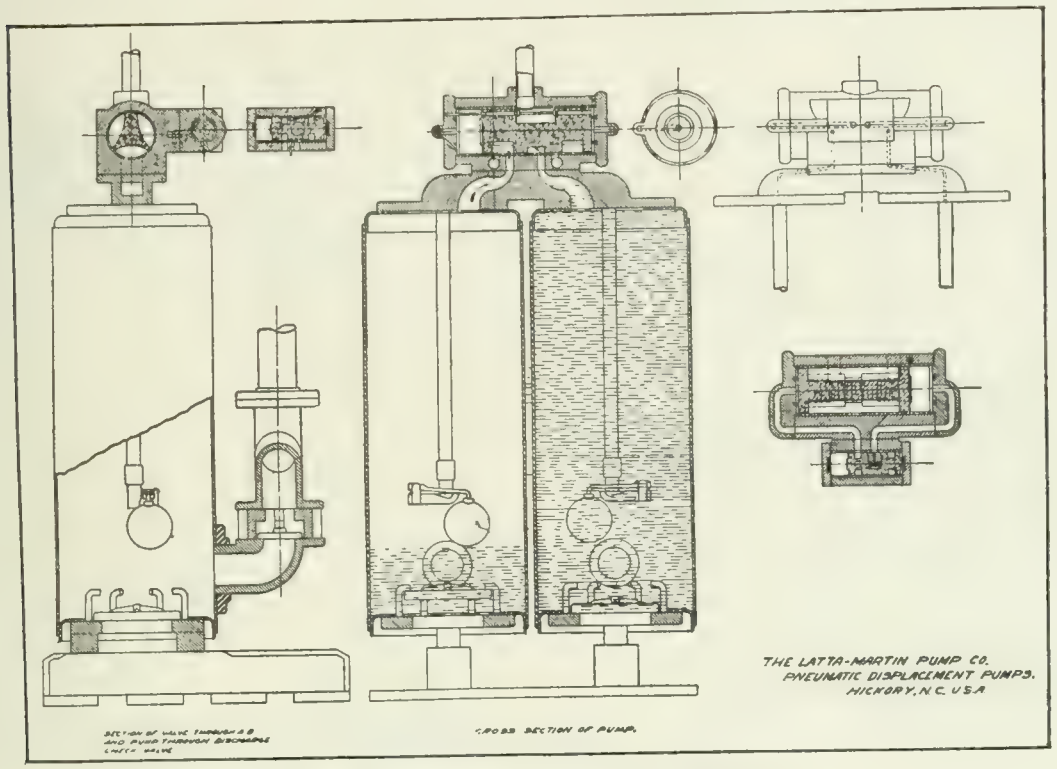

FIG. 1.—COMPRESSED-AIR DISPLACEMENT PUMP.

Now, substituting in our formula the values so far obtained, we have,

$$V = 1.1 \frac{38.5 \times 100 \times 75}{144 \times 15} = 148 \text{ cu. ft. free air per minute,}$$

showing a total efficiency referred to I.H.P. in steam cylinder of compressor of approximately 19 per cent. If the air is reheated to 300 deg., the requirement will be reduced about one-third.

Pneumatic Displacement Pumps.

Fig. 1 is a sectional view of a compressed air displacement pump. This pump uses air non-expansively, but owing to the fact that air comes in direct contact with the water pumped, without the intervention of moving parts, such as pistons or plungers, the work under moderate heads, up to 100 ft., is done in a satisfactory and efficient way.

The pump consists of one or two cylinders with inlet and discharge valves for water, and a valve mechanism controlled by floats or other means for admitting compressed air directly to the surface of the water within the tanks, and for exhausting the air after the water has been expelled. The tanks must be submerged in a suitable sump or cistern properly protected, of sufficient depth to insure that the pump tanks will fill properly by gravity. It will be seen that the pump is really a simple apparatus. Water enters through the large inlet valves at the bottom. Air pressure entering at the top is alternately delivered to the chambers, expelling the water in them through the discharge valves and pipe. When a tank is nearly empty the contained air is exhausted through a port in the valve mechanism, while water replaces it through the foot valve as soon as the air pressure is relieved, the alternate discharge being entirely automatic.

The proper field of this device is that calling for the pumping of water at some distance from the source of power, where there is an unobstructed supply and a limited lift. Valves in the power house on the air line to the pump, or to as many of them as may be needed to pump from a number of sources, control the operation, and pumping must continue as long as air is supplied.

The advantages are that these pumps can be easily installed, and where an existing supply of compressed air is available the cost of equipment is low. There is no pump house to build and maintain at the water supply; the operation is controlled in the engine room; there are no piston or plungers to repair and renew, and the wear on valves is less than in any ordinary direct-acting mechanical pump. Neither lubrication nor packing is required and the attention charges are reduced to a minimum. Its working is not affected by muddy or gritty water.

These facts adapt the pump for dye works, bleacheries, pulp mills, and for handling solutions. It may be used to take water from a cistern or reservoir filled by the air-lift from wells, or placed in a remote sump in a mine or quarry, it can be employed to deliver water to the main pumps.

Since the pump operates by the direct displacement of a volume of liquid by a volume of air under suitable pressure, it follows that simple rules can be given for arriving at the volume of air and pressure needed to do the work.

Reduce the quantity of water in gallons per minute to cubic feet. Multiply the total head (static head plus water-pipe friction) by 0.434; this gives the working air pressure at the pump. Next find the ratio of air pressure to atmosphere, which multiplied by the cubic feet of water per minute gives the cubic feet of free air per minute needed at the pump to displace this volume of water.

Knowing the volume of free air required, 5 to 10 per cent should be added for leakage and clearance according to the special conditions.

This is net, actual free air and not piston displacement of compressor; therefore, in figuring on a compressor to do the work, volumetric efficiency must be taken into consideration, following the general practice in such cases, according to the pressure, size and type.

Problem.—Source of supply, a river; distance from power house, 1000 ft.; lift, 60 ft.; diameter discharge main, 4 in.; quantity of water required per minute, 150 gal.

150 gal. = 150 ÷ 7.5 = 20 cu. ft.

Static head ..... 60 ft.
Friction head 150 gal. per min. in 4 in. pipe 1000 ft. long 16 ft.

Total head ..... 76 ft.

$$70 \times 0.434 = 33 \text{ lb.}$$

$$\text{Ratio } r = \frac{33 + 15}{15} = 3.2$$

Free air $= 20 \times 3.2 = 64$ cu. ft. per minute.

Allow 10 per cent for leakage and clearance = 70 cu. ft. net.

If the compressor selected will show a volumetric efficiency of 80 per cent, the piston displacement required will be $70 \div .080 = 88$ cu. ft. per minute.

$$\text{Theoretical horsepower} = \frac{150 \times 8.33 \times 76}{33{,}000} = 2.88$$

I.H.P. in steam cylinder of compressor = 8.5.

Total efficiency $= 2.88 \div 8.5 = 33$ per cent.

Return Air System.

The elevation or transfer of water and other fluids or semi-fluids by direct displacement with compressed air is so natural and self-evident a proposition as to need almost no suggesting. It appeals at once merely on the ground of convenience and simplicity. But the principle as ordinarily applied has been open to the objection that it was not economical.

One characteristic of the ordinary, plain, displacement pump is waste of power entailed by direct release of the displacing air after the fluid is ejected from the pump tank. This air, after doing its work, is still at practically full pressure, therefore having all its potential energy of expansion. Its direct exhaust into atmosphere after displacement is the throwing away of this expansive power without any useful effect.

If air pipes are carried back from the pump to the compressor so as to add the residual pressure after displacement to the reverse side of the compressor piston, where it will help in compressing air into the pump tank, we have a return-air, expansive displacement pump, operating at good economy.

Mr. Abrams emphasizes, at this point, the fact that both the plain displacement pump and the "return air" system have the following advantages which are unique in that, while other pumping systems have some of them, no other systems combine them all to such remarkable degree:

1. Simple in construction, installation and management.
2. Wholly automatic in operation.
3. Under instant and complete control from the compressor room, however distant.
4. No delicate mechanism exposed to corrosive or abrasive action.
5. No oil or other lubricant required by the pump.
6. Not affected by any excess submergence except that operation is improved under a hydraulic head.
7. Applicable to the pumping of all fluids or semi-fluids, as well as mud, sand, or any débris which will pass the valves.

Where water is to be pumped, the field of the pneumatic displacement pump and the return-air system is that in which large volumes are to be handled from a generous source of supply, where complete submergence can be secured, such as in a river, lake, mine or quarry sump, large spring or an excavated well. This, at once, opens to them the supplying of water for small municipalities, shops, mills, factories, etc.

The fact that these systems will handle anything sufficiently fluid to pass their valves adapts them also to the handling of solutions in salt works and bleacheries; the moving of semi-fluids, as in pulp mills; the handling of cement, slurry and marl; the pumping of glass sand for glass factories; elevating salt solutions in salt works, and the pumping of sewage.

Under normal conditions it is safe to say that the return-air system will show an average efficiency of 50 to 55 per cent, this efficiency being the ratio of horse-power of water lifted to the indicated horse-power in the steam cylinder of the air compressor, including all losses. It is easy to estimate from these figures just what they mean in terms of fuel saving.

Yet the question of fuel economy is but one argument in favor of the return-air system. Another argument is that the compressed air system may be operated with a far less boiler horse-power, with a corresponding reduction in first cost of boiler plant, interest, maintenance, repairs and firing cost. Where a plant is crippled by a shortage of boilers, the substitution of the return-air system for a less economical pumping system will relieve the embarrassment.

Continuing still further the argument for this system, Mr.

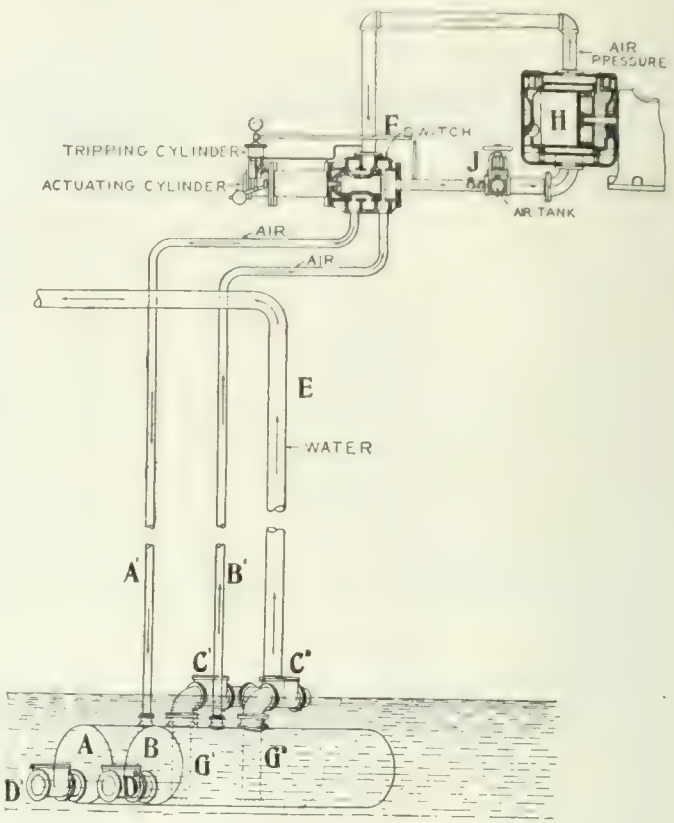

FIG. 2.—RETURN-AIR DISPLACEMENT SYSTEM.

Abrams notes that the tank equipment needs absolutely no care. The operation being entirely under control from the engine room, the engineer can at any time start, stop or vary the pumping. There is no possibility of drowning out the system. In fact, it operates with proportionately less power as the height or head of water above the tanks increases. It cannot become choked by such silt or dirt as may enter a mine sump.

The return-air system cannot be classed as a pump, or as machinery of the kind regularly catalogued and listed. It is a complete system in itself, consisting of an air compressor, a receiver, a reversing switch, two air lines, each leading from the compressor through the switch to one pump tank, and two pump tanks, all in a closed circuit, in which, by a regular cycle of operations, one air volume is compressed, expanded, recompressed and re-expanded, corresponding with a discharge of one of the pump tanks.

The principle of operation is simple. Compressed air is admitted to a tank filled with water, or any fluid, forcing the fluid out through a check valve and pipe line, and at the same time the compressor is drawing air from the other tank, the charge of air being regulated so that when a tank is empty, the other is full, at which time the switch reverses, thereby reversing the action of the tanks.

The cycle of operation will be better understood by referring to Fig. 2; A and B are twin displacement tanks, preferably completely submerged, though they operate if so placed as to

be filled by siphon action. A^1 and B^1 are the two air pipe lines. C^1 and C^2 are discharge check valves preventing the return of the fluid ejected.

D^1 and D^2 are check valves preventing the discharge of the fluid through the inlet. E is the discharge pipe from both tanks.

F is the automatic switch controlling the pumping cycle. G^1 and G_2 are the tank risers.

H is the compressing cylinder of an air compressor. J is the automatic compensating valve which keeps the system supplied with air.

In the diagram as shown, air is being withdrawn by the compressor H from the tank B and is being compressed in tank A. At the same time the fluid is entering the tank B through check valve D^2, while it is being forced from the tank A through the riser G^1, the check valve C^1 and the discharge pipe E.

The mathematical analysis of the system is difficult. Any one interested in a full discussion of the problem will find it fully brought out by Prof. Elmo G. Harris in Vol. 54 of the *Transactions* of the American Society of Civil Engineers.

In order to proportion a plant correctly, the needed data are as follows:

Q_w = the quantity of water to be pumped in cubic feet per second.

h = the total lift, or head, in feet.

l = the total length of air pipes, the distance from compressor to pump tanks.

Having these, we must compute:

Q_a = the volumetric capacity of the compressor, or the piston displacement in cubic feet per second.

V = the volume of each pump tank (cubic feet).

d = the diameter of air pipe (in inches).

D = the diameter of water pipe (in inches).

$H.P.$ = the maximum horse-power required of the steam end of compressor.

From the formula:

$$Q_a = Q_w \quad [1 - 1.4 \log_e R]$$

the following Table I has been prepared, showing the size of compressor, pipes, etc., required for various heads, based on 100 gal. of water per minute; for other quantities, the dimensions will be directly proportional. The table assumes the pump tanks to be fully submerged.

TABLE I.—DIMENSIONS FOR REEVES AIR SYSTEM

Lift in feet	Capacity of compressor in cu. ft. per minute piston displacement for 100 gals. per minute	Min. I.H.P. of air cylinder.	Max. I.H.P. of steam cylinder	Average H.P. of steam cylinder. Air-Lift System.

The air-lift system of pumping, measured on the power basis, is not an efficient method of raising water, but where it is and can be applied, it fills a certain field and in that class of work does service that no other pump can do, and does it in a most satisfactory way. This method of pumping has been most generally applied to raising water from artesian wells. There are not many underground formations in which wells can be located close together without affecting each other when pumping, and for that reason it is best to spread them out on a line of what we call the line of underground flow. Some formations are so tight that wells have but little capacity, and in such formations it is particularly necessary that the wells should be scattered and pumped moderately. For the reason that separate pumping units entail high first cost and labor for attendance, the air-lift system is recommended. An economical central pumping station will serve any number of wells, compressed air being capable of transmission in proper sized pipes for great distances without serious loss.

The required equipment consists of an air compressor located at some convenient point, preferably in some existing power station where it can take advantage of economical steam conditions, an air receiver, and a pipe line leading from the receiver to the well or wells. The pump proper consists of nothing more than two plain pipes, one for air and one for water; these pipes run down inside of the well and are submerged for a certain depth proportionate to the lift when the the pump is at work. Fig. 3 shows the different method of piping wells. All wells are no alike, therefore it is a spec

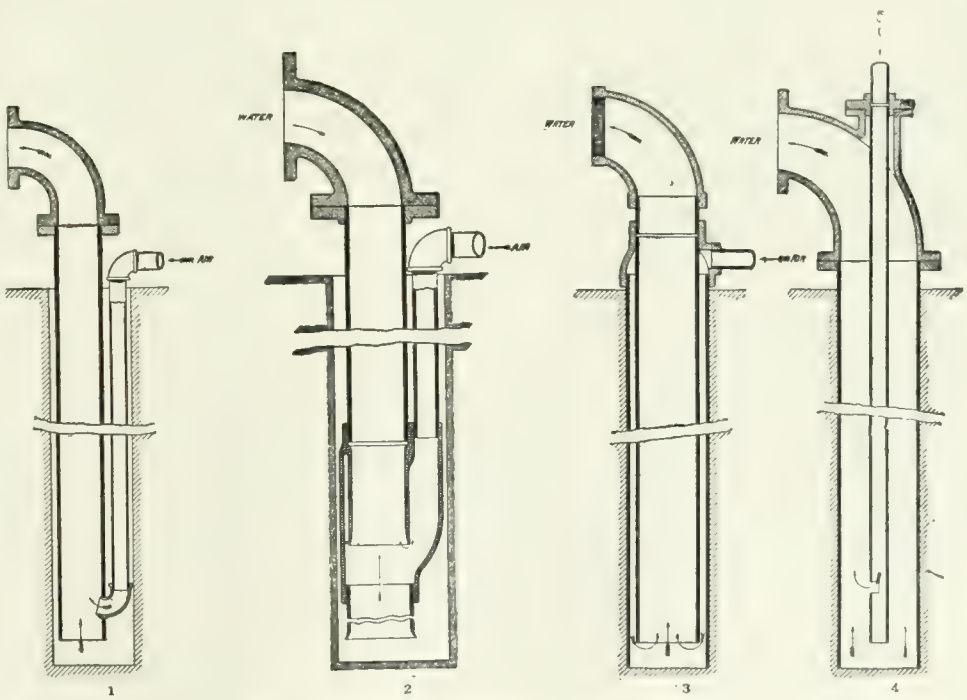

FIG. 3.—DIFFERENT METHODS OF PIPING WELLS.

problem in every case to determine the size and arrangement best suited.

Each method here shown has its use, depending upon the diameter and depth of the well, whether the well is cased or not, the lift, volume of water to be pumped, and character of

the water bearing strata. The arrangement most generally used, where conditions permit, is shown in No. 1, Fig. 3. This is the Pohle or "side-inlet" method, in which the discharge and air pipes are placed side by side in the well, joined by a suitable foot-piece.

In No. 2, Fig. 3, compressed air fills the annular space surrounding the up-take pipe and is free to enter the rising column at all points of its periphery, at the same time acting without obstructing or contracting the discharge pipe anywhere.

Fig. 4 shows the tubular foot-piece. This device aims to provide a means for actually dividing air into fine streams, which we have found to be the best condition in which air can be introduced into the rising main. Air from the supply pipe fills the hollow base of the foot-piece. The base-plate is studded with ¼-in. wrought-iron pipes about 18 in. long extending upwards to a point where the water passes from the foot-piece into the discharge pipe, at which juncture the bubbles of air are released. Ample space is provided for the inflow of water to the foot-piece through the bottom openings, augmented by the larger side inlets shown. Thus we have in the foot-piece designed for a 5-in. discharge pipe a subdivision of air into thirteen ¼-in streams, with the added advantage that these separate small pipes will tend to act as governors to control the discharge of the air.

The usual capacities allowed for the side-inlet method are are follows:

Air Pipe Connection.	Water Pipe.	Size Well.	Maximum Economical Capacity on Moderate lift. Gal. per min.
½ in.	1 in.	3 in	7
¾ "	1½ "	4 "	20
1 "	2 "	4½ "	35
1 "	2½ "	5 "	60
1¼ "	3 "	6 "	100
1½ "	3½ "	7 "	140
1½ "	4 "	8 "	190
1½ "	5 "	9 "	250
2 "	6 "	10 "	350

No. 3, Fig. 3, shows the Sounders system. A central discharge pipe is suspended in the well, the air passing down between it and the well casing. If the well is not cased a second pipe must be used outside of the main discharge pipe, the air, as before, filling the annular space between the two pipes. In estimating pipes under this system it is usual to allow capacities as follows:

Lift, 25 ft., 15 to 20 gal. per minute per square inch area water pipe.

Lift, 50 to 125 ft., 12 to 15 gal. per minute per square inch area water pipe.

No. 4, Fig. 3, is the so-called "central air pipe" system. This method is generally used where the lift is low, and to obtain the greatest possible output from what are termed "strong wells," *i. e.*, wells having a strong static pressure and finding their supply in gravel or open rock formations. The air pipe is suspended in the well without the usual discharge pipe. The proper sized air pipe for different sizes of casing and capacities are about as follows, depending upon the lift and submergence:

Size of Casing	Size of Air Pipe.	Capacity. Gal. per min.
3½ in.	1¼ in.	80 to 100
4 "	1½ "	100 to 150
5 "	2 "	150 to 250
6 "	2 "	275 to 375
8 "	2½ "	500 to 665
10 "	2½ "	775 to 1000

Notwithstanding the fact that the air-lift system has been in commercial use for nearly 20 years and thousands of plants are in daily operation all over the world, no mathematically correct formulas have been published covering the design of these pumps, nor is there exact information at hand for calculating the volume of air and pressure required to operate them under all conditions. This is due to a number of variable factors which enter into each proposition, and if we are to undertake to derive a practical working formula we must assume certain efficiencies for the system, and assume also that the wells will be properly piped to meet the proper relation of submergence to lift.

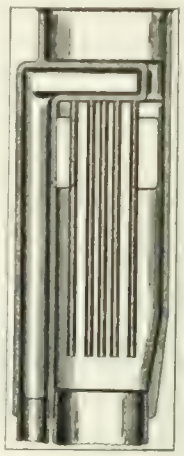

FIG. 4. TUBULAR FOOT PIECE.

Although impossible to construct a formula which can be applied uniformly to all conditions met in this class of work, yet, as Mr. Abrams points out, we can define the trend and introduce certain rules which will permit any engineer to calculate the requirements for any given proposition when the exact data covering the case are known. The data required and the factors entering into these calculations may be reduced to the following:

V_a = free air piston displacement required to raise 1 gal. water.

h = total vertical lift in feet.

H = submergence in feet.

C = constant (efficiency of the system).

Before proceeding, the symbols above written must be clearly understood.

V_a is the free air (piston displacement of the compressor) required to raise 1 gal. of water, due allowance having been made for the ordinary volumetric efficiency of the air compressor. If the compressors are in bad shape or poorly designed, of course, more displacement will be required from such a machine than from a well-designed compressor in good working order.

By "lift" is meant the total vertical lift from the pumping level of the water in the well to point of discharge.

"Submergence" is the depth the air pipe is submerged below the pumping level of the water in the well, and is an important factor in any installation; the percentage of submergence, so often heard of, is the percentage of the total length of pipe which is submerged in the solid water when pumping. The necessary percentage of submergence varies in accordance with the lift; low lifts require proportionally more submergence than high lifts; or, in other words, the necessary submergence decreases as the lift increases. The range of these percentages lies within the following limits: For lift of 20 ft., 66 per cent; for lift of 500 ft., 41 per cent. The average best percentage in the class of work usually encountered will lie between 50 and 65 per cent. Submergence also governs the pressure required, both the starting pressure and the working pressure. The air-lift differs from other pumps in that the pressure necessary to raise the column of water does not depend upon the head, h, but upon the submergence, H, or, in other words, H is the actual head against which the air pressure acts.

The first step in a calculation of this kind is to determine from the lift what the proper submergence should be, and knowing this submergence, the work can be easily calculated on the basis, $P = 0.44\,H$.

We are now realy to calculate the air volume required (free-air piston displacement) to raise 1 gal. of water. The following formula may be used, which closely approximates average practice (in part suggested by Mr. Edward A. Rix):

$$V_a = \frac{h}{C \log \frac{H + 34}{34}}$$

The annexed table also shows the value of C calculated from the efficiency of the system under various heads, with proper submergence.

TABLE FOR VALUE OF C.

h = Lift.	C = Constant.
10 ft. to 60 ft.	245
61 ft. to 200 ft.	233
201 ft. to 500 ft.	216
501 ft. to 650 ft.	185
651 ft. to 750 ft.	156

Problem.—Given a bore-hole, well, or shaft 250 ft. deep, the water in which stands 50 ft. below the ground surface, but which falls 25 ft. when being pumped at the rate of 200 gal. per minute, and it is required to raise the water 25 ft. above the ground:

Standing water level in well, measured from surface	50 ft.
Drop when pumped	25 ft.
Elevation above surface to raise water	25 ft.
Total lift	100 ft.

If the best ratio of submergence for a lift of 10 ft. is 58 per cent, then

$$H = \frac{h \times 0.58}{100 - 58} \text{ or } \frac{100 \times 0.58}{100 - 58} = 138 \text{ ft.}$$

and applying our formula,

$$V_a = \frac{100}{C \log \frac{138 + 34}{34}}$$

and further introducing the value of C from the table, we have

$$V_a = \frac{100}{233 \times 0.704151} = 0.60.$$

$V_a = 0.60$ cu. ft. (piston displacement) per gallon of water; hence for 200 gal. $200 \times 0.60 = 120$ cu. ft. will be required.

The next calculation is to find the starting and the working pressure. Observe that the normal or standing water level is 25 ft. higher than the working, which indicates a submergence at the beginning of operations equivalent to $138 + 25 = 163$ ft. The starting pressure must be just sufficient to overcome that due to the height of the water column above the footpiece.

$163 \times 0.44 = 72$ lb. gage, the starting pressure.

$0.44\,H = 138 \times 0.44 = 61$ lb., the working pressure.

The actual pumping level in a well or group of wells can seldom be known in advance of a test. It is customary to assume certain conditions of lift and submergence, basing such conclusions on experience, and proceed to pipe the wells accordingly. After the piping is installed and the working conditions arrived at, the submergence is altered to suit by raising or lowering the pipe in the well until the best ratio is established.

The quantity of water a well will yield depends upon its diameter and the natural flow. It is also essential that the pipes both for air and water be properly proportioned, for the reason that velocity of flow is an important factor; if too large a pipe is used the air gets through without doing all the work it should, and, on the other hand, if the velocity is too high there is undue friction loss and also inefficient expansion of the air bubbles. The best results are ordinarily obtained by providing for a discharge of 12 to 15 gal. per square inch area of discharge pipe.

Tables are available for determining the friction loss of air pipes. It is, of course, essential to keep this loss within reasonable limits. The flow should not exceed 1500 ft. per minute.

One reason why the air-lift has been so popular, aside from its flexibility and simplicity, is the fact that the yield of a well is frequently increased by its use. Wells can be cleaned of sand, keeping open the water-bearing seams. As there is little apparatus in the well, an unobstructed flow is assured. The air-lift will handle all the water a well yields, but if a given well is equal, at its maximum, to a flow of 50 gal. per minute the air-lift has so miraculous power whereby the yield can be increased.

Water is also purified and improved by the intimate commingling with air on its passage through the discharge pipe. There is a complete aeration as the water flows upward, putting it in condition to throw off sulphur gas, precipitate iron, and in a measure prevent vegetable growth.

SPECIAL USES FOR THE AIR-LIFT.

The pumping of oil wells offers a superior opportunity for the air-lift, and in this line of work compressed air has been pre-eminently satisfactory. One of the advantages possessed by the air-lift, whether it be in pumping water or oil, is the ability of the system to handle sand and gritty matter.

On account of the facility with which the air-lift, owing to the fact that no working parts come in contact with material being pumped, can handle sand, mud, and other substances destructive to ordinary mechanical pumps, it is an ideal method for pumping in the following cases:

1. Slimes, a mixture of water and the very fine portions of crushed ore coming from a reduction plant.

2. Sand and water for stone saws. All preparation necessary for work of this kind is a "master" well or pit sunk to a proper depth to provide the necessary submergence.

3. The air-lift has done excellent work as a dredge pump and if its usefulness along these lines were better appreciated we should see a great many more installations. The arrangement of air-lift units on a scow, with proper facilities for raising and lowering the pipes, presents unexcelled features of simplicity and capacity.

4. Agitation of slimes in the cyanide process also offers an opportunity for the air-lift, as complete and satisfactory aeration can be brought about by placing an air-lift in a cyanide tank specially designed for the purpose.

The air-lift is past the experimental stage and is taking its place with other applications of compressed air where steady, reliable results are appreciated.

Personal

Dr. Frederick G. Cottrell, of San Francisco, who is in charge of metallurgical investigations of the Bureau of Mines, visited metallurgical plants in Denver, Leadville, Salt Lake City and Ely on his return west from New York and Washington.

Mr. W. G. Swart, Western representative of the American Zinc Ore Separating Company, with headquarters at Denver, has gone to Europe on professional business. He will be absent about two months.

Mr. T. A. Rickard, of London, spent a few days in Denver on his return to London from San Francisco. He was entertained at a dinner given by local engineers.

Mr. Bernard MacDonald, of Guanajuato, Mexico, was in Denver recently.

Mr. L. H. Norton, of Silverton, Col., has returned after spending a few months in Mexico.

Mr. R. M. Henderson, manager of the Wellington Mines at Breckenridge, Col., who has been in the hospital in Denver for several months following an accident received at Breckenridge, has returned to his work.

Dr. Erich A. Beck, metallurgist of the Goldschmidt Thermit Company, New York, recently spent two weeks in Colorado on business for his company. He expects to visit Germany this summer.

Mr. Russel Raynolds has been transferred from the Durango plant (Colorado) of the American Smelting & Refining Co., to the Globe plant (Denver), where he will have charge of the research laboratory. **Mr. J. E. Bonsack,** formerly in charge of the latter laboratory, has been transferred to New York.

Digest of Electrochemical U. S. Patents

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

Ore Treatment (*Continued*).

544,610, Aug. 13, 1895, Edward W. Clark, of Butte, Montana, assignor of two-thirds to Edwin M. Clark and The Western Iron Works, of same place.

Relates to the extraction of gold from ores by the chlorination method. The ore is suitably pulverized and mixed with a solution of chlorid of sodium and placed in a cylindrical vat containing rotary stirrers. Within the vat is an anode preferably of carbon, and mercury cathodes are placed in a rectangular vessel, outside of the vat, and communicating therewith by perforations in the cylindrical vat. An electric current is then passed through the solution, chlorin and oxygen being generated at the anode, and it is brought into intimate contact with the ore by the stirrers. The stirrers further have a spiral arrangement which tends to gradually propel the ore to the exit where it is discharged into a second cylinder. After treatment, the mercury is gathered, and the gold removed therefrom.

546,873, Sept. 24, 1895, Edgar Arthur Ashcroft, of Broken Hill, New South Wales.

Relates to the leaching of ores of the Broken Hill type of sulfids. The ore is first roasted and then leached with a solution containing a ferric salt which extracts the zinc oxid and precipitates ferric hydrate. When the leaching is complete, the solution and residues are separated by settling or otherwise, and the residues briquetted with quicklime, for subsequent smelting. The solution containing zinc also may contain silver, gold, copper and other metals which may then be precipitated by the action of metallic zinc applied in the well known manner. The solution, having been freed from interfering metals, is electrolyzed in a cell and the zinc recovered. During electrolysis the zinc is removed and iron added to the solution from iron anodes. The solution is again electrolyzed in another compartment, using carbon anodes, where the ferrous salts present are oxidized to ferric salts. The latter ferric solution is then available for leaching fresh ore. Lead salts present may be converted into lead chlorid by a similar reaction and the lead chlorid subsequently converted into an insoluble sulfate by the addition of sodium sulfate or by any zinc sulfate resulting from the oxidation of the zinc sulfid in the original ore. The lead sulfate will precipitate and may be smelted with the residues obtained from the leaching process.

549,907, Nov. 19, 1895, Alfred L. Eltonhead, of Philadelphia, Pennsylvania.

Relates to the extraction of gold and other metals from ores by the cyanid process. The finely crushed ore or tailings having been leached with a solution of cyanid, the latter is electrolyzed in a rectangular cell, passing through the cathode compartment by a tortuous route. The bottom of the cell is covered with mercury and connected as a cathode. A central compartment of the cell comprises the anode compartment and contains a solution of potassium carbonate or other alkaline carbonate. An anode in the potassium carbonate decomposes the latter, forming potassium or sodium amalgam. The potassium or sodium amalgam reacts with a solution of potassium cyanid in the tortuous cathode compartment, separating the gold by substitution, forming potassium cyanid and gold amalgam. An electrical current of low voltage and high amperage is passed through the potassium carbonate to the mercury. The reformed potassium cyanid may be used in the subsequent extraction of ore. At suitable intervals, the gold amalgam is collected from the mercury cathode and separated in a well known manner.

BOOK REVIEWS.

L'Argent et les Métaux de la Mine de Platine. By **M. Molinié** and **H. Dietz.** 12mo, 309 pages, 93 illustrations, price 5 francs. Paris: Octave Doin et Fils.

A large amount of information for a small amount of money. The metallurgy of silver is a good condensation of the subject, brought pretty well up-to-date. Worthy of special mention are five chapters on "silver in industry," in which are described at length the manufacture of alloys, coins, jewelry, plate, wire, foil, the uses of silver salts, and the recovery of silver from industrial residues. Platinum is satisfactorily handled in 75 pages, and palladium is fairly treated, but iridium is given only one page, and rhodium, osmium and ruthenium barely mentioned. The book is well worth its cost to anyone interested in silver or the platinum metals.

* * *

Der Kautschuk und seine Prüfung. By Prof. Dr. **F. W. Hinrichsen** and Dipl. Ing. **K. Memmler.** 263 pages, 64 illustrations. Price Marks 8. Leipzig: S. H. Hirzel.

As far as the reviewer knows there are but few places in the world where such unique facilities for scientific investigations and tests exist, combined with liberal contributions from practical experience on the part of manufacturers as is the case with the "Kge. Material Prüfungsamt" at Gross-Lichterfelde, near Berlin. Both authors are members of this institution and as the "Prüfungsamt" keeps in closest touch with all industrial problems, no one was better prepared than the authors to write this book. The authors have made the best of their opportunity and are to be congratulated on their success.

The industrial and scientific knowledge of caoutchouc have rapidly increased during recent years. The synthetical and analytical work of Harries Willstaetter and Fritz Hofmann have brought about the artificial production of caoutchouc and although it has so far not been utilized on a commercial scale, the applications of caoutchouc for all kinds of industrial purposes are broadening at such a rate that the results of scientific progress in this field must be of general interest.

Dr. Hinrichsen himself has studied the vulcanization of caoutchouc, applying the methods of physical chemistry to this problem, and has also extended the methods of the analytical determination of its natural and intentionally added constituents. Mr. Memmler deserves much credit for improving and, in fact, redesigning the methods of physical tests of this material.

The book consists of three parts. The first deals with history, properties, chemical constitution and artificial ingredients, theory of vulcanizing, properties of vulcanized india rubber, and manufacture of india rubber materials. The second part deals extensively with the chemical analysis of the raw material before and after vulcanizing and with the examination of the products after continued use. The third part which occupies over a hundred pages of the book, contains an interesting description of experiments and the results of a great many determinations of physical properties which can not be enumerated in detail. Especially this part reflects the genial spirit of A. Martens, the originator of many of the physical testing apparatus used in the material Prüfungsamt. The good illustrations given in the book increase the value of the descriptions.

All three parts contain many literature references. The book as a whole is an excellent introduction into the chemistry and physics of the manufacture of caoutchouc. It should also prove interesting reading for every consumer who wants to familiarize himself with the properties of this material and the latest investigations concerning its preparation. The reviewer enjoyed last summer a personal introduction by both of the authors into their exhaustive work and remembers with pleasure seeing many of the apparatus described in this book in practical and successful use.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine

Vol. X — New York, June, 1912. — No. 6

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

Electric Steel as a Test of a Great Corporation.

In these days when great corporations are subjected to acid and basic tests from many possible and some more impossible viewpoints, ranging from most intricate interpretations of the Sherman law to the simple, sweeping, autocratic distinction between good and bad trusts, this journal, as a plain engineering journal, likes to say a word about the greatest trust of all—the U. S. Steel Corporation—in the Nietzsche spirit of Jenseits von Gut und Böse.

The past hard winter with its innumerable broken-rail accidents has emphasized that it is plainly the business of the iron and steel industry to find means for making better rails. It was but logical that the American Iron and Steel Institute, in which 90 per cent of the iron and steel industry of this country is represented, should, at its recent meeting, deviate from its old policy of devoting all its time to commercial matters and welfare work, and should take up the serious discussion of some of the burning technical problems. What can be done to make better rails? Mr. Wm. R. Walker's paper on electric steel, published in full on page 371, was the answer.

To appreciate the scope and importance of this paper, the position of its author must be understood. Mr. Walker has been in the steel industry almost from boyhood on—as a chemist, in charge of Bessemer and open-hearth departments, in charge of the South Chicago works, as general manager of the Illinois Steel Co., and now in charge of all metallurgical improvements of the U. S. Steel Corporation. He was one of the first American steel men to see the possibilities of the electric steel furnace. It was Mr. Walker's influence and advice which led the U. S. Steel Corporation to take up the electric furnace and to make large-scale experiments on the heretofore untried problem of making steel for large-quantity products, like rails, in the electric furnace. It was on Mr. Walker's advice that many hundreds of thousands of dollars have been spent by the Corporation in its three years of experimental work.

That this was true pioneer work is clearly shown by the one detail of the electrodes. The step from a 5-ton Heroult furnace to the 15-ton size was too big for the amorphous carbon electrode makers. Now their troubles are past. Amorphous carbon electrodes are now made which will not break and which are sold at a reasonable price. But it is significant that if they had been available before, it would have saved over $150,000 on the single item of electrode cost for the Steel Corporation.

In view of all these facts, Mr. Walker's unostentatious paper—written with an almost extreme modesty, so characteristic of its author—really assumes momentous importance in its simple statement of the success of the experiment and of electric steel rails. It foreshadows a big future for the electric steel furnace. Clearly the South Chicago experiment was a necessity. But who could have made it, in view of the expense, but a very big corporation? And was it not the same with Gayley's dry-blast experiment?

[illegible] electric steel furnace on a very large scale the ice has now been broken and the credit for this belongs to the U. S. Steel Corporation and Mr. Walker. Though it is but fair to say that when this issue is mailed, the famous Deutscher Kaiser works in Germany will have done even better by starting a 25-ton electric steel furnace.

Clearly a big corporation can assume, for the advance of civilization, some of the functions of Nietzsche's "Übermensch," when working along legitimate technical lines "jenseits von gut und böse."

Status of the Porphyry Copper Producers.

The Copper Producers' Association report for May 1, 1912, showed an increase during the preceding month in the stock of marketable copper in the United States amounting to 2,927,829 pounds, or a total of 65,295,386 pounds. This is the first report since September, 1911, to show an increase, and only the second since May, 1911. Thus, for nine months of the year preceding May, 1912, a marked decrease was shown in copper production in this country. In view of the improved condition of the copper market, and the coincidental publication of annual reports by the five big porphyry copper producers, a brief analysis of their status may be of interest. A year ago, when low prices and increasing production marked the copper industry, considerable apprehension was felt regarding the effect of the porphyry coppers, on account of their enormous rate of production and cheap cost of operation. To-day those companies are in a still more impregnable condition, and the full effect of their production probably will not be felt this year.

The following tabulation shows the total ore reserves on January 1, 1912, and the mill capacities of the various plants now fully or partly completed:

	Mill Capacity, Tons per Day.	Ore Reserves, Tons.	Grade per Cent. Copper.
Chino	5,000	54,970,646	2.24
Miami	3,000	18,232,000	2.58
Nevada Consolidated	8,000	40,853,371	1.66
Ray Consolidated	8,000	77,314,470	2.17
Utah	21,000	301,500,000	1.53

Nevada Consolidated is running at full capacity, but the others will not reach that point until later this year. Utah has completed the remodeling of only nine sections of its Arthur plant, and the other four sections will not be ready for operation until after the middle of the year. The Utah Magna plant, however, is prepared to run to its full capacity of 12,000 tons per day. Chino, Miami and Ray Consolidated mills are about ready for full production.

Chino commenced production in October, 1911, and Miami and Ray Consolidated in March, 1911. The first ore milled at these plants has not been of a grade or quality equal to that which is expected later. Considerable oxidized ore from near the surface has been treated, and it has been impossible to make a high recovery on this ore, or to reach the normally low costs which are anticipated. Irregular operation, due to the alterations and adjustments usually found necessary in new plants, also has added to the cost of copper produced at Chino. Below are given figures showing the production of copper and its cost at the various plants:

	[illegible] Pounds.	Cost per Pound Cents.
Chino	.....	10.00
Miami (since March, 1911)	15,385,783	9.11
Nevada Cons. (15 mo.)	78,541,270	6.97
Ray Cons. (since March, 1911)	15,721,520	10.75
Utah	98,436,224	7.87

At Chino the average yield for the period was 24.5 lb. copper per ton of ore. In January, 1912, on a yield of only 22 lb. per ton, in two sections treating 800 tons each per day, the cost was only 8 cents per pound, and it is expected that under normal conditions this will be reduced to 7.5 cents. Ray Consolidated also had a higher cost than will prevail this year, on account of shipping concentrates to El Paso. The reduction in cost which will result from shipping to the new A. S. & R. Co. plant at Hayden, Arizona, will amount to 1.5 cents per pound of copper. This will bring the cost down to about 9 cents, and it is expected ultimately to reach 8 cents.

Metallurgical results in the newer mills are showing an improvement over those obtained in the first porphyry mills, and likewise, the remodeled mills are showing a similar improvement. There is still much to be desired, however, in respect to percentage recovery, and it is only when the percentage loss is expressed in pounds of copper that a full realization of the enormous loss is gained. Thus the loss in the Utah mills approximated 40,000,000 pounds copper in 1911, which is more than the total recovery in the Miami and Ray Consolidated mills, as shown in the foregoing table. The achievement of milling rock at a profit when it contains only 1.5 per cent metal is worthy of all commendation, but apparently a still larger problem remains.

Miami apparently leads in percentage recovery, with Utah, Nevada Consolidated, and Ray Consolidated following. No figures are yet available for Chino. Of the Utah mills, the remodeled Arthur plant is proving superior to Magna in economy of operation and metallurgical results, the former showing 70.49 per cent. and the latter 69.28 per cent. extraction. Ray Consolidated has improved metallurgical results since publishing the report, and the recovery has been brought up to 70.32 per cent. on ore carrying 1.68 copper, when 1100 tons were treated per day in each section.

The cost of milling at the Magna plant of the Utah company was 40.06 cents per ton, and at the Arthur plant 48.01 cents. The latter high cost is ascribed partly to the fact that some of the old equipment was used during part of the year, and partly to intermittent operation. When the Arthur plant is fully remodeled and running at capacity, the cost will be lower than at the Magna mill. At Ray Consolidated the cost of milling was 81.6 cents per ton for the period given, but was reduced to 76 cents for the last quarter.

Notable reductions in cost were made by Nevada Consolidated, due to improvements. Increased tonnage was responsible for lowering concentrating costs 15.9 cents per ton, or 25.72 per cent. The cost of roasting was reduced 8.3 cents, or 12.71 per cent. per ton of concentrate. By burning California oil instead of coal, the cost of reverberatory smelting was lowered 63 cents per ton of charge, or 24.31 per cent. The reverberatory charge was increased from 223.5 tons per day

to 359 tons. Basic-lined converters of the Peirce-Smith type are being installed and will gradually replace the old acid-lined converters, which, however, have been run for some time with a basic brick lining.

The sixth big porphyry producer will enter the field this year, viz., Inspiration Consolidated, in the Miami district, Arizona. Preliminary tests show the probability of saving 75 per cent. in a concentrator of 7500 tons daily capacity. If this is realized, Inspiration Consolidated may add 75,000,000 pounds of copper per annum to the already great flood of metal now pouring from the five plants before mentioned.

Steel Production in 1911.

The official statistics of steel production in the United States in 1911, as recently presented, are of considerable interest. The total (steel ingots and castings) was 23,675,501 gross tons, against 26,094,919 tons in 1910, which was the record, a decrease of 9.2 per cent. A curious feature is that in four of the past six years the production has been more than 23,000,000 tons and less than 24,000,000 tons, while in 1908 the production was only 14,023,247 tons, while in 1910 the production mounted to the 26,094,919 tons just mentioned. The average of the six years was 22,600,000 tons.

A feature of the steel statistics which strikes the casual observer quite forcibly is that, for the first time in history, the "production of steel" exceeded the "production of pig iron," the 1911 figures being 23,649,344 gross tons for pig iron and 23,675,501 gross tons for steel. Of course, every one knows that the production of steel as commonly reported is not the production of steel in commercial form. Omitting 1908 as an off year, the production of rolled steel, weighed as rails, skelp, forging billets, structural shapes, wire rods, black plates for tinning, etc., averaged in 1906, 1907, 1909 and 1910, 77 per cent. of the production of steel ingots, excluding castings. The 1911 production of steel embraced 23,029,479 tons of ingots and 646,022 tons of castings, and applying 77 per cent. to the ingot production we have 17,700,000 tons as the probable production of rolled steel, and even adding the production of steel castings we have a total of steel in commercial form much below the 23,649,344 tons of commercial pig iron produced. The loss of 23 per cent. from the ingot to the rolled form is due in small part to the production of scale, which usually goes back through the blast furnace, and in very large part to the production of steel scrap, which almost invariably goes into the open-hearth furnace, though occasionally into the Bessemer converter. Thus we have material which passes twice over the ingot scales, so that the "production of steel" is really the record of the ingot scales, plus the production of steel castings. The statistics may be misunderstood, but as presented they are strictly accurate, for the American Iron and Steel Association says that such and such a number of tons of "steel ingots" was produced. That is true; the ingot is produced when molten steel is poured into the ingot mold and allowed to solidify.

Hitherto the increment in the production of steel ingots and castings over the quantity of pig iron used therefor has been less than the amount of pig iron used for purposes other than steel making, such pig iron being used for the manufacture of iron castings and for puddling. In 1911 such appears not to have been the case, but probably it was, although to a less extent than formerly, for there is good reason to believe that a large tonnage of stocks existing at the beginning of the year were used during the year in iron foundries, so that the consumption in this branch of the iron industry was larger than the production. However, a general study of the statistics shows that the production of steel has been increasing more rapidly than the consumption of iron in foundries and iron puddling mills.

For but the second time in its history, the basic open-hearth steel industry lost ground, its output being 15,292,329 tons in 1910 and 14,685,932 tons in 1911. The other time was in the off-year 1908. In every other year a new tonnage record was made. From 1897 to 1910, thirteen years, the increase was from 1,056,043 tons to 15,292,329 tons. Relative to total steel produced, of course, basic open-hearth steel has gained every year, constituting 58.5 per cent. of the total in 1910 and 61.1 per cent. of the total in 1911.

Acid open-hearth steel has lost ground, both relatively and absolutely. The 1911 output was less than in eight past years, the earliest of those being 1901, which showed 1,037,316 tons, the 1911 production being 912,718 tons. The cause is obvious, for practically as good steel can be made in the basic open-hearth as in the acid, and from much cheaper raw materials.

The race of the processes for supremacy is now ended, and a resume may be of interest. In 1900 practically two-thirds of all the steel made was Bessemer. In 1908 the total open-hearth exceeded the Bessemer, but this was rather an empty honor, since the Bessemer production was much below its record. In 1909 not only did the total open-hearth production exceed the best production (in 1906) of the Bessemer process, but the basic open-hearth production alone did so, and now we have it that in 1911, 62 per cent of the steel was made by the basic open-hearth process and 66 per cent. by the acid and basic open-hearth combined, the Bessemer contribution being less than 34 per cent.

The crucible process has yielded in much the same manner as the acid open-hearth, the crucible steel production in 1911 being 97,653 tons, exceeded by ten previous years, the earliest of which was as long ago as 1899. The record crucible output was 131,234 tons, made in 1907, a year in which the total steel production was substantially the same as in 1911.

A comparison of basic pig iron and basic open-hearth steel production in the past two years shows how great has been the increase in the use of the new processes, which use little or no scrap. In 1910 the percentage of basic pig iron produced to basic open-hearth ingots and castings produced was 61.5 per cent., and in 1911, 59.5 per cent., an average of 60.5 per cent. Prior to 1905 the proportion was generally less than 50 per cent. The works which use cold pig iron probably use nearly, if not quite, as much scrap as formerly, but the works which use direct furnace metal get along with relatively small quantities of scrap. It should be noted that steel produced by the duplex process is simply classified as basic open-hearth steel. The open-hearth furnace has the last word, the Bessemer vessel being merely an adjunct, regarded as of no more importance in fixing the character of the steel than the mixer.

Iron and Steel Division of the American Institute of Mining Engineers.

The Council of the American Institute of Mining Engineers, at its meeting on April 26, established an Iron and Steel Division to represent the interests of the Institute in the mining and metallurgy of iron and steel; its business to be in charge of the following Committee, upon which shall rest the responsibility of securing papers and discussions on iron and steel for the meetings of the Institute:

Charles Kirchoff, Chairman; Charles F. Rand, Vice-Chairman; Bradley Stoughton, Secretary (165 Broadway, New York City); John Birkinbine, James Gayley, Henry D. Hibbard, Henry M. Howe, Robert W. Hunt, Julian Kennedy, Charles K. Leith, Richard Moldenke, Joseph W. Richards, F. W. C. Schniewind, Leonard Waldo, William R. Webster, Felix A. Vogel.

The Committee has met and formulated plans for carrying out its intention of securing papers and discussions dealing with all phases of the mining and metallurgy of the ferrous metals, and to such an extent as will make the American Institute of Mining Engineers the foremost iron and steel association in America, useful alike to the theoretical as well as the practical iron and steel man. The following subjects have been suggested: geology, mining and preparation of ores; concentrating, nodulizing, sintering and briquetting; manufacture of coke and other fuels; refractory materials; blast furnace, bessemer, open-hearth and electric-furnace practice; the duplex process; treatment, physics and chemistry of iron and steel, including metallography, and a campaign has already been started to secure papers and discussions on: alloy steels, heat treatment of steel, the duplex process, the thin-lined blast furnace, fuel gas for open-hearth furnaces, ore concentration, manufacture of pig iron, mechanical charging of blast furnaces, gas producers, charcoal iron, electric furnaces, recent improvements in open-hearth furnaces and practice.

The Committee will use its utmost endeavors to bring the papers presented on iron and steel to the attention of all members qualified to discuss them, and to stimulate a continuance of the discussion until all available data and information of interest have been secured for the *Transactions of the Institute.*

The Present Status in the Propaganda for a Change in the Patent Law.

There is now a decided activity—almost too much of it and tending in too many different directions—to procure a practical result so much to be desired in the propaganda for a change in the patent law to which we have referred repeatedly in our last issues.

On April 15th and 16th a joint meeting of the representatives of various national societies of engineers and lawyers was held in Washington, D. C. The following societies were represented: American Electrochemical Society, The American Institute of Electrical Engineers, The American Institute of Mining Engineers, The American Society of Mechanical Engineers, The Chemists Club of New York, The American Institute of Chemical Engineers, The Inventors' Guild, The Patent Law Associations of Washington and Chicago, and The New York County Lawyers Association. There was a long discussion in which the legal element predominated. The only outcome of this meeting was a petition to Congress to defer action on the patent bills now before it and the recommendation for further conferences of delegates from the bodies represented at that conference and from similar bodies which shall be invited to participate.

Since then the most important development has probably been a message from the President of the United States to Congress which emphasizes the fact that, "the present laws of the United States were enacted in practically their present condition in 1870, before the development of the industrial conditions which obtain to-day." Various criticisms of the present patent law which have been raised by different parties, are briefly reviewed.

The message concludes as follows: "Great care should be taken in any revision of the statutes relating to patents and patent rights not unduly to interfere with vested interests which have been properly created under the existing laws, or to impair the efficiency of a system from which so much benefit has been derived by the country. I am of the opinion that a careful study of the patent laws should be made by a commission of qualified persons appointed for that purpose with instructions to report such revision of those laws as may be necessary to harmonize them with the best thought and needs of our time; and I therefore recommend the enactment of a statute authorizing the President to appoint a commission to investigate the present state of the patent law and to report what, if any, changes or amendments should be made to conform that law with modern conditions and acquirements." The message of the President was referred to the Committee of Patents.

New bills on patent law have been introduced in Congress and the interesting hearings on the original Oldfield bill have been continued. When they are completed we intend to give a concise analysis of the arguments brought forward by the different parties at these hearings.

Among the distinguished engineers who testified at the hearings were Mr. H. Ward Leonard and Dr. L. H. Baekeland.

The Right of Employer and Employee in Questions of Priority

Last year (our Vol. IX, page 457, September, 1911) we gave an account of a decision in a U. S. Patent interference case between Mr. D. E. Parker and Mr. G. F. Brindley which went deeply into the legal right of employer and employee in questions of priority of invention.

The decision was in favor of G. F. Brindley, to whom the priority of invention was awarded. He figured in the case as the junior party and as Mr. Parker's employer (as the representative of the Niagara Electro Chemical Co., or the Roessler & Hasslacher Chemical Co.).

The case was appealed, but on appeal the examiners in chief of the U. S. Patent Office have now confirmed the former decision in sweeping fashion.

The decision, which is signed by Messrs. T. G. Steward, Frank C. Skinner and Fairfax Bayard, as examiners-in-chief, is herewith given almost in full:

"This is an appeal by the senior party and patentee, Parker, from a decision of the examiner of interferences awarding priority of invention to the junior party, Brindley." . . .

"The question is one of originality, for both parties are claiming the same embodiment of the invention as their reduction to practice. The invention was embodied in practical form during the month of May, 1905. Parker filed his application on May 18, 1906, and obtained a patent, No. 909,017, on January 5, 1909. Brindley filed about a month later than the date of this patent to Parker, or on February 17, 1909. Parker claims that he, and not Brindley, conceived of the main plan of the invention and that his disclosure to Brindley eventuated in the aforesaid embodiment of the invention.

"At the time the invention in controversy was brought into being, Brindley was the works manager and Parker was the machine-shop foreman of the Niagara Electro-Chemical Company. Brindley's period of service with this company extended from August, 1895, when the company was organized, until May 1, 1906. Parker entered the employ of the company on March 28, 1904, and remained the machine-shop foreman until November 16, 1905.

"Although it was during the period of Parker's employment that the invention was reduced to practice, it is con-

tended, on behalf of Brindley, that certain things which were done prior to the date of Parker's employment constituted material steps in the evolution of the invention. Parker, in his capacity of foreman, superintended the actual construction of the apparatus in which the invention was embodied, but the fact of this supervision is of little weight in the determination of the controversy, since, whether Parker was the originator of the invention or not, Parker would, in any event, have carried into effect the plan which the company adopted.

"Brindley and Parker undoubtedly stood in the relationship of employer and employee, for Parker was subordinate to Brindley and being so was bound to carry into effect any orders given him by Brindley.

"It will be observed that, as above indicated, Parker obtained a patent before Brindley filed his application and that the date of Brindley's application was upwards of four years later than the date of the reduction to practice, which occurred in May, 1905, and upwards of three years later than the date (May 18, 1906) of Parker's application.

"Although, under ordinary conditions the fact that the senior party to an interference has obtained an antecedent patent places upon the junior party a heavy burden of proof, yet it would seem to be true that in a case like the one at bar, in which a question as to the origin of the invention is to be determined, a conclusion that the junior party is the only one of the two interferants who is an inventor at all, may be reached without giving any especial weight to the fact that the junior party filed a belated application.

"In the present case, the fact that Brindley and Parker, respectively, bore the relation of employer and employee, is sufficient, we believe, to offset any presumption of originality that may be deduced from the fact that Parker is a patentee. But whether or not this is true in the broad sense, there is no reason to doubt the soundness of the proposition if coupled with the qualification that, as in the present case, the employer was the first to seek the desired result, as well as the first to devise and experiment with means to the end, which, in some form, appeared in the final embodiment of the invention. It is admitted by Parker that Brindley contributed certain of the ideas which resulted in the reduction to practice, but these ideas, it is claimed, involved nothing new and patentable and, therefore, are to be disregarded.

"We are not, in this controversy, dealing with the individual elements of the combinations expressed in the various counts of the issue, but are considering combinations which, while made up of a number of elements, are entities which, for the purpose of the interference, cannot be separated into their constituent elements." . . .

"As we have already intimated, the employer, Brindley, will be presumed to have made the invention if he had in view the object sought to be obtained thereby, as well as means corresponding in a general way to that which was eventually found to be adequate for the purpose.

"The invention in controversy had its origin in the desire to produce and market fused peroxide of sodium, to which the Niagara Electro Chemical Company has applied the term "oxone." The Oxylithe Company of France had been marketing a preparation called "oxylithe," which consisted of compressed peroxide of sodium. The "oxone," or fused peroxide of sodium, was to be manufactured as a competitor of this "oxylithe" and, hence, the officers of the Niagara Electro Chemical Company were anxious to produce it on a commercial scale. The first experiments were made at Perth Amboy, New Jersey, by one Philipp, a research chemist of the Roessler & Hasslacher Chemical Company. Philipp's first report is dated January 16, 1904, and this, as will be observed, is prior to any date claimed by Parker for conception, and prior to the date, March 28, 1904, when Parker entered the employ of the Niagara Electro Chemical Company. It is satisfactorily established by the record that the term "oxone" was for the first time used in a letter addressed to Brindley on March 9, 1904, and so, it appears, that prior to the time when Parker became associated with Brindley the desired product was not only given a name, but that experiments were begun for its practical production.

"We do not deem it important to review herein the history of the various experiments that were conducted during the course of aforesaid experimentation, for the details of the various apparatus that were used during this period are fully set forth in the decision of the examiner of interferences, and in the briefs of the respective parties.

"In our view of the case, since it is clear that Brindley first devised or used means corresponding to some of the elements of the issue, while seeking to attain the desired end, which was the production of "oxone," and Brindley was Parker's employer, such contributions as may have emanated from Parker must be regarded as being merely ancillary to the main plan of the invention. We consider this to be the law, even if the apparatus first used by Brindley did not comprehend the whole invention, for we are determining whether it was the contributions of Brindley or those of Parker, neither of which involved the entire structure of the counts of the issue, that led to the production of that combination. Brindley was the first to seek the result, the first to initiate the experiments, and the first to direct attention to certain elements which eventually became features of the new and patentable combination in which each of those elements, by being merged into that combination, became possessed of a new attribute.

"In these cases of originality between employer and employee, the presumption is rightfully in favor of the employer who is by experimentation seeking to attain a particular result, the reason for the presumption being due to the confidential and close relationship of the parties which renders it difficult to later determine to what extent the thoughts of the employer may have been impressed upon the employee's mind. The employee may honestly believe that a vital suggestion originated with him, when, as a matter of fact, the idea originated with the employer and had been revealed unconsciously in some forgotten conversation.

"The following cases are in point: Milton vs. Kingsley, 75 O. G., 2193, 7 App. D. C., 531; Miller vs. Kelley, 96 O. G., 1039, 18 App. D. C., 163; Gedge vs. Cromwell, 98 O. G., 1486, 19 App. D. C., 192; Gallagher vs. Hastings, 103 O. G., 1165, 21 App. D. C.; Kreag vs. Geen, 127 O. G., 1581, 28 App. D. C., 437; Larkin vs. Richardson, 127 O. G., 2394, 28 App. D. C., 471.

"We, furthermore, think that Brindley, the employer, ought to prevail, notwithstanding his delay in applying for a patent, for the record shows that he promptly filed his application after the patent to Parker was issued.

"A ground of appeal is that the examiner of interferences erred in not making a recommendation concerning public use of the invention for more than two years prior to the date of Brindley's application. This is not an appealable question, and the appeal is dismissed as to this ground. Also, we decline to make a recommendation as to public use, since there appears to be no evidence satisfactorily showing that the use of the invention was public, although it is shown that the product was sold.

"The decision of the examiner of interferences awarding priority to George F. Brindley, the junior party, is affirmed."

The Western Metallurgical Field

Unwatering Leadville Mines.

Progress is being made in the project to unwater the mines in the Fryer Hill district, at Leadville, Colorado. In September, 1911, it was proposed to organize a company to install suitable pumping machinery to unwater a mining area which is now under water, but which is known to contain bodies of valuable ore. The plan was mutual in its proposed benefits, for the pumping company was to receive only a small royalty on ore actually extracted and treated as a result of the unwatering of the mines. In January, 1912, a communication was

sent to the owners of the property in Fryer Hill notifying them of the proposition, and asking their support. This elicited such a general commendation of the scheme that further steps were taken to draw a suitable contract, binding the pumping company to install a pumping plant, and requiring the owners of the property to work their mines after the same were unwatered. These contracts were sent to the mine owners last month.

Inasmuch as the success of the project depends on almost unanimous co-operation of property owners, this feature has had to be considered in drawing the contracts. The following provisions are among the more important: If the owners of 95 per cent of the acreage in the district shall execute the contracts on or before the first day of August, 1912, the pumping company agrees to erect and place in operation on or before the first day of April, 1913, pumping equipment having a capacity of not less than 1000 gallons per minute. This equipment will be placed at the most advantageous point, perhaps at the El Paso shaft, and the pumping shall continue until the district shall have been unwatered to a level of a horizontal plane passing through the bottom of the El Paso, which is the deepest shaft in the district. Within thirty days from the time any property shall have been unwatered the owners shall begin work with five men for each 10 1/3 acres owned, and shall operate their mines so as to take out the greatest amount of ore practicable. If work is not so begun by the owners within thirty days of unwatering, the pumping company automatically secures a lease on the ground and may sub-lease it; but if the pumping company is unsuccessful in securing sub-leasers within ninety days, the property shall revert to the owners. From these provisions it will be seen that the success of the scheme depends on the activity of the mine owners, for if they do not work their mines the pumping project fails. The pumping company can be successful only in the event of continuous and successful mining. The district will either be a scene of great activity, or remain in its present dormant state.

The schedule of royalties decided upon is as follows:

Value of Ore per Ton	Royalty
Up to $5.00	5%
$5.00 to $7.50	6%
$7.50 to $10.00	7%
$10.00 to $12.50	8%
$12.50 to $15.00	9%
Over $15.00	10%

Several contracts have been signed, and the work of sending out the balance has proceeded as rapidly as the magnitude of the project would permit. It is hoped and expected that the idea will meet with approval, and that Leadville will experience a great revival as a result of this endeavor.

Vanadium and Uranium in Colorado and Utah.

Southwestern Colorado and southeastern Utah form the principal vanadium and uranium field on the North American continent. Owing to the isolation of this region and the desultory nature of the actual mining work which has been carried on by a number of small operators, it has been difficult to arrive at any exact idea of the magnitude of the industry. General information and unreliable rumor have credited the field with greater resources, production and profit than actually exist. As a consequence, the annual report of the Colorado Commissioner of Mines for 1911 is a welcome document, for it endeavors to give some sound facts concerning this part of the metallurgical field.

As stated in our issue for October, 1911, page 482, the only metallurgical plant in this district is that of the Primos Chemical Co., at Newmire, Colo. Here vanadiferous sandstone is treated at the rate of about 30 tons per day, producing iron vanadate which is shipped to Primos, Pa., for further treatment. Recently it has been announced that the Colorado Vanadium Co. has secured the old National mill at Sawpit, near Newmire, Colo., and will remodel it for the treatment of vanadium ore. It is also known that the Vanadium Ore M. & M. Co., of Grand Junction, Colo., contemplates the erection of a plant at Grand Junction for the treatment of carnotite ores which the company owns in the Utah part of the field.

For the most part, however, the production of vanadium and uranium ore is shipped from Colorado and Utah to Pennsylvania and to Liverpool, England. The Colorado shipments from Placerville during 1911 amounted to 1515 tons of vanadium ore mined in Montrose county. The ore averaged 3.5 per cent metallic vanadium, and the average price paid f. o. b. cars at Placerville was $70 per ton.

Not enough development has been done to determine the extent of the ore bodies, and practically all the ore mined thus far has been taken from lenses in sandstone strata which are exposed on one or two sides. The cost of mining is considerable, while the cost of exploration is still greater on account of the irregular thickness of the ore lenses.

Pittsburg-Silver Peak, Nevada.

The litigation in which the Pittsburg-Silver Peak property at Blair, Nevada, has been involved for about 12 years, seems in a fair way to be settled. The company received a favorable decision at the hands of the United States Court of Appeals in San Francisco over a year ago, but the case has been in the hands of the Nevada Supreme Court since that time. It is expected, however, that a decision will soon be rendered by the latter court, and since it is improbable that the case will be carried further, a favorable decision now is expected to end litigation.

The company is making a good record for low cost of operation and production, a late report placing total operating costs at $2.70 per ton, which is exceeded by but few low-grade properties. The mill, in which recovery is made by amalgamation and cyanidation, is being equipped with a tube mill for regrinding coarse sand, and it is expected that this addition will reduce the time of cyanide treatment and increase recovery by about 1 per cent. The mill contains 120 stamps and is treating more than 500 tons per day, with a recovery of between 90 and 91 per cent. One tube will be tested on one unit of thirty stamps before the entire regrinding equipment is placed.

Mayday-Idaho Suit, Colorado.

The Mayday mine in the La Plata mountains, southwestern Colorado, has been a producer of wonderfully rich smelting ore since about 1904. Shortly after its development by A. E. Reynolds, of Denver, considerable attention was attracted to the district, with the result that the Idaho mine was developed by W. A. Stewart, of Cripple Creek, into a similarly rich producer of gold. Both mines continued to produce until December, 1910, when a suit was filed in the United States court by Reynolds, alleging that, owing to a faulty survey of a section line, he was entitled to considerable ground then claimed by the Idaho company. As both mines had proved good producers, the suit was contested and brought to a decision on April 22, 1912. The decision is favorable to Reynolds and the Mayday company, but an appeal will undoubtedly be taken to the United States Supreme Court. In the meantime the Colorado smelters are deprived of shipments of rich smelting ore, and the American Smelting & Refining Co. holds $85,000, representing the net return from the last shipment made by the Idaho company prior to the filing of the suit. The disposition of this money will depend on the final decision in the case.

Company Reports.

The tenth annual report (1911) of the *United States Reduction and Refining Co.*, Colorado Springs, Colo., is not designed to inspire the stockholders with encouragement or hope for future profit from the company's operations. The Standard chlorination plant at Colorado City was closed at the end of the last fiscal year, and existing ore contracts turned over

to the Golden Cycle company. The smelter at Canon City is still idle, although a lease was granted to parties who intend, if possible, to re-treat the old slag dump for its zinc content. The only remaining activity of the company consists in the tailings cyanide plant at Florence, Colo., where the old dump of the Union chlorination mill is being re-treated by cyanidation. Even this plant is not proving satisfactory, and it is considered doubtful whether more than the plant investment and interest will be obtained from operations. The tailings plant was originally designed to treat by continuous decantation, but so much difficulty was encountered from various causes that the continuous decantation scheme has been abandoned, and the plant is run on straight sand-leaching principles. About 800 tons per day are being treated, and operations probably will cease by fall.

The seventh annual report of the *Nipissing Mines Co.*, Cobalt, Canada, for the year 1911, contains some interesting metallurgical information. A new mill for the treatment of first grade ore was started February 1, 1911, and is now treating the entire product of the mine. The process, which was devised by Mr. Charles Butters, consists in amalgamation in cyanide solution in a tube mill, where more than 97 per cent of the silver in the ore is recovered as amalgam. The residue then undergoes the regular cyanide treatment whereby an additional extraction is made. A refinery has been erected, and the entire product of the mill is shipped as fine silver. The cost of the mill and refinery was $57,122, and the first year's operation has shown a substantial profit compared with shipping the ore to a smelter.

Careful experiments on low-grade dump ore run through the high-grade mill indicate that a good extraction can be made on the dump material by the amalgamation and cyanidation treatment, and that the net returns will exceed those obtained by the usual concentration methods. Consequently a mill to treat 200 tons per day is now in course of erection and will be started before the end of the present year. All ore will be transported to the mill by tramways, where the first-class ore will be removed, and the fine stuff treated in the jigs. The ore resulting from these operations will be sent to the high-grade mill for treatment. The balance will be crushed in cyanide solution by 40 stamps of 1500 lbs. each, pass through tube mills, amalgamated if found desirable, agitated and sent to a Butters filter. Precipitation will be by zinc dust, collecting the precipitate in a Merrill filter. The precipitate will be refined in the high-grade mill.

The Iron and Steel Market.

Market developments in the iron and steel trade in May were not of striking importance, there being simply a continuance of the strong condition established in April. Specifications against old contracts for finished steel products were heavy, and almost uniformly in excess of current output, so that the mills closed the month with more actual business upon books than at the opening of the month. Strictly new buying decreased, but this was to be expected in the circumstances of buyers generally being well contracted, in an advancing market.

The steel industry is operating now at almost full capacity. Many plants are operating at absolutely full capacity, but the showing as a whole is pulled down by the fact that in a few lines, particularly wire and pipe, demand is not sufficient to engage the full capacity. The production in steel is easily the heaviest on record, passing the previous high rate attained in the early months of 1910. Pig iron production, however, is materially below the record, as the merchant furnaces are operating at only about two-thirds their greatest previous rate. The country is making pig iron at the rate of between 29,000,000 and 30,000,000 tons annually, the best previous record having been about 31,600,000 tons, in February, 1910, while the production from October 1, 1909, to April 1, 1910, was at the average rate of 31,000,000 tons. An increase in the merchant furnace rate is to be expected, and would probably have occurred before this had it not been that coke has reached a very high level and idle furnaces going into blast must as a rule contract at the high level, while the operating furnaces as a rule have old contracts made at much below the present level. A number of these contracts expire June 30th. To justify paying the higher prices current the blast furnaces require higher prices for pig iron, but the advancing tendency is not very marked and the experience of an actual scarcity may be required to adjust matters.

Railroad buying was relatively heavy in May. Several railroads purchased rails when their purchases made last winter had been assumed as sufficient to carry them through the season. Orders were placed in May for about 30,000 cars, against orders for only 40,000 cars during the preceding four months of the year, and the car shops enter June with more business on books than on January 1st, though at that time they were very well supplied through the burst of buying which occurred in the closing three months of last year.

New buying in steel products, outside, perhaps, of that involved in railroad material, is likely to be relatively light during the next few months, but the mills are so well filled with business that full operations for several months can be predicted with confidence.

Pig Iron.

There has been steady buying in most districts, though not for delivery far ahead. Southern iron has experienced a sharp advance since last report, on relatively light sales. Quotations are now as follows: No. 2 foundry iron, Birmingham, $11 to $11.50; delivered Philadelphia, $15.25; f. o. b. valley furnaces, $13.25; f. o. b. Chicago district furnaces, $14.50; Bessemer, valley, $14.25; basic, valley, $13 to $13.25. Ferromanganese has been advanced $2.50 and the regular price for second half contracts is now $48.50, Baltimore, while small lots for prompt shipment have been bringing from $50 to $60.

Steel.

The mills are well sold up on billets and sheet bars and are practically out of the market. Consumers are well covered by contracts, but are not getting entirely satisfactory deliveries. Quotable prices, which are largely nominal, are: Billets, $20.50 to $21, and sheet bars, $21 to $21.50, f. o. b. maker's mill, Pittsburgh; billets, $20 to $20.50, and sheet bars, $20.50 to $21, f. o. b. maker's mill, Youngstown. Wire rods are $25 to $26, Pittsburgh.

Finished Steel.

Prices have shown no important change since last report. The American Sheet & Tin Plate Company on May 17th advanced its prices on all coated tin mill products by advancing its minimum on tin plate from $3.40 to $3.50. On May 21 the National Tube Company reduced its discount on steel boiler tubes one point, making an advance equivalent to about $2 a ton. The new card discount on 3½ to 4½ inch is 74 per cent., beyond which two extra fives are customarily given on large orders.

Current prices, f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.25 cents.

Shapes, 1.25 cents.

Steel bars, 1.20 cents.

Iron bars, 1.25 cents, Pittsburgh; 1.30 cents, Philadelphia; 1.20 cents, Chicago.

Sheets, blue annealed, 10 gage, 1.40 cents; black, 28 gage, 1.90 to 1.95 cents; galvanized, 28 gage, 2.95 to 3 cents.

Tin plates, $3.40 to $3.50 for 100-pound cokes.

The Non-Ferrous Metal Market.

Since our last report the non-ferrous metals have practically held the positions given at that time. Considerable activity has been noted in tin which is in an excellent statistical position. Lead has been the dullest of the metals, while the business in copper and spelter has not been unusual.

Copper.—Owing to the business transacted by second hands who had secured copper on speculation, the largest sellers have not done a large volume of business. European demand has been very light, and domestic consumption comparatively small. Prices are held up, however, and the last reports are, for Lake, 15¾ to 16 cents, and for electrolytic, 15.55 to 15.65 cents.

Lead.—Business has been unusually dull, but the A. S. & R Co. has maintained its prices at 4.20 cents, New York. Business has been transacted by other sellers at 4.15 cents. St. Louis market ranges from 4.02½ to 4.05 cents.

Tin.—The excellent demand for this metal has given it an unusually good position which probably will be held. Prices have gone as high as 46⅜ cents, New York, for May tin, but at the last report this had fallen off to 45⅞ cents. Higher prices may prevail.

Spelter.—Both buyers and sellers seem to have been content to transact little business, as the former were well supplied and the latter were not disposed to press sales. Later in the month some producers did cut prices and made sales at varying prices for future deliveries. The last quotations are 6.50 to 6.60 cents, New York, and 6.35 to 6.45 cents, St. Louis.

Other Metals.—Domestic producers of aluminium have raised their prices to meet those of Europe, and the prevailing price is 21 to 22 cents, New York. Business in antimony has been moderate, and prices are quoted at 6⅞ to 8⅛ cents for various brands. Quicksilver is steady at $41.50 to $42, New York, and $41.50, San Francisco, for flasks of 75.

CORRESPONDENCE.

The Introduction of the Tube Mill into Metallurgy.

To the Editor of Metallurgical and Chemical Engineering:

SIR:—On page 266 of your May issue is an abstract of a paper read before the Canadian Mining Institute by Mr. Henry Hanson, in which credit is given to Dr. Ludwig Diehl for the first introduction of the tube mill in metallurgy.

I am confident that this is an error. The tube mill is an American invention and was first used for the fine grinding of ores in 1894, in the Moulton mill, Butte, Montana, owned by former Senator W. A. Clark.

New York City. R. F. ABBÉ.

What is Steel?

To the Editor of Metallurgical and Chemical Engineering:

Sir:—Prof. J. W. Richards' definition of steel, "all varieties of usefully malleable iron" in your May number, page 266, is interesting to me because it is the first part of that which I proposed in 1908 and communicated to the American Institute of Mining Engineers, which was, "Steel is a variety of iron which at some temperature is malleable to a useful degree; it is made by a fusion-process, or when not so made is capable of being hardened to a useful degree." The distinction made that the malleability was useful, was, I believe, novel.

His definition can hardly be accepted, however, because of violence it does to established usage at each of its extremes. Wrought iron is entitled to its name and will keep it. At the other end of the line are Cocker steel plates used for wire-drawing, which are claimed to contain sometimes 2½ per cent of carbon or more, while some cast irons contain less. This prevents 2.2 per cent being proper for the upper limit of steel.

The need for scientific names for iron products, including those now called steel which will fit into the scientific classification of iron and steel, is felt and acknowledged by all who have given the matter much thought. Instead, however, of extending or abridging the current meanings of the term steel, would it not be better in order to avoid adding to the confusion now existing, that new scientific names be coined to designate different species, such as (1) usefully malleable iron, and (2) fused usefully malleable iron, and others? Such names might in time get into common use, the chance for which would be increased if they were short.

Prof. Richards calls it a false principle of classification to use the method of manufacture as a basis. Abstractly speaking this is true when the same product may be made by different methods, but when the product itself shows how it was made, as in this case, it may be permissible and more convenient to say that it was welded (wrought) or fused, than to describe it by the characteristics which welding or melting gives.

Plainfield, N. J. HENRY D. HIBBARD.

* * *

To the Editor of Metallurgical and Chemical Engineering:

SIR:—Mr. Hibbard misses much of the point of my article "Steel." We both both know and agree upon what *is* steel, we agree upon the facts, as they exist in the present arbitrary and illogical use of the term; there is no need of disputing that point.

What is needed is a resolution to use the grand, old, historic term in a consistent, logical, scientific way, and this can be done by the simple expedient of making *useful malleability* the *one* decisive characteristic of steel, distinguishing it from cast-iron. Under this proposed classification, wrought iron can keep its name, no one wants to take it away, but logically its malleability should class it as a variety of the broad class "steel." If "Cocker steel plates" used for wire-drawing, at the other extreme, are not usefully malleable (as I suspect is the fact), they are cast-iron, and not steel.

My proposition regarding the content 2.2 per cent. of carbon, was to use it only as a *supplementary* criterion, in case doubt existed as to whether the material was usefully malleable or not. I believe that a material with 2½ per cent. carbon should be called steel, *if it is usefully malleable;* and a material with 2 per cent. carbon should be called cast-iron if it is under no conditions usefully malleable.

My only object in proposing to broaden the term "steel" so as to include wrought iron within it as a variety, is to get theory and practice to agree upon a meaning of the term which is both logical and practical, acceptacle alike to science and industry. Mr. Hibbard says in effect: Word the definition to correspond to present usage, and let it go at that. But that does not remedy anything, it does not improve matters one jot or tittle: as well try to reform a man by enumerating his bad habits—and stop there. What is wanted is some modification of the meaning to be attached to the term "steel," such as will end the inconsistencies of present usage and put the nomenclature on a logical, orderly and scientific basis.

We neeed to look forward a little, to lay straight foundations for future building. The term "steel" has changed its meaning within the last fifty years, from a reasonably definite meaning to a hybrid usage which, from the standpoint of a scientific classification is "neither fish, fowl nor good red herring." We agree that it cannot be forced back to its former limited but definite meaning. What shall we do? Stand forever deploring the unfortunate facts: or shall we, like master builders, find a simple way of straightening out the situation, grasp it, and on that basis reconstruct a classification that needs no apologist? If we can, by the one simple change I have proposed, achieve this much-desired rationalization of the term "steel," is it not worth doing? We should do it, for the sake of correcting present inconsistencies and of avoiding others that may easily and will surely arise unless some such step is taken. J. W. RICHARDS.

Lehigh University, South Bethlehem, Pa.

The Installation and Use of Pyrometers in Steel Mills.

Equipment and Methods of Control at Illinois Steel Co.'s Works.

BY C. S. GORDON.

The first practical pyrometer was devised in 1782 by Wedgewood, an English potter, for use in operating his kilns. He depended upon the contraction of clay at high temperatures for his measurements.

In the ceramic industry Seger cones having various degrees of fusibility are used. These cones have a tendency to curl over when certain temperatures are reached, but, of course, are valueless to show whether the temperature has fallen.

Fusion-point pyrometers have been used, making use of the known melting points of different metals and other substances. These were the first to enter into the manufacture of steel, the temperature of the blast furnace blast being measured by holding a rod of metal or other substance with a known melting point at a place where the blast would strike it. For instance, if a rod of pure silver would just melt, the temperature of the blast was known to be about 954° C.

The next class of pyrometer to enter into the manufacture of steel was the thermo-electric pyrometer, which is still being used for medium high temperatures (500 to 2500° F.), while for exceedingly high temperatures (2500 to 6000° F.) the radiating and optical pyrometers are being used.

The manufacturers of steel are to-day the most extensive users of the pyrometer for the measurement of high temperatures. In some instances the employment of pyrometers has advanced to such a degree that it has been necessary to employ a pyrometer expert and to establish a laboratory for the express purpose of repairing and standardizing the many instruments of the company.

The South Works of the Illinois Steel Company were the first to establish such a laboratory. This laboratory has been in operation since June 5, 1911, and is located in the main laboratory building of the South Works, South Chicago, Illinois. The benefits of the laboratory and of the knowledge of the man in charge have been extended to the several other plants of the corporation in the near vicinity, including the Gary Works, at Gary, Indiana; the Buffington plant of the Universal Portland Cement Company at Buffington, Indiana; the Joliet Works, at Joliet, Illinois, and the Milwaukee Works, at Milwaukee, Wisconsin.

This has resulted in a great saving of time and expense for the different plants, because through this section of the country there are no manufacturers of pyrometers, which would necessitate the shipment of all repairs to the Eastern cities.

The pyrometer is a very delicate instrument, and consequently should be handled with great care. In most cases the operator of a pyrometer does not realize the delicacy of the instrument, and, therefore, handles it as he would handle a more massive instrument. Then he wonders why he did not get results, or why the instrument is out of calibration, or why the thermo-couple is broken. The chances are ten to one that the instrument has not been properly handled; sometimes it is due to carelessness, but more often to ignorance.

The fact that an instrument is out of calibration may be unknown to the workman. He turns his readings over to the superintendent, who in turn figures out results which are incorrect. The superintendent may have seen the reading taken, which would make him positive that his results were correct.

Such an example came to the writer's notice only a few days ago. In one of the boiler rooms a pyrometer was being used for over a month for taking temperatures in the fire box of a gas-fired boiler and another pyrometer was being used to take the stack temperatures. Results showed a very high heat efficiency. The writer had occasion to use the instrument which was being used under the boiler, and was surprised, on checking, to find its reading to be over 260° F. low at the point where it had been used in the previous tests, while a check of the pyrometer in the stack showed it to be reading correctly.

In the use of the thermo-electric pyrometer there are two sources of error which only about one operator out of ten can correct or even understand, and in many cases these errors may be as much as 250° F.

First, the error due to the cold-end temperature of the thermo-couple. In most cases the pyrometer is calibrated with a cold-end temperature of 77° F. (25° C.), which is considered the average inside atmospheric temperature. The millivoltage generated depends on the difference of temperature between the cold end and hot end or junction of the thermo-couple. Consequently, should the cold-end of the thermo-couple be at a higher temperature than that at which it was calibrated, the pyrometer readings will be low an amount equal to from 1 to 1/3 of the amount above the temperature at which the thermo-couple was calibrated, depending upon the alloys used for elements of the couple. This error may be corrected by changing the zero setting of the instrument or by adding the correction to the temperature readings.

Second, there is an error due to the temperature coefficient of resistance of the pyrometer. The thermo-electric pyrometer is nothing more than a low-resistance millivoltmeter. The resistance of the coil increases with rise in temperature, which reduces the amount of current flowing through the instrument, and this in turn reduces the temperature reading. This error averages from two to three per cent. for every ten degrees centigrade rise in the temperature of the meter movement.

The location of a pyrometer is a very important factor in obtaining correct results. It is important that the pyrometer be installed where the workmen can read the temperatures. This necessitates the installing of the instrument near the furnace or source of heat, which may mean in a building where the atmospheric temperature is very high. Under these conditions it is necessary to determine the temperature of the cold end of the thermo-couple and also the temperature of the instrument to obtain correct results.

In some instances the writer has seen pyrometers installed where, if the wind was from a certain direction, the instrument and the cold end of the thermo-couple would be at the same temperature as the outside atmospheric temperature. If it was a moderately warm day the results would be correct or nearly so, while if it was a very cold day the results would be from 75 to 100° F. high. Should the wind change to another direction the pyrometer and cold-end temperature of the thermo-couple would be heated by the warm air radiated from the several furnaces, bringing the temperature of the pyrometer and cold end of the thermo-couple to 150° F., which caused the results to be from 100° to 150° F. low.

It is such errors as the above mentioned that the large companies wish to reduce to a minimum. In the heat treatment of a large roll for steel mill work or in the heat treatment of a carbon-steel tool, 100° F. is an exceedingly large error. It is an error which might cost a company several hundred dollars.

The pyrometer expert of the Illinois Steel Company makes inspections of the different installations throughout the plants at least once every two weeks, instructing the operators of the instruments in their use and determining the correction factors. In some cases the location of the instrument has been changed in order that the correction factor might be more constant. Where the temperature of the meter or cold-end of the thermo-couple is exceedingly high or is variable through a wide range of temperature a water jacket is used. If several thermo-couples are used with one meter, the average cold-end temperatures are determined and the zero setting

of the instrument is adjusted to this temperature, making the meter reading as nearly correct as possible.

At the time of inspection the permanent installations are checked against a standard portable indicating instrument which is standardized before leaving the laboratory and again checked after being returned to the laboratory. With this system the different departments know that when they have a set of temperature readings they are correct.

Types, Makes and Uses of Pyrometers in Different Departments.

In the South Works of the Illinois Steel Company there are 46 thermo-electric pyrometers used by the **blast-furnace department** alone. Forty-four of these are Bristol combination sets and two are portable indicating instruments used for checking the combination sets. One of these is a Bristol instrument with a scale range of 1600° F., the other is a Brown instrument with a scale of 3300° F.

The Bristol combination set consists of a smoked-chart recording instrument and a Bristol switch-board-design indicating instrument connected through a switch-box to one thermo-couple. The switch-box contains a double-pole, double-throw knife switch for each instrument. To the center of these switches are connected the thermo-couple leads. A resistance coil is connected across one side of the double-pole double-throw switch, exactly equal to the resistance of the instrument connected to the opposite side. The purpose of this resistance is to compensate for the resistance of the circuit should the operator wish to cut out one meter or should it become defective. By reversing the switch the meter remaining in the circuit will register correctly.

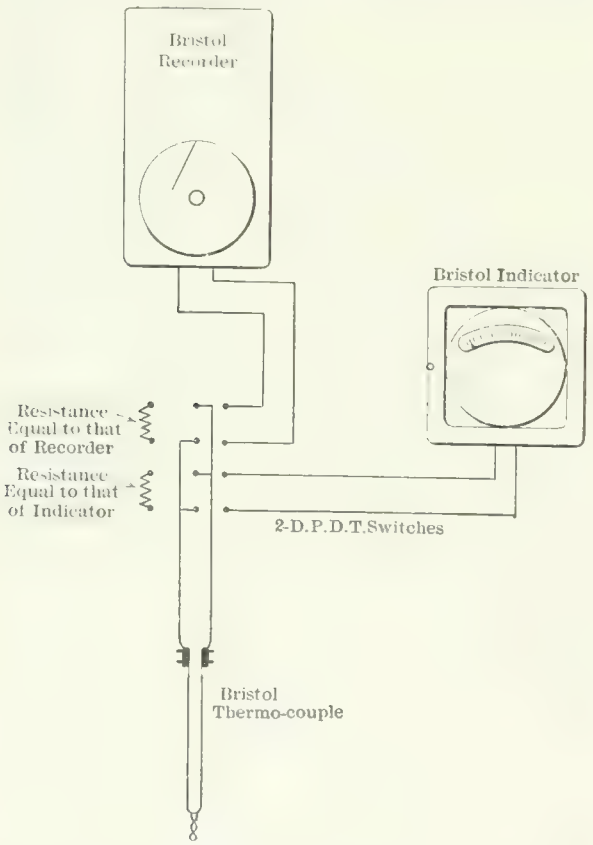

FIG. 1.—COMBINATION SET.

The distance of the thermo-couple to the switch-box in some cases is as much as 200 feet, and that from the switch-box to the recording instrument 695 feet, and from the switch-box to the indicating instrument 220 feet. This makes a total length of lead from the thermo-couple to the recording instrument of 895 feet and from the thermo-couple to the indicating instrument of 420 feet.

The No. 12 flexible, rubber-covered duplex leads are all installed in wrought-iron pipe to protect them from fire and mechanical injury.

In the blast-furnace department the pyrometers are used for two purposes. First, for the measurement of the hot-blast temperatures, which range between the temperatures of 800° and 1200° F. The maximum average practice is 1150° F. and minimum average practice 850°F. In the installation of these pyrometers the thermo-couples are installed from the top of the blast-pipe and are protected by the use of a nickel protecting tube. The location is in the pipe between the hot-blast main and the furnace bustle pipe.

From this location of the thermo-couple the lead extends to a small brick building, known as the pyrometer house, located near the furnace stoves. In this building is located the switch-box containing the two double-pole double-throw switches. At the side of the switch-box is a dust-proof box containing the indicating pyrometer, which is for the use of the stove tender. A blackboard is placed near this instrument and every hour the temperature is tabulated. This is done in order that the superintendent or foreman may have a means of checking the temperatures read on the indicating instrument against those tabulated by the recording instrument which is located in the main blast-furnace office.

All the recording instruments are placed in a consecutive order on a large switch-board located in the main office, where the superintendent may at all times tell at what temperature the blast is being blown to the furnace.

Secondly, pyrometers are employed in the blast-furnace department for the measurement of the temperature of the top gas. Top gas is the name applied to the gas generated in the furnace. This gas is brought down into large chambers, known as dust catchers. The dust settles to the bottom of these chambers, where it is drawn out from time to time while the gas is piped off through large mains for use in the engine and boiler rooms. The pyrometer thermo-couple is located near the top of this chamber or dust catcher, being put in from the side. The leads extend down and across to the pyrometer house, as mentioned above, to the switch-box.

In this case the switch-box only is located in the pyrometer house, the indicating instrument is located at the foot of the charging elevator, where the workman operating the charging scale car may know the temperature of the top-gas. The top-gas temperature varies with the charging and ranges between 150° and 500° F. In this case the recording instrument is also located in the main office.

The indicating instruments are all of the Bristol switch-board type, Model No. 162, with the Weston millivoltmeter movement. Those used for hot-blast temperatures have a range of 1600° F., while those used for the top-gas temperature have a scale range of 1100° and 1260° F.

The recording instruments used are all Bristol smoked-chart Model No. 137, with the Weston millivoltmeter movement. Those used for hot-blast measurements have a temperature range of 1600° F., while those used for top-gas temperature measurements have a temperature range of 1100° F.

The thermo-couples used are all the 1600° F. standard Bristol base-metal alloy couple with a bessemer-steel element against a nickel-copper-steel element generating about 60 millivolts at a temperature of 1832° F. (1000° C.) with the cold end temperature 24° C.

The next most extensive user of the pyrometer is the **metallurgical department.** This department requires instruments for measuring higher temperatures than any other department of the steel mills. The metallurgical department of the South Works has one Hoskins portable indicating thermo-electric pyrometer, type P. H., with a scale range of 1400° C., and one Hoskins recording pyrometer, thermo-electric, type P. R., scale range 2000°F. With these two instruments they have several types and lengths of the Hoskins nickel nickel-chromium thermo-couple, some being as much

as 15 feet in length. These long thermo-couples are used chiefly in the heat treatment of rolls, which are heat treated in the various mill soaking pits. One Le Chatelier recording pyrometer, thermo-electric with a platinum platinum-rhodium thermo-couple, is used for laboratory work exclusively. One Keiser-Schmidt single-jewel type indicating thermo-electric pyrometer, with a Heraeus platinum, platinum-rhodium thermo-couple, scale range of 1600° C., is also used for laboratory work.

One Fery radiation pyrometer of the portable indicating instrument type is used for measuring temperatures which are too high to be measured by thermo-electric pyrometers or in such cases where it is impossible to take the temperature measurement with a thermo-couple. It is used for such purposes as the measurement of temperatures in open-hearth furnaces, temperatures about 1600° C., temperatures of molten metal coming from the open-hearth, temperatures of metal being poured into moulds about 1500° C., temperatures of reheated ingots for rolling about 1200° C., and for measuring temperatures of slag and molten metal at blast furnaces and Bessemer converters.

This instrument is also used for determining temperatures at the **electric furnace,** some of which are as follows:

Finished steel from electric furnace 1495° C.

Temperature inside furnace before charging 1300° C.

Temperature of charge of bessemer steel before charging furnace 1500° C.

Temperature inside furnace after running forty minutes 1425°C.

Slag skimmed from metal 1400° C.

Temperature of empty furnace just after pouring 1500° C.

The metallurgical department also has a Thwing radiation portable indicating pyrometer. This instrument is a fixed-focus instrument, suitable for quick reading of a hot-body, such as the temperature of a rail, or ingot or plate passing through the rolls.

They also have five Wanner instruments. These Wanner optical pyrometers are the most desirable instrument for use where it is impossible to use a thermo-electric pyrometer, because they are easily carried from place to place and are quickly focused. In many cases where a very accurate temperature measurement is desired both the Fery and Wanner are used and the average results taken.

Another department using a number of pyrometers is the **steam engineering department.** This department handles the general mechanical engineering tests of the plant. They have one Bristol quick-reading 3000° C. indicating pyrometer with three platinum, platinum-rhodium thermo-couples. This instrument is very seldom used by this department, but is kept on hand in good repair for emergencies.

Further there are three Bristol smoked-chart recording instruments with scale ranges of 1100°, 1800°, and 2000° F., respectively. At present these are being used as follows:

The 1100° instrument is kept in a first-class condition for general testing work.

The 1800° instrument is used in the pit of a waste-heat boiler located in the open-hearth plant. The waste heat from one of the open-hearth furnaces is used to operate a 200-hp. boiler. The temperature in the fire box range from 900° to 1200° F.

The 2000° instrument is used for measuring temperatures of the gas generated by the gas producers at the open-hearth plant. These temperatures are used in connection with the taking of gas analyses.

The **open-hearth department** also has two instruments of its own which are used for the same purpose, one a Bristol smoked-chart recorder scale, range 1800° F., the other a Bristol indicating pyrometer, scale range of 1600° F.

The steam engineering department also has a Bristol, portable indicating pyrometer, scale range 2000° F., and a standard portable, indicating Hoskins thermo-electric pyrometer, scale range 2550° F. This pyrometer is used as a standard for checking pyrometers installed throughout the plant and is made with an aluminum pot so that it will be light and easily handled. It also is calibrated with a rheostat so as to reduce to a minimum the error due to the temperature cofficient.

Some of the uses found for pyrometers by the steam engineering department are measuring fire-box temperatures under boilers, comparison of temperatures at different points in the fire-box, measuring stack temperatures, measuring waste-heat temperatures, measuring temperature of superheated air and gas-producer temperatures.

The **mechanical department** also uses two Hoskins pyrometers, both being used in the blacksmith shop. One is used for the determination of the critical points of tool steel and is known as a recalescent outfit. It consists of a Hoskins portable indicating instrument and a very small thermo-couple.

The critical point is obtained by clamping two samples of the steel over the twist of the thermo-couple and then heating it slowly. The needle of the meter will rise gradually to the decalescent point, at which it will hold for a few seconds; the sample may then be taken from the furnace and allowed to cool; the needle will begin to drop, indicating the cooling of the sample, but at a certain point the needle will again hold for a few seconds before continuing to drop. This point is known as the decalescent point.

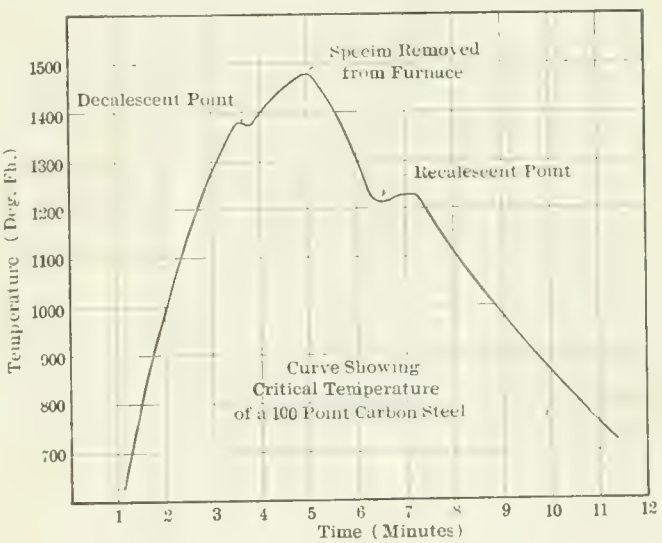

FIG. 2.—HEATING AND COOLING CURVE SHOWING CRITICAL TEMPERATURES.

The critical point or decalescent point is a point necessary to know before perfect results can be obtained in hardening tools. It depends on the composition of the steel. If it is a pure carbon steel, this point depends upon the amount of carbon. If it is an alloy steel, it depends upon the amount of other metal and also the kind of alloy, but the average critical points vary between the temperatures of 1250° and 1450° F.

The second pyrometer of this department is installed at the hardening furnace, where it is equipped with a calibrated rheostat and thermometer so as to reduce the error due to temperature change of the meter, to a minimum. It is also equipped with a double-pole switch and several thermo-couples, one being used in the tempering furnace, a second in the oil bath used for drawing, and a third thermo-couple in a gas forge furnace.

The **chemical department** also uses a number of thermo-electric pyrometers in the laboratories. The most extensive use is for the determinations of carbon contents of steels, ferro-alloys, and graphite by the combustion method as described in Hoskins Bulletin No. 5. The thermo-couple is

placed in the furnace alongside the combustion tube containing the combustion boat of steel.

We find in use in the South Works of the Illinois Steel Co., at the present time 70 pyrometers of various makes, the resistance pyrometer being the only one which has not found its way into the steel mills.

Illinois Steel Co., South Chicago, Ill.

Radiation Pyrometry.

By G. A. Shook.

II. Theory of Radiation Pyrometers.

In the first paper published in the April issue of this journal, two important radiation laws were given, namely: the total-radiation or fourth power law, and the distribution law.

The working principles of the following two classes of pyrometers are based upon these two laws. In the first class, black-body temperature is determined by measuring the total energy, as in a Féry or Thwing pyrometer, which allows radiations of all wave-lengths to fall upon a sensitive thermo-couple connected to a direct-reading galvanometer.

In the second class, some particular wave length is used and the measurement of temperature is made photometrically by adjusting to equality two photometric fields produced by a standard source and the body to be measured.

The intensity of radiation is varied by cutting down the objective aperture, as in the Le Chatelier, or by a polarizing device, as in the Wauner, or by varying the intensity of the standard itself, as in the Holborn.

Total Radiation Pyrometers.

From a consideration of the Stefan-Boltzmann radiation law we have seen that the energy radiated by a black body is proportional to the fourth power of the absolute temperature, or

$$J = KT^4 \qquad (1)$$

From this relation it is evident that a comparatively rough method of determining the energy radiated would yield fairly accurate results of temperature measurements. Now if the energy from an incandescent body falling upon a given area, could in some way be measured we could get a measure of the body's apparent black-body temperature.

However, this energy is very small, as one knows by experience, and therefore to get even a rough measurement of it requires very delicate and sensitive apparatus.

Since radiant energy is transformed into heat, whenever it falls upon any body, and since, moreover, the temperature of a body increases when heat is imparted to it, the rise in temperature of a given absorbing body might be taken as a measure of the temperature of a radiating body. For example, we might blacken the bulb of an ordinary thermometer and put it in the path of the rays from some hot body. The rise of mercury in the thermometer would be proportioned to the fourth root of the absolute temperature of the hot body in question.

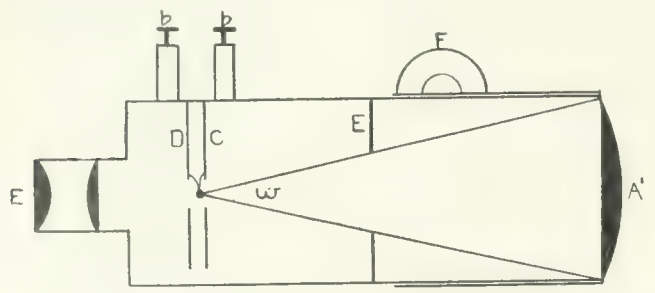

FIG. 1.—FERY RADIATION PYROMETER.

In the total radiation pyrometer used today, the radiant energy is concentrated by means of a lens or concave mirror upon a small metallic disc whose front face is covered with lamp-black. Some form of a sensitive thermometer such as an antimony-bismuth thermo-couple is placed in contact with the disc. The thermo-couple is, in turn, connected to a direct-reading galvanometer.

The Féry radiation pyrometer is shown in detail in Fig. 1. Radiation from an incandescent body is focused upon a minute and sensitive thermo-couple *C*, by means of a lens A^1. In order to calibrate the pyrometer directly in terms of the Stefan-Boltzmann law, the lens should be transparent for all radiations and this is best effected by using a fluorite lens which for temperature above 900 deg. C. does not absorb an appreciable portion of the incident radiation.

F is a rack and pinion for focusing the radiation upon the thermo-junction. The screens *C* and *D* protect the junction from extraneous rays. The diaphragm *E* provides a constant-angle aperture, which is a necessary condition for the instrument to be independent of focusing. The thermo-junction leads are in turn connected to a galvanometer.

In making a temperature measurement the image of the incandescent object is focused upon the thermo-couple by means of the eye piece *E*, and care must be taken that the image is larger than the thermo-couple.

It is evident from equation (1) that if the galvanometer has a uniform scale and the temperature T_1 is known corresponding to a scale reading R_1, the temperature T_2 for any other reading R_2 may be found from the relation,

$$T_2 = T_1 \sqrt[4]{R_2 R_1}$$

When the limit of the scale is reached the calibration may be extended by means of a diaphragm placed before the objective or by shunting the galvanometer. In technical practice, however, a glass lens is used and the instrument is calibrated empirically against a black body whose temperature can be determined.

This instrument is also made with a gold reflector instead of a lens.

Féry has recently brought out a new pyrometer which is similar to the above, with the exception that the temperature is measured by means of a minute expansion spiral consisting of two metals with dissimilar expansion coefficients. This mechanical device renders the instrument more robust but does not admit of so great accuracy as the thermo-element.

In the Thwing pyrometer a long conical mirror is used and consequently a lens is not necessary. All of the rays falling upon the aperture of a conical mirror will ultimately reach the apex by multiple reflections from the side.

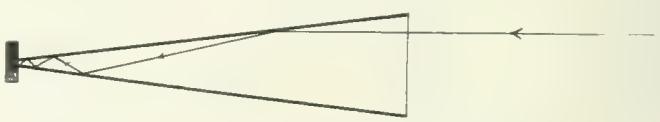

FIG. 2.—PRINCIPLE OF THWING RADIATION PYROMETER.

Hence, if a sensitive thermo-couple is placed at the apex, Fig. 2, it will obtain the same effect as it would if placed at the focus of a lens or concave mirror.

Within wide limits the indication of the instrument is furthermore independent of the distance from the hot body. The instrument, therefore, requires no focusing.

The thermo-couple is connected to a direct-reading portable galvanometer. This type of total-radiation pyrometer is remarkable for its ease of manipulation and sensitiveness.

The Bureau of Standards have quite recently been able to make extremely minute thermo-couples of antimony and bismuth by a very ingenious method. If a bank of these thermo-couples could be attached to the small heater of a radiation pyrometer, the sensitiveness would be considerably increased.

For instance, if a temperature of 600 deg. C. produces a deflection of about one-fourth the galvanometer scale in case of a single thermo-couple, then by using four couples in series the same temperature would produce a full scale deflection. This means that low temperatures could be measured accurately which is now impossible with this type of instrument.

Optical Pyrometers

Although this type of pyrometer is perhaps more useful in many ways than the total-radiation pyrometer, it is in theory somewhat more difficult. If properly analyzed, however, it will be seen that the essential parts of this instrument are not inherently new.

A photometer is an instrument for comparing *luminous intensities*. If a white opaque screen be moved to and fro between two lights until the illumination on both sides of the screen appears the same, the *luminous intensities* of the two lights bear a certain definite relation to each other.

The luminous intensity of a light source depends upon the *brightness* or *intrinsic* intensity and the extent of the luminous surface. For example, if one looks at a small area of an incandescent sheet of metal, it will appear just as *bright* as an area many times as great, but, of course, the larger area will illuminate a photometric screen to a much greater degree than the smaller area.

An optical pyrometer is essentially a photometer which compares the intrinsic intensity, for a particular color, of a hot body with some standard lamp, and which is calibrated in terms of temperature instead of candle-power.

In the case of an ordinary photometer, the two photometric fields which are brought to equality, are illuminated by diffused light, such as is transmitted by a ground glass, so that unless one always examines the same area, which would be impossible in pyrometry, the photometer would not give a true measure of the brightness or intrinsic intensity of the body in question.

Suppose, for example, that we had a large sheet of incandescent metal at a constant uniform temperature. One square foot of this surface would evidently give only one-half as large a reading upon a photometer as an area 2 square feet in extent.

Now since the brightness varies with the temperature, in optical pyrometry we are concerned with the brightness and not with the luminous intensity of an incandescent body. If in the above case, we were to compare the image of the luminous surface produced by a lens, then, evidently, two square feet of surface would simply produce a larger image than 1 square foot, but the brightness would be the same in either case.

Consequently a lens is generally used to produce an image of the radiating body whose temperature is sought. The size of an image formed by a lens does not, of course, depend upon the diameter of the lens, but only upon its focal length, but the size of the lens does effect the brightness of the image. When we stop down a camera lens, we do not change the size of the picture, but we do certainly alter the amount of light that falls upon the plate.

Furthermore, the brightness of the image of an incandescent object is not altered for different positions of the lens from the object, so long as the lens always subtends the same solid angle to any point on the image.

To be sure, as the lens receeds from the object the brightness of the image decreases as the square of the distance, but the size of the image also decreases in the same ratio, so that the illumination is concentrated, as it were, into a smaller space. The brightness, therefore, remains constant.

The eye cannot determine how much brighter one image is than another, but when two images are brought close together it can determine with accuracy when they have the same brightness.

There are four essential things to be considered in the manufacture of an optical pyrometer, namely:

1. A sensitive photometric screen.
2. A method for varying the intensity of the incident radiation.
3. An appliance for producing monochromatic light.
4. An invariable standard lamp.

Now since a thorough knowledge of the optical pyrometer must involve some notion of these details and furthermore since an improvement upon any of the pyrometers now in use must be an improvement upon some of these essential parts, they will be taken up to some length.

1. There are a large number of photometric screens now in use, varying in sensitiveness over a wide range. In order that a photometric screen be sensitive, the two photometric fields, to be compared, must be uniform in brightness and must be separated only by a very fine line.

All the screens devised today are the results of attempts to meet these two requirements. In order to avoid any assymetry one field is sometimes surrounded by the other, as in Fig. 3.

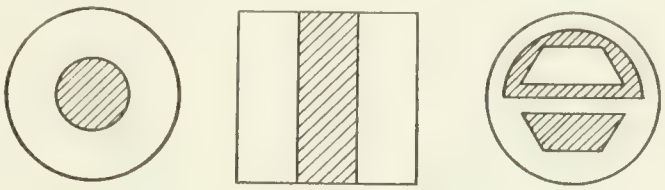

FIG. 3.—PHOTOMETRIC SCREENS.

The most familiar screens are: the Richie, a plaster paris wedge; the Jolly, two paraffine blocks separated by tinfoil; the Bunsen, a translucent greasespot on white paper, etc.

There are also other photometric devices which make use of images reflected from mirrors or shadows cast by obstacles.

Two of the most sensitive photometric screens, which by the way have never as yet been applied to any pyrometer, are the Lummer-Brodhun cube and the Brace prism. The simplest form of the Lummer-Brodhun cube is shown in Fig. 4.

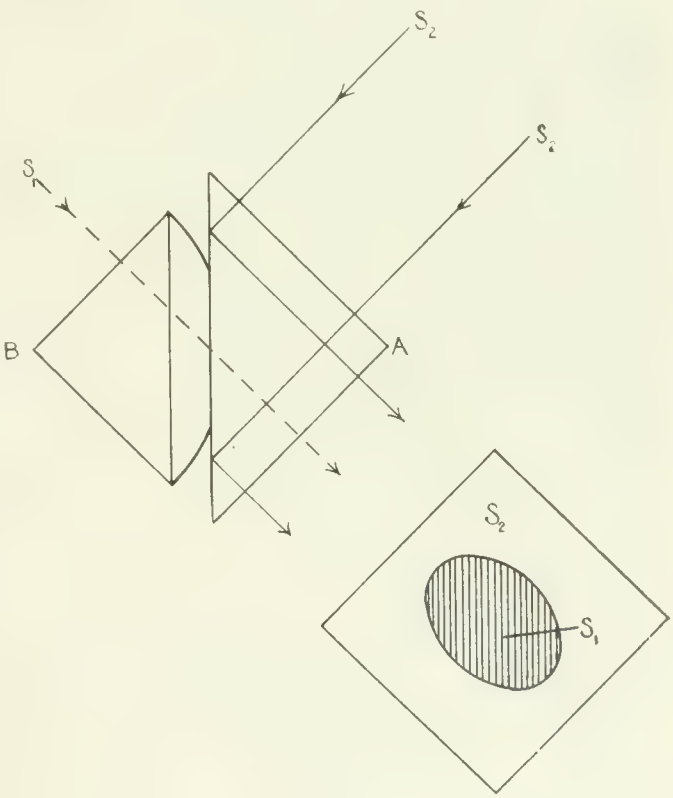

FIG. 4.—LUMMER-BRODHUN CUBE.

A is a right-angled prism with a plane hypothenuse surface, but the hypothenuse surface of B is convex, with the vertex ground flat. Light from S_1 passes through the central portion just as it would through a solid cube, so that the plane ground surface is illuminated by S_1. Light from S_2 will be transmitted through the central portion and totally internally reflected from the region surrounding the plane ground surface so that the appearance is similar to that shown. Since the prism B can be accurately ground and closely pressed to A the dividing line between the two photometric fields is extremely small.

The Brace prism is made up of two similar 30-deg. prisms cemented together as shown in Fig. 5.

A strip *e f*, is silvered on one face *c d*, of one of the prisms. Light from the two sources S_1 and S_2 enters the prism as shown and an observer on looking in the direction *c o*, will see the

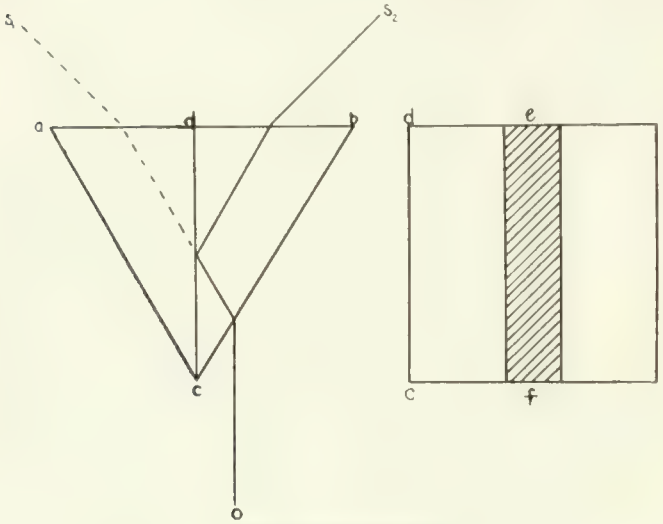

FIG. 5.—BRACE PRISM

face, *d c*, illuminated by monochromatic light. The color of the face depends on the inclination of the rays. The upper third and lower third of the face are illuminated by transmitted light from S_1 while the central third is illuminated by reflected light from S_2.

2. In order to obtain a photometric balance, it is necessary to vary the brightness of one or both of the images in a continuous manner. The method should also be determinate, *i.e.*, it should be such that the variation can be expressed mathematically, so that it can be used in the pyrometer equation,

$$t = \frac{K_2}{K_1 - \log J} - 273 \qquad (2).$$

Since in most pyrometers the intensity of the standard lamp is constant, it will be taken as unity in the following equations. In the case of an ordinary photometer, with two light sources fixed at either end of a graduated bar, equality of brightness is obtained by moving the photometric screen between the two lights.

The intensity of the unknown light in terms of the standard light taken as unity, then becomes

$$J = \left(\frac{d_x}{d_s}\right)^2$$

where

d_s = distance from screen to standard lamp, and

d_x = distance from screen to unknown source.

An adjustable diaphragm, with a square opening, placed close to the lens which forms the image, is a convenient arrangement for a portable pyrometer. Here

$$J = \left(\frac{l}{s}\right)^2$$

where

s = length of one side of the square opening.

A narrower wedge of smoked glass may also be used with advantage since it admits of easy calibration. In this case

$$\log J = C_1 x$$

where

C_1 = constant and

x = thickness of the wedge

or $\log J = C_1 l$

where

l = distance the wedge is moved in the direction of its length.

Lower temperatures can, however, be measured with the diaphragm.

If in order to obtain monochromatic light some form of a spectroscope is adopted, then the incident energy may be varied by varying the width of the collimator slit. This is generally accomplished by means of a screw with a divided head, in which case,

$$J = \frac{1}{w}$$

where

w = width of slit,

or

$$J = \frac{1}{n}$$

where

n = reading of the divided head.

A polarizing device is also convenient for portable instruments, but it absorbs considerable light and is rather difficult

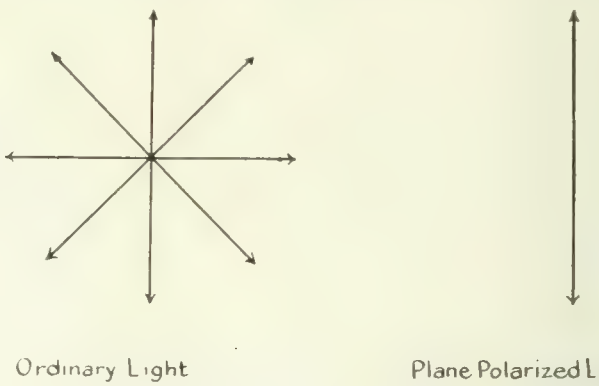

FIG. 6.—ORDINARY AND PLANE POLARIZED LIGHT.

to construct. Now we know that light vibrations are perpendicular to the direction of propagation of the light and if by any means these vibrations, which are in all possible directions in this perpendicular plane, are reduced to one direction, the light is said to be plain polarized, Fig. 6.

If the two beams of light under consideration are plane polarized, they may be brought to equality by means of a Nichol's prism, which transmits only plane polarized light. If s_1 and s_2 represent amplitudes of vibration of two light sources and Φ the angle of rotation of the Nicol, necessary to bring the two fields to the same brightness, from Fig. 7.

$$\frac{s_1}{s_2} = \tan \Phi$$

But since the intensity is proportional to the square of the amplitude,

$$\frac{J_x}{J_s} = \frac{s_1^2}{s_2^2} = \tan^2 \Phi \text{ or}$$

$$J = \tan^2 \Phi.$$

3. Monochromatic light—red being generally used—can be produced by means of red glass and except in refined work, this is quite satisfactory. Ordinary red glass, however, cannot be used since it really transmits more than one color. Glass which is nearly monochromatic can be obtained, however, but it is sometimes necessary to use a combination of two or three pieces.

The mean wave length of the glass can be found by placing it before the slit of a spectrometer which has been calibrated in terms of wave length. To obtain light that is strictly monochromatic, a slit and a dispersion prism are generally used. The prism spreads the light out, as it were, into various colors and any particular color can be utilized by screening off the others.

4. As for a standard lamp, there is not much choice. Any oil or gasoline lamp in a place subject to drafts is likely to give trouble. Such a lamp does not require constant standardizing, however, if the tip of the flame is always brought to the same fiducial mark and if oil from the same source is always used.

A small round wick burner is not very satisfactory, since the flame, in any slight draft, is constantly getting out of the field of view.

If a small portion of a rather large flat flame were utilized, it might prove very satisfactory. Such a lamp could undoubtedly be so designed that it would not be affected by drafts.

While an electric incandescent lamp is free from these difficulties it must be constantly compared with some standard lamp. The best method of keeping a check on an electric lamp is by means of an ammeter and rheostat. It is not unreasonable to suppose that with a suitable compensating device a constant intensity electric lamp could be made, so that slight changes in voltage would not affect the intensity materially. It could then be run on any commercial 110-volt line.

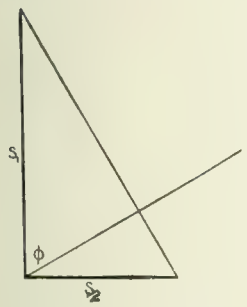

FIG. 7.—AMPLITUDE DIAGRAM.

Wauner Pyrometer.—It has been shown that the luminous intensities of two bodies may be taken as a measure of their temperatues, if monochromatic light is used, and since luminous intensities may be compared by the rotation of a Nicol prism, we have a convenient means of measuring high temperatures.

In this method comparison is made between a standard lamp and the body whose temperature is sought. The standard used is a 6-volt incandescent lamp which is in turn compared with some primary standard as an amyl acetate lamp.

For this work the primary standard is used merely as a check for the more convenient electric lamp and so long as it is reproducible so that the comparison lamp can always be brought to the same condition, we are not concerned with its intrinsic intensity or temperature.

Photometric comparison is made of the standard lamp and the unknown source by adjusting to equal brightness two halves of a photometric field by means of a polarizing arrangement, monochromatic red light being produced by a direct vision prism.

The intensity of the unknown source in terms of the comparison lamp, taken as unity, is

$$J = \tan^2 \Phi$$

where Φ is the rotation of the Nicol prism.

Le Chatelier Pyrometer.—Le Chatelier's optical pyrometer compares the luminous intensity of the red radiation from the body whose temperature is derived with the red radiation from a standard light source.

The radiation from the body whose temperature is to be measured traverses the diaphragm *D*, Fig. 8, and the objective *O*. A part of the radiation grazes the right edge of the mirror *M* and is brought to a focus at the focal plane of the eye piece *A*. Light from the central portion of the flame of the comparison flame *L* traverses the objective O^1, is reflected from the inclined mirror *M* and is also brought to a focus in the focal plane of the eye piece.

Thus two images, one of the source whose temperature is sought and one of the comparison flame, are found side by side, in the focal plane of the eye piece. These two images are simultaneously observed by means of the eye piece *A* provided with a piece of red glass for rendering the radiations that enter the eye, the same wave length.

By adjusting the size of the aperture in the diaphragm *D* these two images can be brought to the same brightness. The distance from the objective *O* to the focal plane of the eye piece can be varied in order to focalize the radiation from the luminous source and the distance can be read directly from a scale engraved on the draw tube. The aperture in the dia-

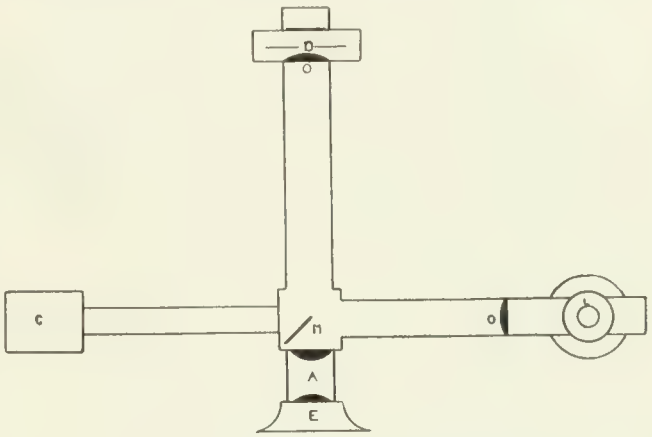

FIG. 8.—LE CHATELIER OPTICAL PYROMETER.

phragm *D* is square and the length of one side can be read directly from the screw head which operates it.

The intensity of the unknown source in terms of the intensity of the comparison lamp taken as unity, becomes

$$J = \left(\frac{1}{s}\right)^2$$

where *s* denotes the length of one side of the square aperture *D*. Due to the lack of monochromatism of the red glass this instrument is not so accurate as the Wauner.

Holborn-Kurlbaum Pyrometer.—In this method the luminous intensity of the comparison source is varied until a photometric balance is obtained between its image and the image of the incandescent object in question.

In the H.-K. (Holborn-Kurlbaum) pyrometer shown in Fig. 9 a small electric lamp *L* is placed in the focal plane of the objective *O*, and the same is viewed by means of an eye lens *E*.

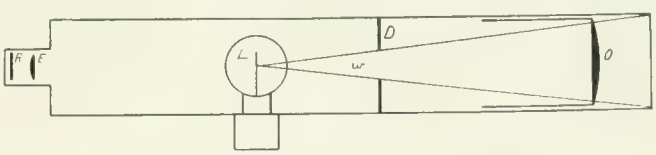

FIG. 9.—HOLBORN-KURLBAUM PYROMETER

In making an observation the pyrometer is focused upon the object whose temperature is sought, thus bringing the image of the object in the plane of *L*.

The current through the lamp is adjusted by means of a rheostat until the lamp filament disappears against the bright background. The value of the current strength can be read direct from a milli-ammeter.

In order to measure temperature with this instrument, it must be empirically calibrated by means of a black body. A curve may then be plotted with current in milli-amperes and temperature in degrees C.

To determine an unknown temperature, it is only necessary to focus the instrument upon the object in question and adjust the current through the lamp until the filament disappears against the bright object. The pyrometer then indicates black-body temperature unless black-body conditions are realized, in which case it indicates true temperature, *i.e.*, thermodynamic temperature.

The reading of the ammeter will be independent of the distance of pyrometer from object so long as the solid angle *w* in Fig. 9 is constant. This is accomplished by means of the diaphragm *D*. When the instrument is focused for distant ob-

jects, *i.e.*, when O is drawn near L, the solid angle w would be increased if it were not for the diaphragm D.

The light which reaches the eye is rendered approximately monochromatic by a red glass, R, placed before the eye piece, but for temperature below 800 deg. C. this is not necessary and above 1200 deg. C. two glasses are generally used.

The H.-K. pyrometer is probably the most sensitive pyrometer now in use.

Morse Thermo-Gage.—This is somewhat similar to the Holborn-Kurlbaum pyrometer, in that it utilizes the disappearing-filament principle, but it is not nearly so precise, since it is not provided with any lens system or monochromatic glasses. It is simply an incandescent electric lamp in a black tube and it is operated and calibrated in a similar manner to the Holborn instrument.

Urbana, Ill.

Calculation of Furnace Charges.—V.

By Regis Chauvenet.

The preceding "type" problems were one and all presented under the suppositions: (1) That matte has already been "taken out," (2) that the "conversion" factors have been applied, reducing all bases to the two standards, viz., FeO and CaO, (3) that the figures denoting percentages in the analyses have been simplified by addition and subtraction, so as to present integers only for use in computation.

The student must observe that in all of this *preparation* there is no difference between the excess and the equation methods. The same is true of the "proof," which can be done perfectly in one way only, viz., by taking the ascertained weights of the materials and having calculated from their analyses the respective total of each constituent, add like to like, and make the numerical comparison, when, if the computation is entirely correct, the proportions will exactly conform in ratio to the "requirements" on which the problem was "set up."

But as to the operation proper, the equation method claims directness, and obviates all necessity of trial and readjustment. It is, furthermore, better suited to complex cases. Looking over the five cases given in Article IV it is seen that there is very little more work in the solution of the last case than of the first. Yet the complexity rises from the first to the last of these cases, as to number of constituents involved.

In those problems in which there is but a single adjudication, between one "acid" and one "base" the equation method claims no special advantage. But in a very great majority of copper and lead smelting problems there will be more than two "elements" to be charged, and more than one base to be considered. We follow here the usual rule, which is to class all bases under one group or the other, viz., iron-oxide or lime.

In regard to alumina we have already shown the common iron practice, that is, to regard it as "acid" and add its percentage to that of silica.

Another practice has been briefly mentioned, i. e., to neglect the element entirely, in calculation, trusting the fluidity of the slag to "take care" of it. The practice might, however, if pushed too far, play a disagreeable trick on the practitioner some day.

Two facts, neither of them very clearly proved, but probably to be classed as reasonable "working theories," may be stated about the action of alumina in the smelting furnace.

(1) In a very basic mixture it probably takes up the "acid" rôle, and in so far an element of safety, i. e., by preventing what might otherwise be a dangerous condition, the stiffening of the slag owing to excessive basic contents.

(2) It is safer to figure on alumina in an acid rôle at the high temperatures of the iron furnace than at the lower range of lead and copper smelting.

In the calculations hitherto illustrated, little attention has been paid to formulas, and in the five "type" cases setting forth the method of equations the requirements were confined strictly to "percentage" slags.

The reason why it is not necessary to make much account of formulas has been partly explained. It is, in a word, because any formula may be transformed into the analytical form in a few minutes' work.

There are cases, nevertheless, in which it may be easier not to translate into the complete analytical form, but to make our statement dependent directly upon the chemical ratio. Some illustrations follow. The reader will, of course, have noticed that in the examples we have made the slag requirements in round numbers. This was chiefly for the sake of simplicity in a first presentation, but we will now point out that in the consideration of formulas we may often secure ratios that will serve as factors much simpler than the requirements derived from "translating" from formula into full analysis.

Example.—Let the type chosen be a singulo silicate, with iron oxide in twice the molecular ratio of lime.

$$4FeO,\ 2SiO_2 + 2CaO,\ SiO_2$$

The molecular weights are $3SiO_2 = 180$; $4FeO = 288$ and $2CaO = 112$.

No very great arithmetical "perception" is needed to see that these numbers approximate the ratio 3:5:2. It is true that this also comes out plainly in the analytical form, viz.:

SiO_2	31.03 per cent
FeO	49.65 " "
CaO	19.31 " "

but anyone used to looking at numbers with their ratios in mind would see the ratio without having to take the trouble of converting the formula into the analysis. There are cases in which the "chemical" numbers are manifestly in simple ratio, when the anlaysis does not so quickly reveal the latter.

Let us now set up a problem on the above "formula."

We shall now assume materials not quite so simple in analytical percentage figures as in the "type" cases.

	Ore.	Iron flux.	"Stone."
SiO_2	30	$8x$	$7y$
FeO	14	$76x$	
"Base"	6	$7x$	$52y$

It is in this way that the analyses may always be set down in using the "equation" method. As we are going to let 100 x *equal the pounds of iron flux and* 100 y *equal the pounds of limestone,* we write the letters x and y directly into the analyses for reference afterward.

Here, as elsewhere, we set down trivial details. This one might raise a smile because of its trifling nature. We smile also. But we do not cancel the detail. We know that every little scrap of precaution against error is of value. One of these is to always use the same order of procedure, another is to use the same abbreviations, an important one is to "label" your side calculations, for though at the moment of making them you know well enough what they mean, you may have a good deal of trouble in finding them later if they are lost amid a maze of "scribble" figures.

Requirement.—As we found above that the ratio of 3:5:2 for silica, iron-oxide and lime respectively satisfied our formula pretty closely, we adopt it. Now we write:

$$SiO_2 : FeO = 3 : 5 = 30 + 8x - 7y : 14 + 76x$$
$$FeO : base = 5 : 2 = 14 + 76x - 6 + 7x + 52y.$$

Nothing remains but the mechanical work of reducing these proportions to equations and solving them. It is this extreme simplicity of statement as substituting the "excess" calculations, that constitutes the advantage of the method under discussion. The values of x and y are as below:

$$x = 0.8866 \ .\ 100x = 88.66 \ .\ y = 0.3913 \ .\ 100y = 39.13$$

That is, take 88.66 lb. of the "iron flux" and 39.13 lb. of the "stone."

Proof.

	SiO_2.	FeO.	Base.
From the ore	39.00	14.00	6.00 lb.
From the "flux"	7.09	67.38	6.21 "
From the "stone"	2.74		20.35 "
	48.83	81.38	32.56 lb.

These three summations, representing the respective weights of the constituents, are exactly in the triple ratio of 3:5:2, as required

There are many who object to the use of equations in any computation, and we have even seen in a well-known metallurgical work a chapter devoted to "slag calculation" in a highly unsystematic form, followed by a self-congratulatory remark that there was no "*x*" or "*y*" in the method.

To such, however, as are not terrified by the first elements of algebraic statement we will propose the testing of this "slag method" by the time needed to complete the work. The last problem cannot be called very complex. Try it by excess and adjudication, then by equations, as here illustrated. The method can certainly not be charged with indirectness. No one who has once used a process which goes straight to a precise answer will afterward be content to use approximations and re-adjustments.

The operator can choose for himself in any case whether to calculate upon original analyses or to accept a reasonable approximation.

In iron metallurgy formulistic requirements are no longer much regarded. The astonishing variations which can be tolerated in the ratio between the "acid" ($SiO_2 + Al_2O_3$) and the "base" indicate that the question of formula assumes less importance at these high temperatures. In short, fluidity of a slag being only partly a matter of composition and partly a matter of temperature, considerations other than those of the oxygen ratio come into play.

Slags from the lead furnace (and probably from other operations) which show a distinctly crystalline structure will, it is claimed, always be found to have a chemical formula as the expression of their compositions.

Certain formulistic "types" with analyses and ratios either exact or approximate are annexed. They could be varied almost indefinitely. They are not introduced as primarily "working types," but merely to show how in many cases fairly simple ratios may be substituted for percentages of analytical statement. Much has to be left to individual device in the simplification of data.

The "ratios" which are placed to the right of each analysis do not in any case greatly differ from the relative proportions of the latter, and in some cases they are practically identical. Introduced as factors in a statement by proportion they would in most instances simplify the "setting up" of the problem.

The slags presented are all of the "two base" type, assumed as usual as iron oxide and lime.

Simplified analyses are also annexed, i.e., original analyses slightly revised by elision of fractional parts.

Some Well-Known "Formulas."

(1) Singulo with iron oxide and lime in equal chemical ratio.

$(FeO)_2, SiO_2 + (CaO)_2, SiO_2$

	Per cent.	Per cent.	Ratios.
SiO_2	31.91	32	15
FeO	38.30	38	18
CaO	29.79	30	14

(2) Sesqui-silicate, same ratio as between iron and lime.

$4FeO, 3SiO_2 + 4CaO, 3SiO_2$

	Per cent.	Per cent.	Ratios.
SiO_2	41.28	41	5
FeO	33.03	33	4
CaO	25.69	26	3

(3) Bi-silicate, iron oxide and lime in equal ratio.

$FeO, SiO_2 + CaO, SiO_2$

	Per cent.	Per cent.	Ratios.
SiO_2	48.39	48	15
FeO	29.03	29	9
CaO	22.58	23	7

(4) Singulo, iron oxide twice chemical ratio of lime.

$4FeO, 2SiO_2 + 2CaO, SiO_2$

	Per cent.	Per cent.	Ratios.
SiO_2	31.03	31	3
FeO	49.65	50	5
CaO	10.31	19	2

(5) Sesqui-silicate, iron oxide twice lime.

$8FeO, 6SiO_2 + 4CaO, 3SiO_2$

	Per cent.	Per cent.	Ratios.
SiO_2	40.31	40	15
FeO	42.98	43	16
CaO	16.71	17	6

(6) Bisilicate, iron oxide twice lime.

$2(FeO, SiO_2) + CaO, SiO_2$

	Per cent.	Per cent.	Ratios.
SiO_2	47.37	47	6
FeO	37.90	38	5
CaO	14.73	15	2

We now return to an actual computation, taking for the purpose the iron furnace problem already given in article III, both analyses and requirements as to composition of the slag being identical. We repeat the data however.

Analyses of the iron ore, coke and limestone.

	Ore.	Coke.	Limestone.
SiO_2	4	4	5 per cent
Al_2O_3	2	1	2 " "
MgO	4		2 " "
CaO			50 " "
Fe_2O_3	90		" "
Carbon		95	" "

Requirement for the slag is that the "acid" considered as *silica plus alumina* shall be to the total "bases" (CaO + MgO) as 10 : 12.

Find limestone required for 100 lb. of ore, also for 100 lb. of coke.

This was done by the "excess" method in article III, we now do it by the equation method.

(1) Ore 100 lbs. Limestone $= 100\ x$ lb.

"Acid" $= 6 + 7\ x$ lb. Base $= 4 + 52\ x$ lb.

$12(6 + 7\ x) = 10(4 + 52\ x)$ or, in equation form:

$72 + 84\ x = 40 + 520\ x$.

Whence

$x = .0734$ and $100\ x = 7.34 =$ lb. limestone required.

(2) Coke. Since "acid" in the coke is $4 + 1$ or $5\ x$ we have

$12(5 + 7\ x) = 10\ (52\ x)$.

$x = .1376$ and $100\ x = 13.76 =$ lb. limestone required.

That is, we take for each 100 lb. ore, 7.34 lb. limestone, and for each 100 lb. coke, 13.76 lb. limestone.

These results are identical with those previously found by the excess method. Proof by "checking out" was given in full in article III, so it would be superfluous to repeat it here.

This is an exceedingly simple case. We have already mentioned that the advantage of the equation method comes out in complex problems, but even here comparison will show that the computation is less by many figures than by getting the "excess."

We have said that "formulas" are not much used in iron smelting. However, we now give one problem with a formulistic requirement.

This also has been given in article III. In it, we shall regard alumina as a base, and instead of making a separate computation for coke, we assume the latter as constant, and as 70 *per cent of the weight of the ore.*

Analyses of material.

	Ore.	Limestone.	Coke.
SiO_2	8	6	8 per cent
Al_2O_3	5		" "
MgO		6	" "
CaO		40	" "
Fe_2O_3	87		" "

Take 100 lb. ore as usual as basis for calculation.

Reduce alumina and magnesia by "factors" to the lime basis, instead of "lumping" them by mere addition. After presenting the "revised" analyses, figure for a "singulo" silicate on the lime basis alone.

Take out 3 per cent silica from the ore, for silicon in the pig metal.

Factors are 1.4 for MgO and 1.65 for Al_2O_3.

CaO equivalent for Al_2O_3 in the ore $= 1.65 \times 5 = 8.25$.

CaO equivalent for MgO in the stone $= 1.4 \times 6 = 8.4$.

Revised analyses (iron omitted, 3 per cent off of the silica).

	Ore.	Stone.	Coke.
SiO_2	5	6	8 per cent
"CaO"	8.25	54.4	" "

70 lb. coke will give $8 x \times .70$ lb. SiO_2 which added to the 5 lb. in the ore will give us $5 + 5.6 = 10.6$ lb. SiO_2 to be reckoned in the slag from ore and coke.

Call the limestone 100 x.

$SiO_2 = 10.6 + 6 x$. $\quad$ $CaO = 8.25 + 54.4 x$.

Calculation of the ratio in the lime singulo formula shows that it will contain 35 per cent silica and 65 per cent lime, that is:

$$10.6 + 6 x : 8.25 + 54.4 x = 35 : 65.$$

100 $x = 26.44$ lb. = limestone to be added.

Compare with result in article III. The discrepancy, which is less than half a pound, is merely apparent, being due to dropped decimals in the "excess" computation.

Computation of a Copper Matte and Slag Case by Equations.

Again comparing length of the operation, we find that the equation is far ahead in preparation and statement. The use of the "factors" is the same in both. Ten minutes suffices for preparation, solution and proof.

We shall mix two ores and use an "iron flux," limestone and coke.

Analyses of material.

	Ore I.	Ore II.	Iron flux.	Stone.	Coke.
SiO_2	45	42	5	4	8
Al_2O_3	6	3	2	2	4
Fe	20	23	63	.	. .
Cu	12	6	. .	. .	. .
CaO	3	6	2.3	46	.
MgO	1	4	.5	6	
S	6	9	.		
As	1		. .	.	.
C	. .	. .	. .	. .	88
Deficit	6	7	27.2	42	. .
	100	100	100	100	100

The 63 Fe in iron ore = 81 of FeO.

Coke to be assumed as 12 per cent of the weight of the ore charged.

The two ores are to be mixed so as to obtain eight (8) per cent of copper in the mixture.

100 lb. of the "mix" is the basis of calculation, as usual.

Assume no loss of sulphur or arsenic in the smelting.

"Convert" all the bases except iron oxide to the lime basis, alculating slag as of two bases, viz: FeO and CaO.

In presenting analysis of the "mix" *add in the silica and alumina from the 12 per cent of coke,* so as to bring the coke into the general computation without having to treat it separately.

Assume the usual ratios for copper and iron with sulphur, viz.: Cu_2S and FeS, and put all the arsenic into speiss assumed as Fe_5As.

Requirement for the slag is that:

$$SiO_2 : FeO : CaO = 4 : 5 : 2.$$

(1) Coke is 12 per cent of the ore. As its silica is 8 per cent of its own weight, we have $8 \times .12$, say 1 lb. silica added for each 100 lb. ore. and $4 \times .12$, say 0.5 lb. alumina added for each 100 lb. ore. It will be convenient to incorporate these little additions into the analysis of the "mix" and have done with the slight complication of the coke ash. That is, from that point we calculate exactly as though these little quantities had formed part of the ore constituents.

(2) Mix the two ores. The rule is easily applied, as follows:

The copper percentage of the richer ore is 12, the percentage of the required mix is 8; then, $12 - 8 = 4$

Also the required percentage minus the lesser percentage is $8 - 6 = 2$.

Take the weights of the two ores then, inversely as these figures, i.e., 2 parts of ore I to 4 parts of ore II., which of course reduce to 1:2 parts.

Add each percentage figure in analysis No. I to twice percentage figure of same element in analysis No. II and divide each sum by three.

Analysis of the mixed lot *adding in the coke ash as directed* will be:

SiO_2	44	per cent
Al_2O_3	4.5	" "
Fe	22	" "
Cu	8	" "
CaO	5	" "
MgO	3	" "
S	8	" "
As	.33	" "

(3) Take out matte and speiss.

(a) Copper. $4 : 1 = 8 : 2 = Cu_2 : S$.
Weight of copper, 8 lb.; of sulphur 2 lb.; of Cu_2S = 10 lb.

(b) Arsenic with iron, $75 : 5 \times 56 = 15$; $56 = .33 : 1.23 =$ Fe with As. Weight of the "speiss," $1.23 + .33 = 1.56$ lb.

(c) Residual sulphur with iron.
Original sulphur was 8 lb., taken out for copper 2 lb., remains 6 lb.
$32 : 56 = 4 : 7 = 6 : 10.5 =$ iron to combine into matte.
Weight of sulphur = 6 lb.; of iron 19.5 lb.; weight of iron matte 16.5.

(d) Residual iron to be computed into the slag.
Original iron 22 lb., taken out by arsenic 1.23 lb., by sulphur 10.5 lb., total 11.73 lb. $22 - 11.73 = 10.27$ lb. residual iron.
Fe : FeO = 56 : 72 = 10.27 : 13.2 = lb. FeO to be used for slag.

This completes "taking out the matte." The slag problem is "cleared" of sulphur, arsenic, copper, and of all the iron except the 13.2 FeO which must be figured with the group of "iron" (in this case all really iron) in the final adjudication.

The next procedure is to "convert" alumina and magnesia into "lime."

(4) *"Conversions."*

(a) Ore.
Al_2O_3; $4.5 \times 1.65 = 7.4 =$ CaO from alumina.
MgO; $3 \times 1.4 = 4.2 =$ CaO from magnesia.
CaO; $5 \times 1 = 5.0 =$ CaO actual lime.

Total..... $16.6 =$ CaO for computing.

(b) Flux.

Al_2O_3; $.2 \times 1.65 = .33 =$ CaO from alumina.
MgO; $.5 \times 1.4 = .7 =$ CaO from magnesia.
CaO; $2.3 \times 1 = 2.3$ CaO actual lime.

Total..... $6.3 =$ CaO for computing.

(c) Stone.

Al_2O_3; $2 \times 1.65 = 3.3 =$ CaO from alumina.
MgO; $6 \times 1.4 = 8.4 =$ CaO from magnesia.
CaO; $46 \times 1 = 46.0 =$ CaO actual lime.

Total..... $57.7 =$ CaO for computing.

We have in this case assumed the Stoichiometric conversions, instead of merely adding the weights arbitrarily to the lime figures. It is certainly a more rational proceeding.

It may be neglected when the alumina or magnesia is in very small percentage.

We are now ready to present the completely "prepared" analyses, using the usual convention of 100 x for the "flux" and 100 y for the limestone.

Revised analyses ready for computation.

	Mix + ash.	Iron flux.	Stone.
SiO_2	44	5 x	4 y
FeO	13.2	81 x	..
CaO	16.6	6.3 x	57.7 y

Formulistically the requirement is too far from the singulo: $2(FeO)_2SiO_2 + (CaO)_2SiO_2$, analysis of which would be as follows:

SiO_2	31
FeO	50
CaO	19

It is fairly close to the sesqui-silicate; $2(FeO)_4(SiO_2)_3 + (CaO)_4(SiO_2)_3$, whose analysis is:

SiO_2	40.3
FeO	43.0
CaO	16.7

For the ratio $SiO_2 : FeO : CaO = 4 : 5 : 2$, on which we are to compute, gives the exact analysis:

SiO_2	36.36 per cent
FeO	45.45 " "
CaO	18.18 " "
	99.99 " "

The equations are at once set up as follows:

$(SiO_2 : FeO = 4 : 5)$ $5(44 + 5x + 4y) = 4(13.2 + 81x)$.
$(SiO_2 = 2CaO)$ $44 + 5x + 4y = 33.2 + 12.6x + 115.4y$.
$x = 0.5631$ $100x = 56.31$. $y = 0.05853$ $100y = 5.853$.

That is, we take 56.31 lb. of the "flux" and 5.853 lb. of the limestone.

Proof. (Assemble expressions for constituents and find values in pounds by substitution.)

	SiO_2	FeO	CaO
Ore, etc.	44.0	13.20	16.6
Flux	2.816	45.61	3.55
Stone	.234	.....	3.38
	47.05	58.81	23.52

Compare these weights and we find that:

$47.05 : 58.81 : 23.53 = 4 : 5 : 2$ exactly.

If, in using the values of x and y in the "proof" we find that *two* of the constituents come out in exact ratio, but the third is more or less "off," there is an error in *all three* of the quantities, and the equation must be solved again. This is sometimes a puzzle to the inexperienced computer, who imagines in such a case that the two quantities which come out "straight" must be correct, and that the only error is in the third. This is not true. The proof must bring out the triple ratio perfectly; then it is certain that all the "elements" are correctly determined.

Here we may again remind the operator that if he has been computing for a slag which is impossible under the conditions imposed by the materials, he will get a "minus" value for one of his unknown quantities. In the above case, a very slight increase in the "bases" in the ore, with corresponding decrease of silica, would bring y to a minus value; in other words, there would be more than enough "base" in the other constituents, and the use of the limestone would be uncalled for.

Now, to re-state conditions and outcome of the problem, and get composition of the products, we charge:

Ore mix	100 lb.
Coke	12 "
Iron flux	56.31 "
Limestone	5.85 "

Products: Slag, 129.39 lb., composition by ratios as per requirements, analysis as stated above.

Matte and speiss, 28.06 lb.

Composition:

Copper	28.51 per cent
Iron	41.80 " "
Sulphur	28.51 " "
Arsenic	1.17 " "
	99.99 " "

Considerable time may be saved in the solution of equations similar to the above by dropping fractional parts. To this there are certain objections. The most important is this, viz.: just as in bookkeeping, a slight difference in the "balance" may indicate a much larger one in fact, so in a check on operations like the above (since if you omit small fractions you are certain not to obtain a perfect proof), you are left in an uncertainty as to whether the failure to "balance" is due to the dropping of decimals, or to some actual error in computation.

The proper place for "short cuts" in any operation must be left to the judgment of the operator. The best check after all is the execution of the problem in all its rigor, because you then have the satisfaction of a perfect proof. *It is all right to drop decimals of pounds from the results.*

We close this series with a few problems, which are left without operations, though the answers are given. They are all of the same general nature as those hitherto presented, and all may be easily solved by the method of "Representative equations."

(a) Three ores, supposed to be each obtainable in suitable quantities, are to be mixed for smelting without addition of any other material, i.e., they are to constitute a "self-fluxing" mixture. Analyses, *so far as regards slagging* elements, are as follows:

	I.	II.	III.
Silica	50	10	20
Iron oxide (FeO)	20	70	10
All other bases	10	5	40

Assume 100 lb. of No. I as basis for the mixture. The slag produced is to have this composition, viz.: Silica, 40; Iron oxide, 30, and all other bases, 30 per cent. Find weights of the other two ores.

Answer.

No. I	100 lb.
No. II	37.1 "
No. III	113.7 "
Weight of ore charge	250.8 "

Proof.

	SiO_2.	FeO.	Bases
I	50.00	20.00	10.00
II	3.70	25.97	1.85
III	22.74	11.37	45.48
Totals	76.44	57.34	57.33

76.44 : 57.34 : 57.33 : 40 : 30 : 30.

(b) We have a calcined ore, to be smelted for matte with-

out any additional fluxes. The following assumptions are made as to action in the furnace, viz.:

All the copper enters the matte. Three-fourths of the lead and one-half of the zinc also go into the matte, taking precedence of the iron. All remaining sulphur goes into the matte as FeS.

One-half of the zinc goes into the slag, and one-fourth of the lead. All iron not in matte goes into the slag.

Take 100 lb. of the ore, find weight and analyses of matte and slag. No allowances for losses.

Analysis of the ore.

SiO_2	27.3	per cent
Cu	11.9	" "
Fe	37.5	" "
Zn	2.0	" "
Pb	1.0	" "
CaO	4.0	" "
S	7.0	" "
O and loss	9.3	" "
Total	100.00	" "

Answers.

Weight of matte per 100 lb. of ore taken = 26.65 lb.

Analysis of the matte as follows:

Cu_2S	55.91	per cent
FeS	35.27	" "
ZnS	5.63	" "
PbS	3.19	" "
	100.00	" "

Weight of slag per 100 lb. of ore taken = 73.35 lb. Analysis:

SiO_2	37.24	per cent
FeO	55.23	" "
CaO	5.45	" "
ZnO	1.71	" "
PbO	0.37	" "
	100.00	" "

(c) A partly roasted ore contains:

SiO_2	62.00	per cent
Al_2O_3	10.00	" "
Fe	14.42	" "
Cu	6.40	" "
S	4.51	" "

Take out matte Cu_2S + FeS, use for flux a limestone containing 10 per cent silica and 50 per cent lime. Slag is to be a bi-silicate, no special ratio being required as between bases. Find analysis of the slag.

Answer

SiO_2	56.38	per cent
Al_2O_3	8.07	" "
FeO	9.68	" "
CaO	25.87	" "
	100.00	" "

(d) Copper matte smelting, ... *flux except limestone.*

Analysis:

	Ore.	Ash of coke.	Limestone.
SiO_2	30.00	80.00	7.00
Bases	13.00	20.00	52.00
Fe	28.00	.....	.....
Cu	6.00	....	...
Zn	6.00	.	.....
S	12.00		.....
Def.	5.00	..	...
	100.00		

Calculate for 100 lb. ore. *Coke to be twelve and a half per cent of the ore.* Percentage of ash in the coke = 16.

Condition for slag is simply "Silica, 40 per cent, all bases, 60 per cent."

The following assumptions are made:

All copper goes into matte as Cu_2S.

Half of the iron goes into the matte as FeS half into slag.

Half of zinc for matte, half for slag.

Excess of sulphur over these requirements is supposed to be lost.

Find. First. Weight of the matte and its composition.

Second. Weight of limestone required.

Answers.

Weight of matte to 100 lb. ore = 34 lb.

Composition as follows:

Iron	41.2	per cent
Copper	17.6	" "
Zinc	8.8	" "
Sulphur	32.4	" "
	100.00	" "

Limestone required per 100 lb. ore = 28.92 lb.

The student wishing to acquire familiarity with this method of slag computation will find the exercises and illustrations here given quite enough to render its practice both convenient and rapid.

Circular on Regulations for Illuminating Gas.

The National Bureau of Standards is about to issue a circular entitled "State and Municipal Regulations for the Quality, Distribution and Testing of Illuminating Gas." This circular (133 pages, uniform in style with other Bureau circulars) has been prepared after conference and correspondence with a large number of gas engineers and inspectors; and it represents, as nearly as possible, the average opinion of many men active in the field of gas manufacture and gas testing.

Part I of the circular gives a summary of the municipal gas ordinances now operative, presents a general discussion of municipal gas requirements, and proposes an ordinance largely compiled from the best ordinance requirements now in force.

Part III quotes a few ordinances typical of those recently enacted and gives the main portions of state gas laws now in force affecting gas quality, pressure and meter accuracy.

The circular does not concern itself with financial regulation of gas companies, nor does it include any discussion of the comparative value of various methods of works management. It deals mainly with the candlepower, heating value, purity and pressure of the gas and gas meter testing.

The present publication has grown out of the investigation of the methods and standards employed in gas photometry and gas calorimetry, undertaken by the Bureau three years ago. A second circular on the methods of testing employed for official inspection work is now being prepared. Although it cannot be expected that the regulations for or methods of gas testing will ever be entirely uniform throughout the country, it is believed that if the results of a comprehensive investigation of the subject are published a greater uniformity of method, and in some cases more accurate measurements will result.

The attitude of the Bureau of Standards is entirely advisory and its intention is to place in the hands of the technical and general public an impartial and, as nearly as may be, an accurate summary of the facts which must be considered in connection with the fixing of standards of quality and the testing of illuminating gas.

Revision of the circular from time to time is contemplated in order to amend the recommendations as to the requirements to adapt it to new developments in the gas industry.

The circular is now in press and will be ready for distribution soon after April first. Copies may be obtained free of charge by addressing The Director, Bureau of Standards, Washington, D. C.

A Shaking Inclined-Screen Hydraulic Classifier*

BY LEWIS B. SKINNER.

A great deal of time and money has been spent in designing and developing various forms of classifiers. Almost without exception inventors have worked along the lines known as "direct" classification, i.e., a system in which, either with or without the addition of hydraulic water to the pulp, the coarsest particles are separated first and the slime last, with intermediate grades. This system offers the very serious objection that the finer grades become greatly diluted, especially when a hydraulic stream has been used in separating each of the coarser grades. This makes it necessary to thicken the fine grades, and introduces complications in mill design and operation. When, therefore, Dr. Richards advocated the use of "indirect" or "inverted" classification, wherein the slime could be eliminated first and the coarse grade last, with corresponding intermediate grades, he took a step in advance, and classification was simplified and improved.

Nevertheless, it has seemed to me that further improvements might be made in the Richards pulsator classifier by (1) providing means independent of the hydraulic water for transporting

FIG. 1—HENDERSON CLASSIFIER

the bed of ore along the supporting screen; (2) forming a more uniform bed of ore on the screen; and (3) making the device less sensitive to variations in feed. The first of these conditions was realized in a classifier designed by Mr. R. M. Henderson, manager of the Wellington Mines Co., Breckenridge, Colo. This classifier was described in METALLURGICAL AND CHEMICAL ENGINEERING, November, 1910, page 621. It is shown in plan and side elevation in Fig. 1.

In this classifier the hydraulic water is without pulsation, the feed flows by gravity down the 45 deg. inclined-bottom of the box and is acted upon by the streams of hydraulic water issuing through horizontal slots in the bottom. The first compartment receives no hydraulic water and gives an overflow of slime. The succeeding compartments receive increasingly stronger currents of hydraulic water and yield increasingly coarser products. The sixth product issues from a vortex sorting column beneath the fifth compartment. The discharge openings of the various compartments are arranged on a descending line parallel with the bottom of the classifier. Although Mr. Henderson says that this device gave excellent classification, it was still open to some criticism. The capacity was comparatively low and there was a tendency for the hydraulic water coming through one narrow slot at high velocity in each compartment, to force too much coarse pulp up into the various compartments, whence it would have to settle again with no hydraulic water or vibrating motion to agitate it before arriving at the next slot. This caused "banking up."

From the suggestion offered by this classifier, I thought that improvement might be made in the standard Richards pulsator by the use of a sloping instead of a horizontal screen. I built a machine placing the screen at an angle of 22½ deg. and got good results, but came to the conclusion that even less pitch would be better. The inclination of the screen made possible the use of gravity for the transportation of the ore, assisted by the vibration produced by pulsations. The largest particles rolled down the screen fast, the intermediate not as fast, while the lightest remained behind. In this way all particles tended to reach their proper compartments by gravity alone and were more properly acted upon by just the hydraulic current necessary to separate them from the balance of the material.

After experimenting with this machine I found classification materially improved, screen analyses and analytical work showing the different grades to contain coarse gangue and fine mineral. Instead of using fixed overflow gates on the different compartments I used adjustable slides with a comparatively small hole in each to regulate the quantity of hydraulic water drawn from each compartment. The slides were so arranged that the head of water in any compartment was about one inch *higher* than in the *preceding* compartment, thus reversing the condition in the standard Richards machine. By this arrangement the difference in head between the water column in the last and the first compartment tended to create a gentle flow of water counter to the ore stream, instead of parallel with it as in the Richards machine, thereby preventing fine material from getting beyond the compartment in which it should have been sorted out. The counter current, of course, would take the path of least resistance which would be at the top of the bed where the finer material would be.

I argue that if one wishes to dissolve a soluble gas in water he does not parallel the gas stream and the solvent stream. He has them run counter to each other. Just so, in a classifier, the ore stream should not be parallel to the water current, but should be opposed to it. This is possible in classification only by using gravity to move the ore, with the water flowing in the opposite direction; and in this type of classifier this can be done only by screen inclination.

The wearing of screens in this design was materially reduced. In the original machine the screen was changed every two weeks or so, until a punched screen was substituted for woven wire, and even then the wear was excessive, as the screen lasted only about three weeks. In the original Richards they cracked at the edges on account of the weight of the ore carried. With the inclined screen, however, it was necessary to make but one change of screens in over a year, and this change was necessary on account of the carelessness of a workman who damaged a screen which had been in service for nine months.

Further experience with the altered classifier just described convinced me that still greater improvement was possible, provided the different forces acting in the classifier could be brought under separate means of control, and each made to do its work independently of the others. Some form of the vibratory or pulsating motion is certainly desirable, but in order to be most efficient it should act as a separate force and not as a quality of the hydraulic water. The idea of the shaking classifier then suggested itself. In this, an eccentric motion imparted to the classifier box would act as a disentangling and transporting force, while non-pulsating hydraulic water would

*Part of a paper read before the Colorado Scientific Society, Denver, entitled, "A Critical Discussion of the Richards Pulsator Classifier." The original paper gives in detail the results of the author's investigations which led him to evolve the design of classifier presented in this abstract.

furnish the necessary sorting-column water. I tried to design a machine so as to shake the screen independently of the classifier box, but came to the conclusion that stuffing boxes would be too difficult to maintain; and, in addition, found an advantage in shaking the material in the sorting columns.

In the Richards pulsator classifier, the pulsating force is applied practically vertically in an attempt to keep the ore bed free and open, and to disentangle the pulp in the sorting column. It occurred to me that a shaking motion applied horizontally would more suitably maintain the ore in condition to be acted upon, by aiding materially in transportation, and that disentanglement in the sorting column would be more pronounced by a sidewise impulse than by a vertical.

The result of this study and experiment is the evolution of a classifier of the following description. See Fig. 2. A box adapted to be shaken longitudinally is divided into six vertical compartments, "C_1" to "C_6" with an inclined screen "S" placed between the compartments and the corresponding hutches "H." The inclination of the screen is not more than 15 deg. Hydraulic water without pulsation is introduced into the hutches, the velocity being regulated suitably for each compartment. The screen, so called, is in reality a miniature grizzly made of spring-brass bars 1/40" thick, spaced 1/40" apart. The space blocks are so placed as to come directly beneath the compartment partitions and thus avoid the formation of bare spots at those points. As mentioned before, the discharge openings in each compartment are arranged so that the head of water in any compartment is about one inch higher than in the preceding one.

In operation, the ore pulp is fed in the usual manner, and falls onto the inclined screening surface "S." The shaking motion tends to act strongly upon the heavy particles and less strongly upon the intermediate, so moving them at the desired velocities along the inclined screen, while the fine tends to remain behind. By using an inclination of only 8 deg. I tried to stratify the material as nearly as possible with the idea of picking off the lighter supernatant layers; but I found that the more nearly the screen approached the horizontal, the poorer the classification became; and that trying to use little hydraulic water in No. 1, more in No. 2 compartment and so on caused "banking up," variable distribution to tables and constant changes. When I arrived at an inclination beyond 15 deg. I found that, for our ores (silicious lead and zinc sulphides), the coarse material rolled down the screen too fast, with the shaking type, and that too high differences of head in the sorting columns would have to be maintained, i.e., the head in, say No. 6 compartment would be nearly three inches higher than in No. 5. This caused a too violent cross-current underneath the opening "F," so tending to disturb the quiet conditions sought Since the difference between the greatest inclination necessary and the least is only some five or six degrees, this adjustment may be provided for by raising or lowering one end of a standard design.

Since building the shaking classifier I have found that it would have been better not to design the machine with the screen at one continuous inclination, but to put the screen on a curve, or with a slight angular change in each compartment as shown in Figs 3 and 4. No water at all is needed under the feed compartment or under No. 1, as the overflow from No. 1 is the fine material that would not in any case quickly settle to the bottom of the feed compartment, but is held in suspension in the water fed in with the pulp and overflows at "D_1". At "C_1" the screen inclination should be pitched at a sufficiently

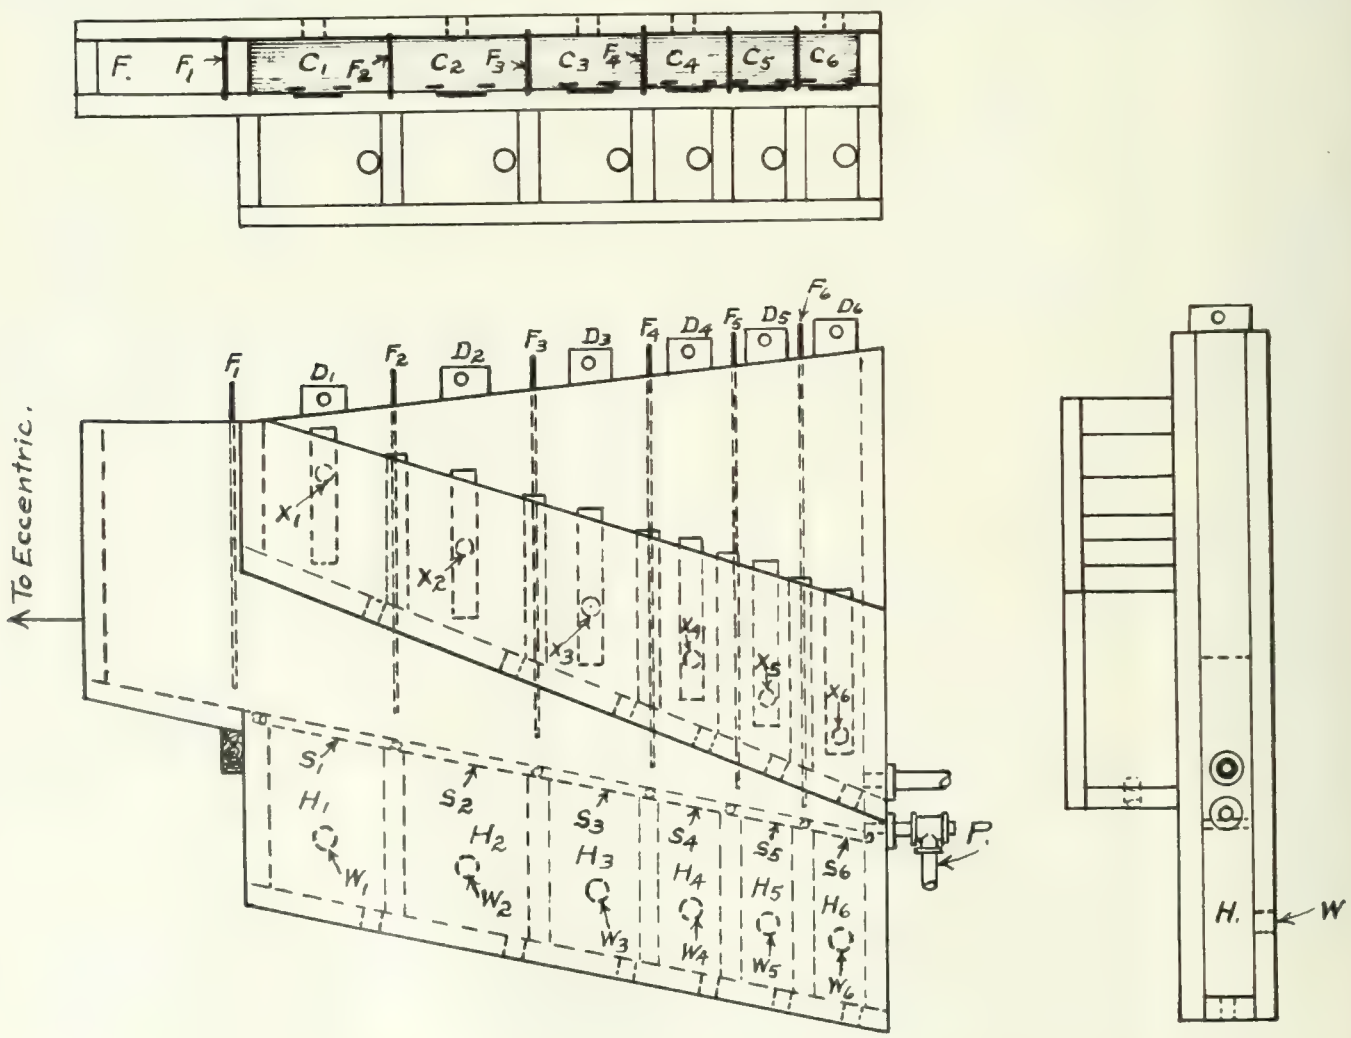

FIG. 2.—SHAKING CLASSIFIER.

steep angle to allow of the easy flow of the pulp which does settle. In falling through the column of water in the feed compartment and by being acted upon by this feed water rising, all the sorting effect that can be hoped for is had on the material (slime) which rises in "C_1." Slime pulp may be considered almost as a fluid for all practical purposes in ore dressing. At the No. 2 compartment the screen should have a slightly lesser pitch from the horizontal, as it is desired to retain coarser particles than those composing the slime in No. 1. At "C_2" the angle should be less than "C_2," as it is apparent that there is also a decreasing amount of ore as we pass along. The distance on the screen is less and we wish to retain certain sizes

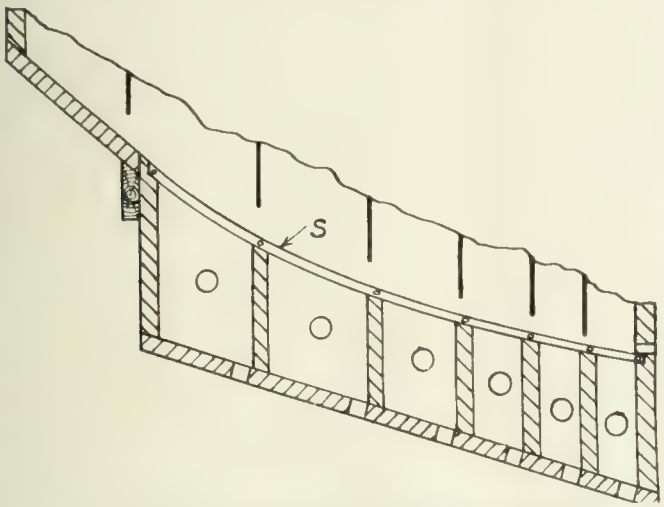

FIG. 3. SHAKING CLASSIFIER WITH CURVED SCREEN

continually growing larger which can remain behind at decreasing inclinations. In other words, the angles in each compartment should be steep enough to allow gravity to carry from it that material not desired in that compartment, without any need for water transportation; and at the same time it should not be so steep as to tend to cause those to roll away which should properly rise.

For classification I have found that the principle applied in magnetic work, that of selecting material from a layer "one particle thick," is much to be desired over that in which bedding or stratification is used, with a lifting off of supernatant layers. In the latter case there is too much tendency to entanglement. Further, with the "one particle thick" idea the hydraulic water may issue through all parts of the screen area in a given compartment at equal velocity, as there is not that resistance due to banks of ore, compelling the water to come through small parts of the screen area at a higher velocity than that in the sorting column above, and so blowing up oversize into this sorting column. It has actually worked out with the machine now installed that there is some accumulation on the screen in compartments 1 and 2, showing the necessity for increased inclination here. As a consequence, we have to use a little too much hydraulic water; but farther on the ore passes along so that there is no appreciable accumulation. I tried using a little more hydraulic water under Nos. 1 and 2, to prevent any apparent accumulation, but found, as I expected, that more oversize material would be discharged on account of the disturbance. Now, if the angle were greater, even less hydraulic water could be used in the finer size compartments than now, and better work had.

In regulating the inclined-screen shaking classifier, there is no damming of ore or "banking," and a proper regulation would be as follows: First, admit the pulp of as thick a consistency as possible; regulate the discharge slides so that the holes are as high as possible on No. 1, and as near the screen as possible on No. 6 compartment. These discharge holes, on a 6-compartment machine will run from 5/8" diameter on "D_6" to about 1¼" on "D_1" with the intermediate holes in proportion, the machine handling 50 to 100 tons per day. In passing it might be well, however, to call attention to the fact that the larger holes "X" at the first compartments will not actually discharge as much water as will the smaller at the back end owing to the difference in heads in the sorting columns.

The hydraulic water should be so regulated that no appreciable amount of ore can be felt on the screen. If this occurs, more hydraulic water must be used at the compartment where the bed has accumulated. If the screen is so bare that the small particles cannot be felt rolling down to the last compartment, some hydraulic water should be turned off. This should result in a proper division of pulp to the tables or other separating devices. Also, there should be a gradually reduced opening of the hydraulic water valves from "W_6" to "W_1," "W_1" opened little if any. Whether this has been properly performed may be checked by the result that there should be about an inch increase of head in each compartment from "C_1" to "C_6." If oversize shows on any table the gate "F" between its compartment at the classifier and the next below should be raised to allow this oversize to pass.

If, on account of the average screen analysis, the arrangement should not show definite progressions in elevation of the discharge openings "X," the holes "X" should be made larger or smaller to allow of a larger or smaller amount of sorting-column water to discharge. I have found it almost imperative on our ores, if a vortex sorting column is not used at the last, to have a seventh classification discharge from the screen level at "P." At the end of the classifier above the discharge opening "P" we have a ½" pipe connected to the water supply. This is for use of the workmen who may open it to throw on a little more water when the supply of ore is a little coarse and to shut off when there is a considerable amount of fine. This pipe valve, when opened and closed, possibly once in several days, saves the other adjustments from disturbance when once satisfactory. I have run for months without finding any need of change, as the sorting column velocities have the same effect on a given size, and the effect of gravity rolling a particle down the screen to its proper compartment is practically the same whether the tonnage is large or small.

Of course, the pulp delivered to the tables will be more or less diluted in proportion to the tonnage fed, with the classifier water remaining uniform, but all the tables receive their pro-

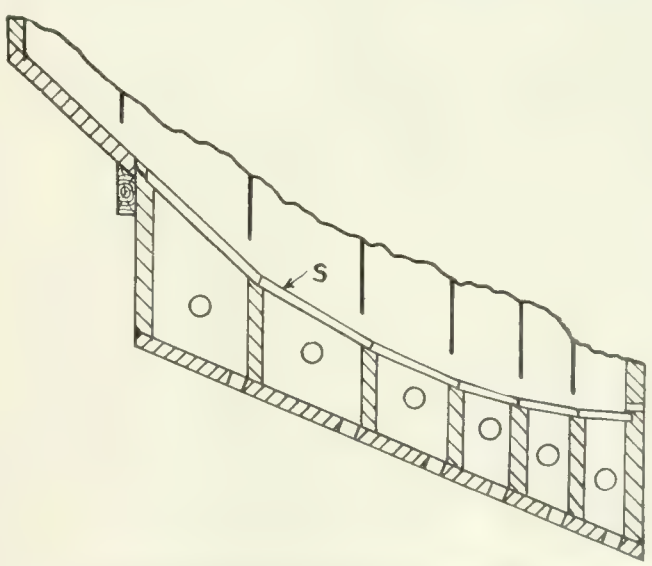

FIG. 4. SHAKING CLASSIFIER WITH CURVED SCREEN.

portionate amounts, and do not vary back and forth between the fine and coarse tables, as in a classifier where the tonnage and other variables determine the overflow in the different compartments.

To sum up: The machine itself is automatic or "fool proof," which, in any machine, is greatly to be desired. There is not

the necessity for continual adjusting by an expert to take care of variation of operation. Close adjustments may be made, and these only tampered with when the valves clog or changes are necessary from wear.

After having this design in mind for some time, I suggested its use to Mr. R. M. Henderson, and he built and installed two machines working on the inclined-screen and shaking principle. He informs me that the first installed did excellent work and

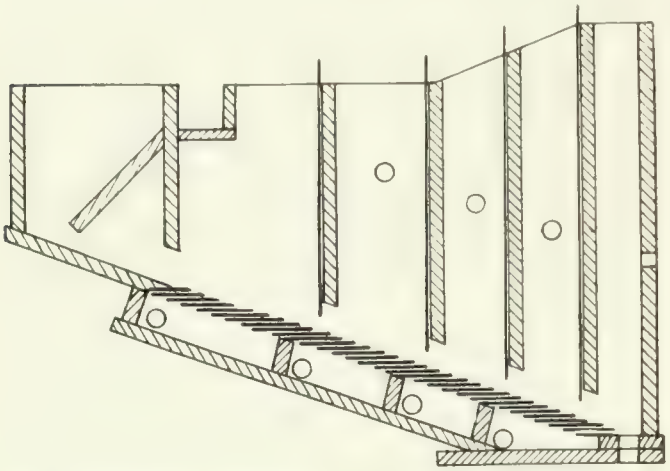

FIG. 5.—SHAKING CLASSIFIER WITH MODIFIED SCREEN SURFACE

that in his experience, he had never seen as good classification. The second classifier which he built at the Wellington Mill, was not so successful, due to his alterations in design of the perforated screening surface which tended to mix and disturb the ore. See Fig. 5. The falling from step to step as shown in this screen surface is objectionable, as will be seen if studied from the foregoing arguments.

Western Chemical Mfg. Co., Denver, Colo.

Belt Conveyors*

By Lincoln DeG. Moss.

During the war with the Seminole Indians, biscuits for the troops were baked at St. Augustine on a machine invented by W. R. Nevins of New York City, who employed an endless canvas belt conveyor running on flat idlers. During the 60's the Choice & Gibson brickmaking machines employed flat, endless belts to carry molded bricks from the pug mills to the stacks for baking. In the same decade Cook's magnetic ore separator was used at Plattsburgh, N. Y., for carrying ore from a vibrating hopper under a revolving magnet which left the rejected material on the belt to go to a waste pile.

Some eminently practical work was done by Lyster at the Liverpool (England) docks, described in the *Proc.* Mech. Engr., August, 1869. Finding that spiral conveyors in troughs lacked capacity and used a large amount of power, he experimented with endless bands. He developed several essentials, such as the "throw-off carriage," or tripper, so arranged that the dumping pulley could fold down and stop the throwing off of grain; a tripper which could discharge right, left, or back on the belt; the tension take-up; an endless, rectangular circuit with loading chutes and trippers on upper and lower levels. He also used rotary cleaning brushes and an air-blast brush. His tests showed that the helical conveyors required four times as much power to carry 50 tons per hour 100 ft.

He first used concentrating rollers, Chart 1, Fig. 1, to increase the carrying capacity of the belt, which had two plies of canvas covered uniformly with vulcanized rubber. He abandoned this carrying idler, using thereafter 6-in. straight, turned, wooden rollers, because the difference in circumferential speed at the body and rim of the concentrator roll caused a slip at the rim which wore out the belt edges. A point on his belt, which moved 8 ft. per sec. for 10 hours per day and 300 days per annum, would travel yearly over 86,000,000 ft. The central, 6-in. diameter of the roller governs, as it carries the major part of the load. At the 9-in. part of the cone the slip would be over 43,000,000 ft., which explains why his belt edges wore out. With the flat, cylindrical idlers used thereafter, which was the older American practice, he used two diagonal rollers, Chart 1, Fig. 3, to concentrate the load in the center of the belt at loading points.

In this country the Webster Manufacturing Company carried on such work for many years. Early in the 90's iron ore was carried in the Edison mines of New Jersey on belt conveyors. Scraper conveyors had been abandoned, owing to rapid wear. Belts of cotton and of cotton with a rubber cover were used. Concentrator idlers were tried and abandoned, as in England. Flat belts with continuous skirt boards followed, with this fault: Particles of ore got between the belt and the skirt board near the center of a span between two idlers, where the belt sagged under the load; these particles, lodging, cut the belt edges, in time destroying them when the skirt boards were moved in to accommodate the narrowed belt. When skirt boards are used at chutes their lower edges should be a thin sheet of steel, which will not permit a lump to remain long.

Next we note the experiments of Thomas Robins at the Edison plant. Not knowing the researches of Lyster, he learned the same truths. He tried two inclined concentrator rolls, and found that the belt did not "steer" true, but rolled into the apex of the angle at the two pulleys, cutting the belt. The next step was to add a third pulley set horizontally and in the wake of the two concentrators. (Chart 1, Figs. 7-8.)

Oil lubrication gave trouble, as some oil threw out centrifugally on the belts and ate holes in the cover. This must be carefully avoided when using idlers lubricated by oil. Although friction is greater with grease lubrication, Mr. Robins adopted it thereafter, using fixed hollow shafts, with the opening at the center of bearings. This formed collars of grease at the ends of the journals and made a perfect dust guard in the worst situations. Not only is this desirable for idlers in such service, but it is excellent for the main bearings of head and tail rollers, using solid shafts. Several very effective oil lubricated idlers are now made with dust guards.

The belts at first had a cover of uniform thickness, top and bottom. Mr. Robins next built his belts with a thicker carrying cover. This belt is now patented and is in very general use. Then noting that these new belts wore away faster in the center, he made still thicker center, either straight or tapered to the edges. He next made a belt like Chart 3, Fig. 2, which was very flexible in cross-section and had stiff edges to support the catenary between two idlers. His idlers finally were built in one plane, like Chart 1, Fig. 9.

The angle of inclination of the wing idlers was 45 deg. This caused too great a flexure on the belt and actually reduced its carrying capacity, which is maximum at about 30 deg. inclination. (See Chart 3.) An angle of 30 deg. is the maximum used at present, although some old installations using steeper angles are very successful. Troughing a belt has a commercial bearing by increasing its carrying capacity and decreasing the wear caused by the materials. A given quantity of material loaded on a wide belt will be shallower in depth and will cause more wear than when a narrow layer is applied and the rest of the load superimposed upon the first protecting stratum. Troughing such as can be secured by the natural flexure of a belt, without forcing, is not injurious. Belts of ordinary uniform construction will give a considerable natural trough when 24 in. wide and upward. Heavy belts are naturally stiffer than thinner ones.

A rubber belt is not homogeneous, being built up of a number of plies of cotton duck cemented together, under heavy pressure, with rubber. Makers call this the "friction." The built-

*Part of a Paper on Mechanical Conveyors in the *School of Mines Quarterly* (Columbia), April, 1912.

up plies are finally covered with rubber, and vulcanized under pressure. Much of the success of a belt depends on the "friction" between the plies. The purer the rubber used, the better the adhesion. This is usually tested by cutting a ply loose, 1 in. wide, hanging the belt vertically and attaching a weight to the loose strip, adding to it until the weight will just peel the strip loose. This value ranges from 7 or 8 lbs., with inferior belts, up to 26 lbs.; 16 lbs. is excellent.

As the belt bends over either end or tripper pulleys, or transversely by troughing, forces tending to separate the plies are set up, resisted by the elastic, tenacious rubber between the plies. Bending over pulleys is of more consequence than the bend of troughing, as the radius of pulleys is much less than the radius of the trough, and a belt is stiffer along its length than transversely; this is due to the construction of the canvas, which has long continuous longitudinal fibers, unbroken for as much as 400 ft., while the transverse fibers and threads are short, not quite as long as the width of belt, fewer in number, and disconnected.

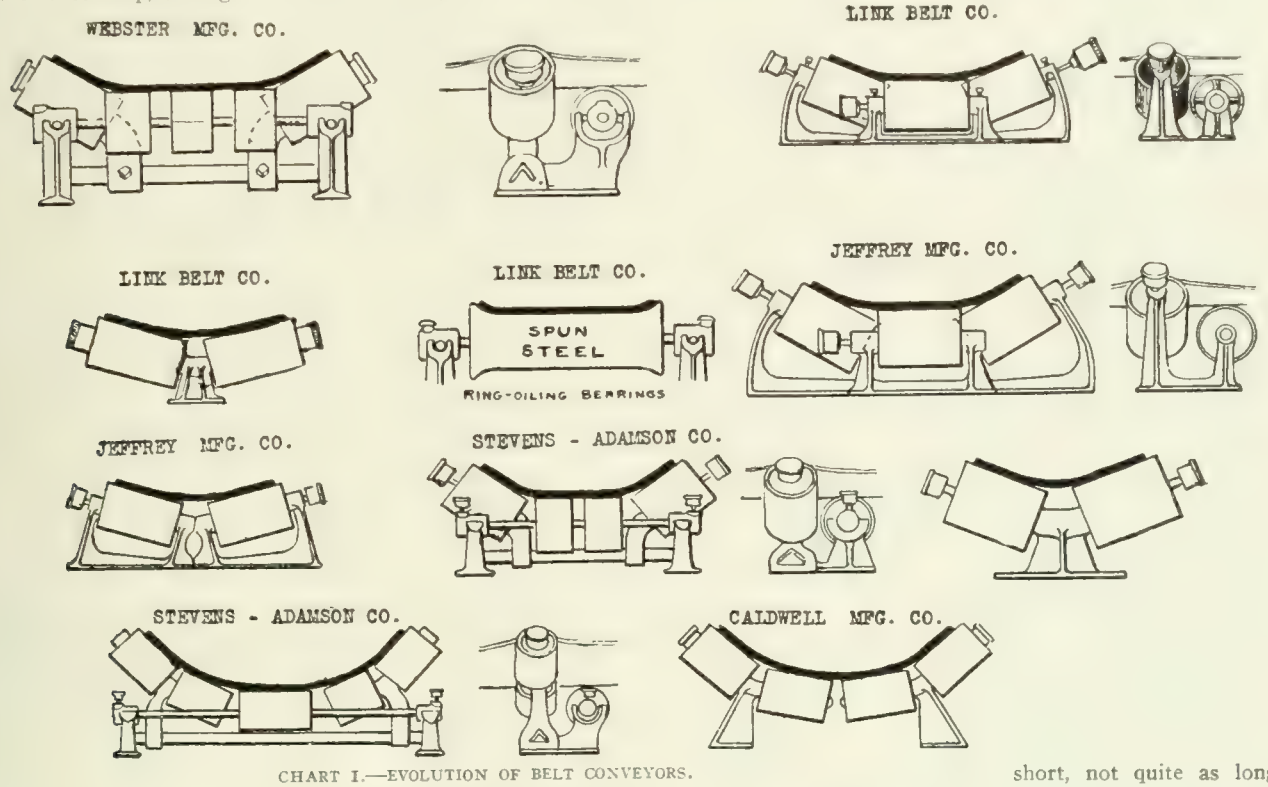

CHART 1.—EVOLUTION OF BELT CONVEYORS.

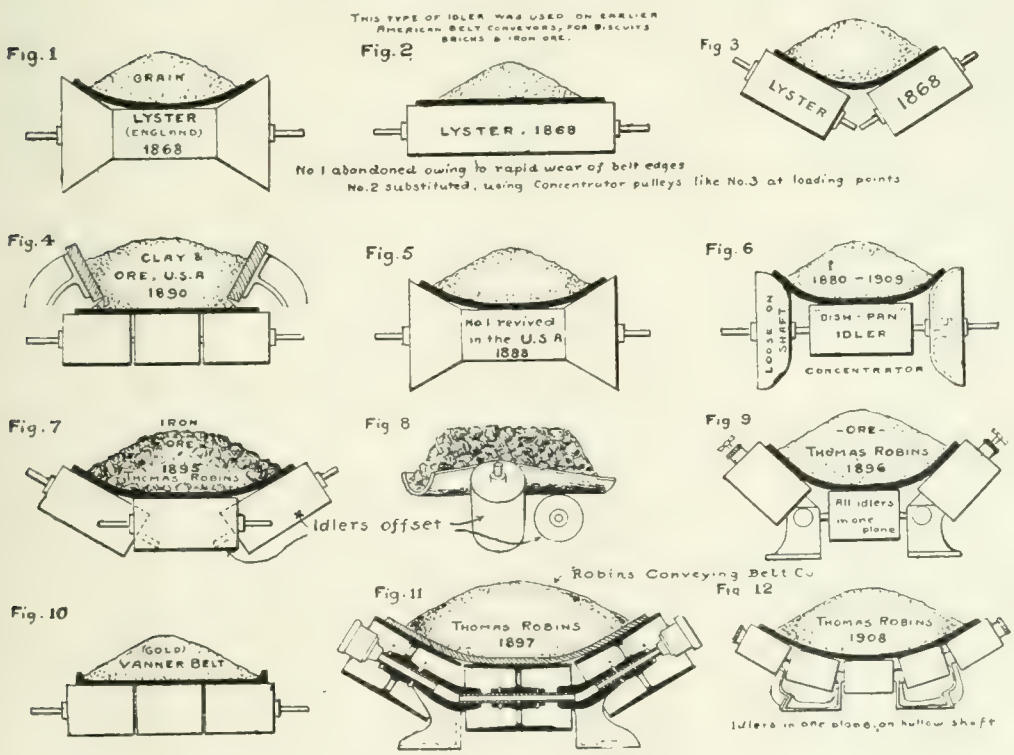

CHART 2.—EVOLUTION OF BELT CONVEYORS.

The wearing cover, for commercial reasons, is compounded with other materials to lessen cost. Success lies in skillful compounding, which will not depreciate the wearing quality to a marked extent. The percentage of adulterant can be found by burning a strip of rubber and noting the residual ash; pure rubber leaves none. A good friction test is valuable. The use of high-grade, long-fibered cotton duck adds tensile strength and increases cost. Tensile strength is not a prime requisite, especially at the high speeds of transmission commonly adopted. Some experts judge the quality of rubber by its taste, but that cannot be formulated. It is safer to trust a reputable maker whose reputation is at stake than to specify how he shall make a belt, for in case the durability is poor and the consumer has specified details of construction he becomes more or less liable.

The durability of a belt depends much on the manner of loading and operating; another factor is length. For a given output and speed, a spot on a belt 100 ft. long will come under a

loading chute twice as frequently as on a belt 200 ft. long and sustain twice the wearing effect of loading. If the chute delivers the material at a fair velocity, in the direction of the belt travel, the wear of loading will be reduced. If the material is fed in a thin, intermittent stream, the rubber cover will suffer much more than if the load is fed on continuously and the belt trough kept full. In the latter case, only a small percentage of the material ever touches the belt. Hence the important rule that a belt should be so proportioned to its load that it will be kept full, and operated at a speed which will require it to run full. When belts are installed with reference to future increase of carrying capacity it is better to operate at first at a low speed, and then change the gear ratio for higher speed at the larger output

If the material carries a fair percentage of fines, such as crushed ore, it is well to arrange chutes as made by Thomas Robins in his early work in conveying iron ore. These chutes had grills or screens which dropped the fines on the belt,

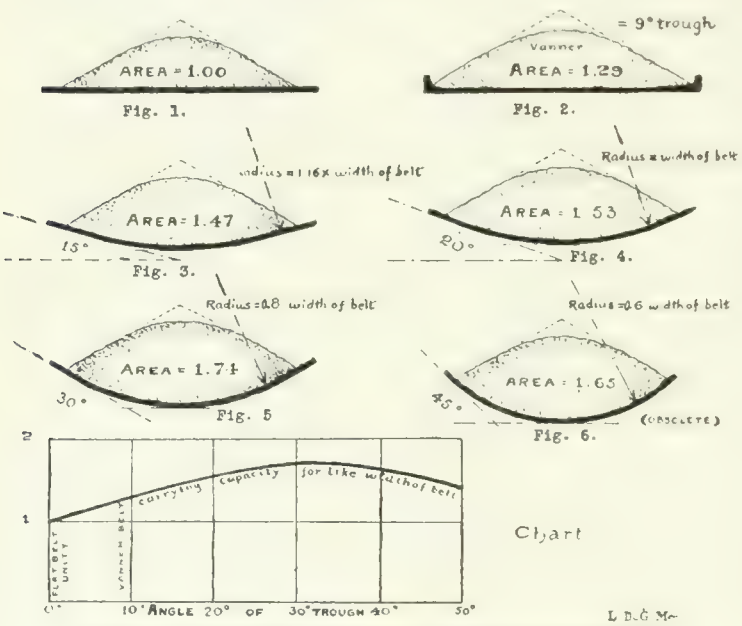

CHART 3.—CARRYING CAPACITY AS FUNCTIONS OF ANGLES

making a bed over its carrying surface to receive the large chunks. Badly arranged deliveries may destroy a belt in less than a week. The best record for durability which has come to my notice is at Louisburg, Canada, in the ship loading trestle of the Dominion Coal Company. Coal is accumulated in a 5,000-ton pocket by railway gondolas and is drawn off by a series of 36-in. Robins belt conveyors which elevate the coal to loading spouts which fill the hold of a 3,000-ton collier in four hours. The belts run at about 700 ft. per minute. The coal is bituminous, with few lumps. The present belt has carried over 3,000,000 tons and is good for more service. For steady, hard service we quote the conveyors of Jones & Laughlin, which supply their Eliza furnaces at Pittsburgh, Pa. The record for one year showed that the conveyor ran for 363 days, 9.2 hours per day, and transported 500 tons per hour. This is a Robins installation.

For a wide range of service, the plant of the New Jersey Zinc Company, at Franklin Furnace, N. J., uses over 200 belt conveyors which handle franklinite (a trifle lighter than galena) from man-size rock down to finely crushed sands, which pass through Wetherill magnetic separators. Many of these conveyors operate in clouds of heavy, gritty dust, which shut out view at a distance of 3 ft. The conveyors are Robins. Those used in the magnetic separation run on bronze pulleys. The hot sands are carried on canvas belts; the wet sands and rock are moved on rubber and canvas belts.

For coal, a life of 1,500,000 tons may be anticipated. For ores, 500,000 to 1,000,000 tons; sand, ashes, and coke follow in that order, coke being the most destructive. The belts are not suited for materials hotter than 150 deg. F., nor for carrying oily substances. They resist water, gases, alkaline or acid ashes, wet cement, and common salt. Many operate entirely exposed to the elements, in hot and cold climates. They resist abrading materials to a remarkable degree. They are not entirely waterproof, for the following reasons: Assume a dredge belt carrying wet tailings of gravel and stone. Fibers of the outer plies of cotton duck project up into the rubber cover, which is put on in a plastic state. The cover, when new, would be 3/16 to ¼ in. thick. As it wears down, these small fibers of cotton carry water into the body of the duck, setting up rot and separation between cover and canvas. Some sharp pointed stones may penetrate the cover down to the canvas and hasten this action.

In the South African mines, considerable balata belting is used for handling wet materials. The belt is composed of cotton duck cemented by balata gum applied at the consistency of milk, under heavy pressure. No vulcanizing is necessary. The heaviest duck used with rubber belting is 32-oz., open weave, to permit the plastic rubber to pass through and bond. With balata belting a 36-oz. duck, closely woven, may be used because the thinner, milklike juice will pass through more readily. For this reason, and also because no heat is used, which diminishes the strength of duck, balata belts are relatively one-fifth stronger. Several oils will dissolve balata gum which is obtained from the Dutch East Indies. The proper mixture of solvents and their elimination after the belt has been made, are trade secrets. It would seem that a belt having a homogeneous, waterproof, balata and canvas core, with a wear resisting rubber cover, would be an ideal conveying belt, provided that a stout bond can be made between the two materials.

The spacing of the troughing idlers should bear a relation to the weight of material on the suspended span between two adjacent idlers. The minimum spacing for heavy ores is 3½ ft.; for coal, 4½ to 5 ft.; for light materials, 6 ft. Return idlers carrying the slack belt may be set 10 to 15 ft. apart. The diameter of pulleys should bear a relation to the number of plies in the belt, just as we use certain ratios of rope diameter to sheave diameter. Other considerations enter. The larger the diameter of driving pulleys the lower the speed becomes, necessitating a larger and more wasteful gear reduction between pulley and motor. It is often difficult to arrange a delivery from the head pulley to the tail of another conveyor, even with small pulleys, and get satisfactory chutes.

Driving pulleys are generally made larger than tail pulleys and tripper pulleys. For rope transmission it is considered that all pulleys, whether drivers or carriers, should have like diameters, if the maximum life is to be obtained from the rope. At the driver the extension of the fibers is that due to driving tension plus the extension due to bending around the wheel. Thousands of belt conveyors are running with pulley diameters of 4 to 5 in. per ply of belt. We consider that a ratio of 6 in. per ply would be preferable if local conditions permit.

A head drive is cheapest and most desirable as a rule. Tail drivers are frequently used, especially when two conveyors are to be driven, one at its head, the other at its tail pulley, by a common motor. The journal pressure on the head shaft of a tail-driven conveyor will be twice that of one driven at the head. Center and intermediate drives are much used, but require more mill work than head or tail drives. It is generally preferable to drive a boom conveyor from the tail end. For heavy driving some very successful installations employ a modification of the old letter S American rope drive. The same principle is used in some Koeppe mine hoists, with two tan-

dem rope sheaves. This drive was first used on a 36-in. Robins conveyor 1050 ft. long between centers, which had a stacking tripper connected with it. This machine was used for filling in swamp land at Riker's Island, New York City, with ashes and dry city refuse. The drive transmitted 80 hp at the tail end, and has since been widely used.

Driving power is measured by (1) arc of contact; (2) tension; (3) coefficient of friction, in the same way that friction drives for Whiting or Koeppe hoists, cable drives and traction elevators are determined, using Rankin's formulas for endless bands. The arc of contact may be increased by using a snub pulley behind the driver. In most examples this snub pulley is entirely too small. The letter-S drive will give twice the arc of contact obtained by a snubbed driving pulley. In driving cables with two drums, the leading drum performs over two-thirds of the work. That is probably true of the letter-S drive applied to belt driving.

The coefficient of friction may be raised from 0.2 to 0.3 by lagging the pulley face with rubber belting bolted to the pulley face with countersunk bolts. Some slippery materials will decrease the coefficient of friction, the fine dust getting between the pulley face and the belt. Water also reduces the coefficient of friction, which explains why we have quoted 0.2 and 0.3 for designing.

The working tension should not exceed 20 lb. per inch width of canvas per ply, nor should it exceed one-fifteenth the ultimate strength on account of the splices, which are made preferably by butting the belt ends together, holding the two ends by tension belt clamps, and connecting with Crescent or Bristol steel belt hooks. It is advisable to pierce the holes with a sharp tool before driving in the lacings, which are clinched on the inner side. Patches may be put in by the same method. Mr. Lyster in 1868 discarded pneumatic sweeping because it required much more power and wore the belt; he therefore used a rotary brush, which was not altogether satisfactory That holds true to-day. In moving damp materials, when cleaning is most desirable, the brushes clog and do little effective work. A water jet spray has been used when moving wet concrete.

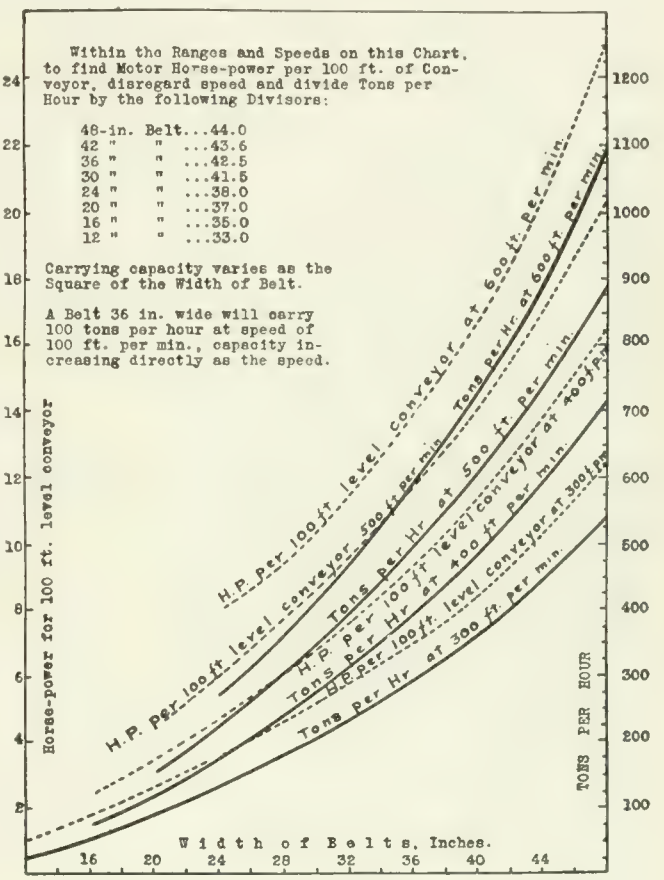
Trippers may be fixed, movable by hand, or moved by power derived from the belt. Fixed trippers require more power, in proportion to the number used, and are justified in few cases. For example, if colliers are to be loaded, taking coal simultaneously at bow, midship, and stern hatches, a fixed tripper at the first and second fixed point and one end delivery for the third point would be the most economical arrangement, the first tripper taking off one-third and passing two-thirds over to the second tripper, which would take one-third and pass the remainder to the end pulley. Over a boiler house bunker, however, with three fixed trippers, and dumping at one point at a time, the coal would be lifted over each preceding tripper and dropped back on the belt, causing needless wear and wasted power.

A hand-propelled tripper running on T-rails will answer in most cases, for, as a rule, trippers are not run back and forth to spread the material, but are clamped down to the rails to build a conical pile and then moved a few feet so as to deliver on the crest of the cone. The extra expense of automatic trippers is often unjustified. The framing of a tripper should be very stiff and substantial, for if elastic the two belt pulleys in the tripper will deflect and cause the belt to run to one side. To correct a tendency to run to one side along the line of the belt, the idlers should be arranged to be canted, by slotting the feet of the pedestals at the bolt holes. Side-guide idlers should be used as little as possible to avoid wearing the belt edges. It is better to train the belt by canting the idlers and end pulleys.

Power Capacity and Efficiency of Belt Conveyors.

Up to the present time these factors have not been well understood, for two reasons: (1) This form of conveyor has been in general use for heavy work, for little more than twelve years, since it was made practical for coarse and heavy materials by Thomas Robins. (2) The engineers concerned in its development have had little time to spare for analysis of the phenomena of this interesting transporter. To aid in clearing up these questions I have prepared Charts 3, 4, and 5. When we cease to generalize, and group observations and data with care, consistent curves of performance, power, and efficiency can be plotted.

For uniformity I have referred efficiency back to the motor input, which can be measured by the wattmeter at the motor



Within the Ranges and Speeds on this Chart, to find Motor Horse-power per 100 ft. of Conveyor, disregard speed and divide Tons per Hour by the following Divisors:
48-in. Belt...44.0
42 " " ...43.6
36 " " ...42.5
30 " " ...41.5
24 " " ...38.0
20 " " ...37.0
16 " " ...35.0
12 " " ...33.0
Carrying capacity varies as the Square of the Width of Belt.
A Belt 36 in. wide will carry 100 tons per hour at speed of 100 ft. per min., capacity increasing directly as the speed.
H.P. per 100 ft. level conveyor at 600 ft. per min.
Tons Per Hr at 600 ft. per min.
H.P. per 100 ft. level conveyor at 500 ft. per min.
Tons Per Hr at 500 ft. per min.
H.P. per 100 ft. level conveyor at 400 ft. per min.

CHART 4.—CARRYING CAPACITY IN TONS PER HOUR

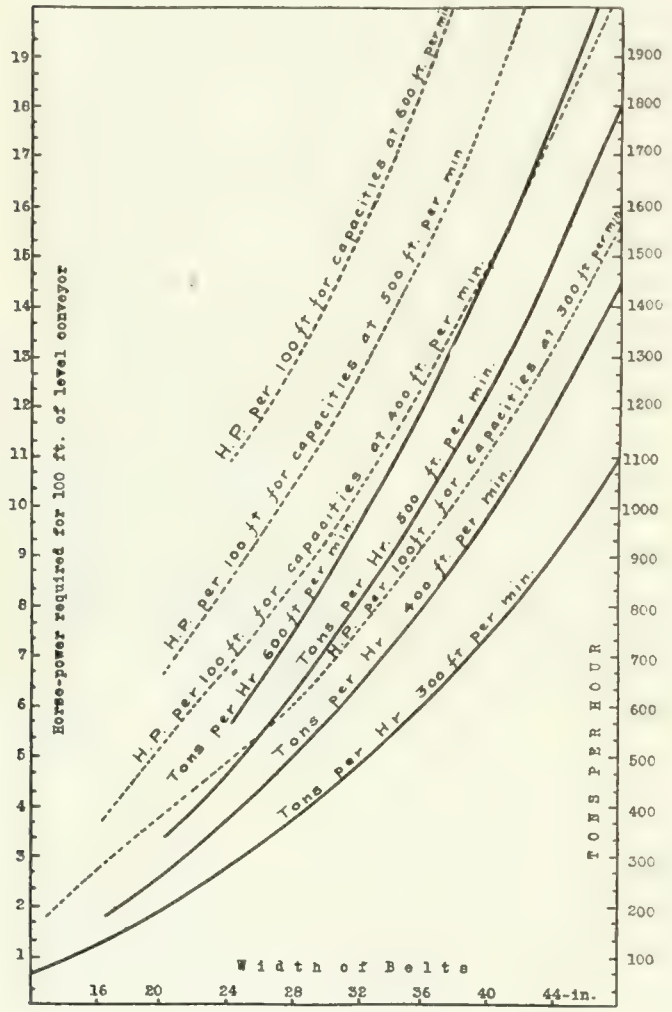
Materials weighing 50 lbs. per cu. ft. Belts troughed to 30° from horizontal trough section equivalent to 1.7 that of flat belt. Also horse-power per 100 ft. of level conveyor. Grease lubrication. For each fixed tripper add 5%, but not less than 0.8 hp. For moveable tripper add 6%, but not less than 1 hp. For lifting on inclines add tons per hour × feet lift ÷ 900.

terminals, and is equivalent, as nearly as possible to the indicated horse-power of a steam engine. This seems more just than to disregard the friction loss in the gearing between conveyor driver pulley and the motor, and to omit the inevitable losses in the motor, as some writers have done.

The great effect on efficiency due to varying density of the materials carried has been generally overlooked, which is also true of observations on conveyors carrying very light loads. One gentleman has stated that his conveyor consumes 90 per cent of the total power in friction; he was without doubt correct. For example, a certain conveyor has a 30-in. belt, 386 ft. long on its carrying side, moving 348 ft. per minute, and carrying 40 tons per hour. It used 13.4 hp with no load and only 14.0 hp when fully loaded, showing 96 per cent friction loss. Another gentleman has a 30-in. conveyor, 400 ft. long, moving 400 ft. per minute and carrying 600 tons of ore per hour. The light power was 15.3 hp, which rose to 33.7 hp when carrying full load, giving a friction loss of about 46 per cent. Each observer was correct. The power required to run a given conveyor with no load, is exactly the same, regardless

of the quantity and density of the material to be fed to the belt, whether it be feathers or galena. But the friction loss in handling a load of feathers would be over 99 per cent, and would fall to less than 40 per cent when carrying galena on the same conveyor.

The wide discrepancy in the efficiency of the two 30-in. conveyors referred to can be further understood by studying Charts 5 and 6. The performance of a 36-in. conveyor, 100 ft.



Horse-power required for 100 ft. of level conveyor
TONS PER HOUR
H.P. per 100 ft. for capacities at 600 ft. per min.
H.P. per 100 ft. for capacities at 500 ft. per min.
H.P. per 100 ft. for capacities at 400 ft. per min.
H.P. per 100 ft. for capacities at 300 ft. per min.
Tons per Hr 600 ft per min.
Tons per Hr. 500 ft. per min.
Tons per Hr 400 ft. per min.
Tons per Hr 300 ft per min.
Width of Belts
16 20 24 28 32 36 40 44-in.

CHART 5.—CARRYING CAPACITY IN TONS PER HOUR.

Materials weighing 100 lb. per cubic foot. Belts troughed to 30° from horizontal; trough section equivalent to 1.7 that of a flat belt. Also horsepower per 100 ft. of level conveyor. Grease lubrication. For each fixed tripper add 5%, but not less than 0.8 h.p. For moveable tripper add 6%, but not less than 1 hp. For lifting on inclines, add Tons per hour × Feet lift ÷ 990.

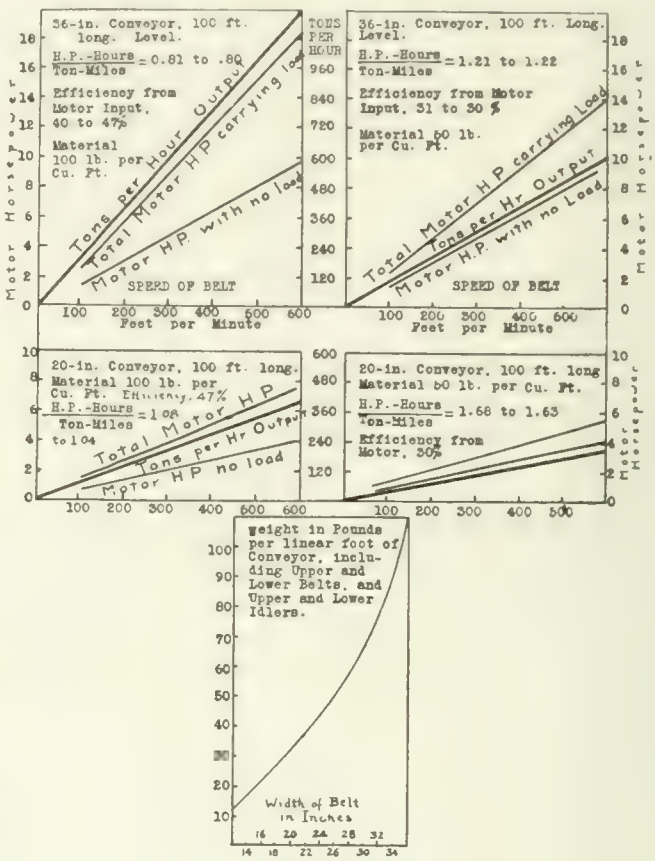
Carrying capacity varies as the square of the width of belt. At every speed in the range on Chart 5 with materials weighing 100 lb. per cubic foot, for every 100 ft. of level conveyor, the following horsepowers are required:

With	48-in.	belt, H.P. =	T. P. H. ÷ 70
"	42	" H.P. =	T. P. H. ÷ 67
"	36	" H.P. =	T. P. H. ÷ 64
"	30	" H.P. =	T. P. H. ÷ 61
"	24	" H.P. =	T. P. H. ÷ 54
"	20	" H.P. =	T. P. H. ÷ 50
"	16	" H.P. =	T. P. H. ÷ 50
"	12	" H.P. =	T. P. H. ÷ 50

long, at speeds up to 600 ft. per minute, is shown, first, when carrying materials weighing 100 lb. per cubic foot, and, second, when carrying materials weighing half as much. For comparison, the performance of a 20-in. conveyor is shown just beneath, handling materials of the same weights per cubic foot.

The total power loss when handling materials weighing 50 lb. per cubic foot is about 70 per cent for either 36-in. or 20-in. conveyors. Of this, about 15 per cent is lost within the motor, and 15 to 20 per cent more in the gear reduction between motor and driver pulley of the conveyor. The gear-reduction loss depends on the quality of materials, proper proportions, with accurate lining and leveling of boxes, and the gear ratio. If the driving pulley is large, the belt speed is low, and the motor speed high, with bearings not proof against grit, the gear reduction loss may reach 40 per cent, and rarely falls below 15 per cent. The conveyor by itself will show 30 to 50 per cent friction loss at the driver pulley.

These charts, I hope, will prove valuable to the profession. Their use will save time in calculations, which require cum-



36-in. Conveyor, 100 ft. long. Level.

Width of Belt in Inches

CHART 6.—EFFICIENCY OF BELT CONVEYORS.

bersome formulas, made in some cases from incomplete and inconsistent data. Carrying capacity may be found by simple inspection for belts from 12 to 48 in. wide at speeds up to 600 ft. per minute. For a given belt, capacity varies directly as the speed, and in direct proportion to the increase in weight of material per cubic foot. For different widths of belts, capacity varies as the square of the width. The motor horse-power per 100 ft. of level conveyor may also be found by inspection. Allowance for grades may be added or deducted by the formula: $T.P.H. \times Ft.$ difference of elevation of receiving and discharging end ÷ 990. Allowance for trippers is made as noted on the diagrams.

The load-carrying cross-section is taken at the most economical troughing which can be obtained by the troughed belt, viz., 1.7 times that of a flat belt of equal width. (See Chart 3.) If flatter troughs, of less carrying capacity, are used, reduce the tons per hour shown on Charts 4 and 5 in proportion, referring to Chart 3. The horse-power will not fall in proportion, because a reduction in carrying capacity of trough does not affect the fixed friction at no load, and it is generally necessary to use a size larger belt to carry the required tons per hour. Data on conveyors having belts wider than 36 in. are meagre, but when properly used fall into the curves as shown. One exceptionally wide belt is in use, a 60-in. Robins, used as

a picking belt for separating barrels, mattresses, bed springs and coarse waste from city refuse.

Designers will find some handy short cuts to results noted on the charts. Especially interesting is the fact, which could not have been discovered without these performance curves, that the power required to operate a given conveyor, 100 ft. long, at any speed up to 600 ft. per minute, may be found at once by using a divisor into the tons per hour to be carried. These divisors for different widths of belts are noted on Charts 4 and 5.

By applying the ton-mile method of comparison we find the simplest of all short cuts. To find the power required to move a given tonnage we may ignore the size of the conveyor and its speed, and simply allow 0.8 to 1.2 hp-hour per ton-mile when the material weighs 100 lb. per cubic foot. For materials weighing 50 lb. per cubic foot, allow 1.2 to 1.8 hp-hours per ton-mile. The smaller figures apply to the largest conveyors, the higher constants to smaller conveyors.

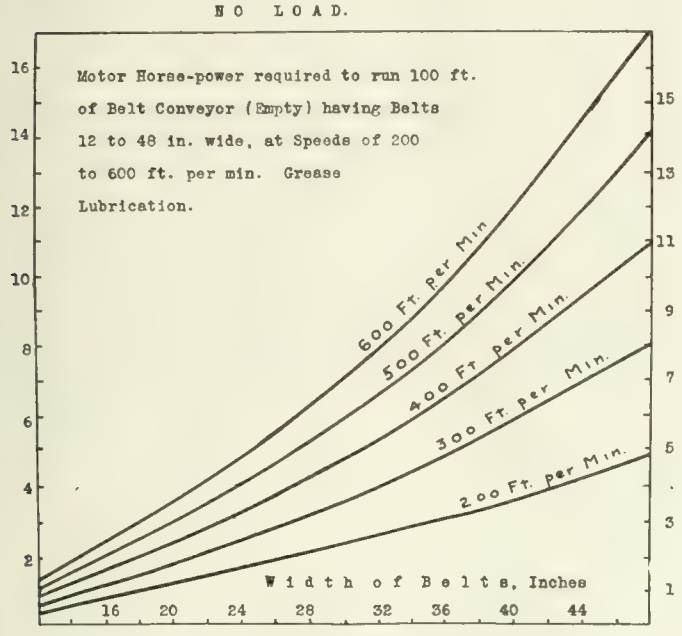

CHART 7.—HORSEPOWER REQUIRED.

Large Conveyors.
T.-M. in 10 hr. x 0.08 to 0.12 = motor h.p., materials 100 lb. per cu. ft. at any speed.
Small Conveyors.
T.-M. in 10 hr. x 0.12 to 0.18 = motor h.p., materials 50 lb. per cu. ft. at any speed.

To lift a load diagonally, belt conveyors may be inclined generally up to 21 deg. At steeper angles there will generally be a small slip backward, which is injurious to the rubber cover. On grades, an unbroken stream should be maintained if possible. Coal is elevated in one case on an angle of 27 deg. by keeping a steady flow from the hopper, which prevents the coal from slipping down. Cement fresh from the mills cannot be carried up an incline unless it is first passed through a short screw conveyor, which expels the entrained air.

The most conspicuous use of belt conveyors as elevators is in the New York subway power house, where coal is elevated by a series of Robins belts, arranged on the switchback principle, to the monitor over the bunkers. The shortness of these switchback conveyors, compared with the long tunnel conveyor and the long distributing conveyors over the bunkers, makes a noticeable decrease in their belt life, for reasons stated earlier.

In an ore mill which runs night and day, a 30-in. Robins elevating conveyor is in use for elevating 500 tons per hour of very heavy, sharp ore, reduced to coarse sand weighing 125 lb. per cubic foot. It contains a percentage of freshly broken quartz, very sharp and angular. This displaced a pair of first-class bucket elevators, which gave much trouble owing to the large capacity, high strains, lift of 80 ft., and the rapid wear by the very abrasive sand. The angle is 23 deg., which should not have exceeded 20 deg., as there is an injurious slip on the belt cover. In this case the fall of a heavy bucket elevator meant a serious and expensive delay, whereas the belt gives signs of distress long before it will fail, and even if the belt pulled apart, the trouble would not be serious.

Generally, we believe that it is better to elevate by bucket elevator and distribute by belt. Belt conveyors have sometimes been improperly used as elevators. Elevating boom conveyors with 30-in. belts, on booms 80 to 90 ft. long, at angles of 20 to 22 degs., are in general use on Western gold dredges for carrying away the wet gravel tailings. A 36-in. Robins belt on a Danube dredge carries 1000 metric tons of gravel per hour. A barge with a reversible pivoted boom conveyor was supplied by the Link-Belt Company, of New York City. Another similar machine was built by the Webster Manufacturing Company for handling limestone on the Great Lakes.

When using the charts for estimating carrying capacity, allowance must be made for the size of lumps in the material. Mine-run coal from the West Virginia fields frequently contains lumps as large as a man's body, requiring a 36-in. belt. Ordinary mine-run bituminous coal has been successfully carried on 24-in. belts. Foundry coke requires a belt 30 in. wide, and ordinary coke a 24-in. belt. Belts for grain require about 4 hp-hours per ton-mile because the material is so light. An 18-in. belt will carry 50 tons per hour and will require 3.8 hp per 100 ft.

Structures for belt conveyors are light, owing to the lightness of the conveyor. (See Chart 6.) Trippers with stiff cast-iron frames range from 1000 to 3000 lbs. When trippers are used on trussed spans, do not forget to put in counters for the rolling concentrated load. Lateral stiffness is very important, to keep the idlers in line; otherwise the belt will not run true. Vertical deflections are of no consequence as regards the running of the belt. A continuous, dirt-tight deck over the return belt is very desirable. This may be worked out into a very stiff system of lateral bracing. A low house with hinged inspection doors is an economical method of covering. A walk alongside, for greasing, inspection and cleaning, is required. Many belt conveyors operate outdoors in all extremes of climatic conditions, with no covering. On exposed trestles, high winds may blow the light belt out of the troughing idlers. To prevent this, a low wind-break fence has been built up on one side, in a few cases.

A conveyor with ball-bearing idlers has been introduced by the Conveying Weigher Company of New York. The diameter of the idler pulleys is 2-3 that of other makers, as the friction is less. A conveyor for carrying coal has been in use for two years, and shows a reduction in power consumption of one-third. The bearings receive no lubrication, being greased with vaseline when first assembled, and closed with felt washers.

The use of aluminium in water purification was first suggested by Brandes and Neff, who took out patents and put their invention on the English market under the name of the "luminator." They claimed that water passed through a launder of aluminum exposed to sunlight was so affected as to cause little or no trouble from the formation of scale in boilers. This invention has been used at various places with greater or less degree of success, but no scientific explanation of the action has been made. Mr. William Cullen, past president of the Chemical, Metallurgical and Mining Society of South Africa, describes in the March, 1912, *Journal* of that society his experiences with a "luminator." He found that its use softened a very hard scale already formed in a boiler, and that the subsequent formation of scale was much reduced. The matter should be an interesting subject for scientific investigation.

Temperature and the Properties of Matter.

By E. F. Northrup

Our understanding of what we term heat is a deduction from phenomena of which we have a direct sense perception. Heat is not directly perceived by any of the senses, but temperature is. In addition to the five senses ordinarily assigned, there is undoubtedly a true temperature-sense. This temperature-sense is more delicate than is ordinarily supposed. If you plunge your finger first into one glass of water, and then into another, you can feel that they are unlike in temperature if they differ by so little as ¼ deg. C. Our temperature-sense for which we probably have an independent set of nerve fibers, only enables us, however, to perceive accurately small *differences* in temperature; the absolute value of any temperature can be judged only very roughly and through a range of but a few degrees. In an analogous way the ear can perceive with great exactness small differences of pitch between two notes, but a keynote must be sounded upon an instrument to enable, in most cases, even trained singers "to get the pitch."

Since our temperature-sense is insufficient to furnish an accurate scale of temperature resort must be had for this purpose to some physical modification in one of the properties of matter which occurs in a regular way with temperature change. The physical means which has been most successfully adopted for establishing a scale of temperature is the change which occurs, when the temperature changes, in the pressure of a gas enclosed in a vessel of constant volume. It is approximately true that the pressure of nitrogen gas, when its volume is maintained constant, is proportional to its temperature and that the pressure of this gas diminishes 1/273 of the pressure which it has at the temperature of melting ice, for every degree centigrade that its temperature is lowered. Hence, if the law continued to hold and the temperature were lowered 273 deg. C. below the temperature of melting ice the gas would have no pressure. The law does not so hold with any actual gas. But Lord Kelvin has shown from thermodynamic considerations that the performance of an ideal gas, in which the law does hold, may be used to assign the lower limit of temperature and to establish an absolute scale of temperature. If a gas has no pressure this means that it is incapable of doing any work, such as raising a piston in a cylinder—or in other words the gas has been robbed of all its energy. When matter has no more energy we speak of it as being absolutely cold and, in a sense, it is dead. The absolute zero of temperature, upon the arbitrary centigrade scale, is, then, 273 deg. C. below the temperature at which ice melts and 373 deg. C. below the temperature at which water boils under the standard pressure of 760 mm of mercury.

The establishment and the increasing of the range of the so-called scale of gas-thermometry has occupied the labors of many physicists of the first rank. The most notable advances in gas-thermometry have been made within the last few years at the Geophysical Laboratory at Washington, D. C., of which Dr. Arthur L. Day is director. In a publication* from this laboratory dated February, 1910, the statement is made that the nitrogen-gas-thermometry scale has been extended by direct observation to the upper limit of 1550 deg. C. with a plus or minus error not exceeding 2 deg. C. Here it must be noted that all extensions of the thermodynamic absolute scale of temperature above this temperature are in the nature of extrapolations. An extrapolation based upon the thermal e.m.f. of a platinum-rhodium thermo-couple has been made up to the melting point of platinum. Other and higher extrapolations are all based upon the assumed truth of two prominent laws of radiation-pyrometry. Extrapolating to the melting point of platinum by the above two methods the agreement is such as to justify an assignment of 1755 deg. C. with a plus or minus error not exceeding 5 deg. C. as the temperature upon the absolute thermodynamic scale at which this metal melts. All that we know of temperatures beyond this is learned solely from the radiant properties of matter.

To fix the scale of temperature up to the melting point of platinum so that this scale may be readily reproduced in any part of the world, physicists have sought for properties of matter which change in a distinct and reproducible way at various points along the temperature scale. Thus for the range of temperature between the freezing and vaporization of mercury, namely 39.5 degs. and 357.2 degs. C. the volume-expansion of this metal in glass or quartz thermometers has proved most convenient. For lower and higher temperatures other properties of matter must be used as reference points. Of all the properties of matter which change with temperature the four which have seemed best to meet the requirements are: the expansion of liquids or solids, the change in the electrical resistance of metals, the thermal e.m.f.s in electric circuits of unlike metals, which have junction points at different temperatures, and the change of state or melting of pure metals and salts which occur sharply at definite temperatures. The most important work of recent years in the fixing of the upper portion of the scale of temperature to the melting point of platinum, has come from the Geophysical Laboratory. The chief object has been to determine very precisely at what temperature, according to the nitrogen-gas-thermometer certain metals and salts, easily obtainable is a state of purity, melt, what e.m.f.s are produced in certain thermo-couple thermometers of standard composition, and how the resistivity of pure platinum varies with the temperature. This work has been largely supplemented, especially in reference to platinum-resistance-thermometry, by the work of the Bureau of Standards at Washington. The fixed temperature points at which standard substances melt and which form a temperature scale by which temperature measuring devices may be calibrated are given in the following list:

The American Journal of Science, Vol. XXX, July, 1910, page 6.

Ice, m.p.	0.0°
Water, b.p.	$100.0° + 0.037\ (p - 760)$
Naphthalene, b.p.	$217.7° + 0.057\ (p - 760)$
Benzophenon, b.p.	$305.4° + 0.063\ (p - 760)$
Cadmium, m.p.	320.2°
Zinc, m.p.	418.2°
Antimony, m.p. (in CO)	629.2°
Silver, m.p. (in CO)	960.0°
Gold, m.p.	1062.4°
Copper, m.p. (in CO)	1082.6°
Diopside, m.p.	1391.2°
Nickel, m.p. (in N_2)	1452.3°
Cobalt, m.p. (in N_2)	1489.8°
Palladium, m.p.	1549.2° within ± 2° C.
Platinum, m. p.	1755.0° within ± 5° C.

With these fixed points assigned any thermo-couple of platinum and platinum-rhodium may have its curve of temperature against thermal e.m.f. determined in any part of the world, when it in turn becomes a secondary standard for the measurement of temperature to the melting point of platinum within an accuracy at the upper limit of approximately 5 degs. One has little conception of the long and painstaking investigation which has been required to obtain the above list of fixed temperature points. Dr. A. L. Day remarks (Trans. of the Faraday Society, p. 145, Nov., 1911): "The way is now open for a direct and accurate calibration of radiation pyrometers throughout the region between 900 degs. C. and 1550 degs. C., which should afford a much more certain basis for extrapolation to those extreme temperatures which no laboratory apparatus can withstand."

The methods of optical pyrometry can only be referred to here as the subject is an extensive one. Suffice it to say, that they depend upon two laws of radiation, one known as the Stefan and Boltzmann law, which states that the total energy which is radiated from the bottom of a deep hole in a body

RELATION BETWEEN TEMPERATURES AND FACTS KNOWN EXPERIMENTALLY

other is known as Wien's law which states that as the temperature of the radiating source is changed the wave length having maximum energy in the spectrum will be changed in such a way that the product of this wave length and the corresponding absolute temperature of the source, is constant. Or otherwise expressed when the temperature increases the wave length of maximum energy shifts toward shorter wave lengths.

The first law is made the basis of pyrometers of the Féry type in which the total radiation from the black body source is focused upon a thermo-junction. The temperature being measured is then interpreted in terms of the deflection of a galvanometer, which if desired, may be automatically recorded. The second law is made the basis of a variety of optical pyrometers, known under such names as the Wanner, the Le Chatelier, the Morse, etc. As in all these the temperature is interpreted by means of the eye automatic recording of the temperature has not been effected. All radiation pyrometers must be calibrated empirically, the calibration extending from about 900 degs. C. to the melting point of platinum. Above this temperature the curve which is assumed to obey the radiation law is a curve of exterpolation, upon data given by the gas-thermometer.

The very high temperatures which are assigned to the sun and stars, to the interior of electric furnaces, or to the positive crater of the electric arc, must all be estimated—one can scarcely say measured—by radiation pyrometers which operate over the extrapolated portion of their calibration curve.

Physicists feel confident as to the lower range of the temperature scale, but its upper limits can only be conjectured. No one pretends to know what inconceivable temperatures may exist in the interior of blazing suns. The surface temperature of some of the stars has been estimated, upon the basis of optical pyrometry, to be 10,000 degs. or more. We will try to help out our imagination of the portion of the temperature scale which has been observed and our corresponding knowledge of the properties of matter at various points along this scale, by means of a chart.

First, we note, in viewing this chart, that if we take the estimated temperature of the surface of the sun as 6000 deg. C. at which temperature we possess but a vague knowledge of the properties of matter, and if we call the range in which human life exists as 140 deg. C., then the region of temperature in which we live is only about 2.2 per cent of the absolute temperature which we study and talk about. In other words, we can only have a direct sense perception of between 2 and 3 per cent of the total range of temperature which we study with instruments. Starting in imagination at the absolute zero or —273 deg. C. we conceive all matter to be without motion, without energy. It is dead. This final condition has never been observed but where hydrogen is frozen and helium-gas liquid the absolute zero has been reached within 3 or 4 deg. and the condition, and a very few of the properties of several kinds of matter, have been observed.

made of any substance is proportional to the fourth power of the absolute temperature. In mathematical language $E = K (T^4 - T_0^4)$ where T is the absolute temperature at the bottom of the hole, or so called "black body," and T_0 the absolute temperature of the body on which the radiation falls. The

Here the suggestion is offered, that as metallic conductors have an enormous conductivity, and as the transport of electricity in metals is presumably carried on by mobile negative electrons which obey the laws deduced from the kinetic theory of gases, we have the result that where matter is without energy and dead electricity is active and in motion. It may well be, therefore, that far below the absolute zero for matter there is another zero for electricity where the active electrons themselves become quiescent. While it is pure speculation it is interesting to inquire if there may not exist a cold for electricity in comparison to whom the absolute zero for matter is a white heat.

At —200 deg. C. or 73 deg. abs. air is liquid. If any astronomical cause, or the lapse of time should permanently lower the lowest temperatures which now prevail upon our earth by only some 160 deg. C. the watery fluids of the earth would become plains of hard crystalline rock which much of the now enveloping atmosphere would cover like a soft white snow, for the cold would precipitate it upon a frozen and dead world. We now easily produce this temperature in making liquid air and it is found that many kinds, at least, of the bacteria which are at once man's friends and deadliest foes, still survive. Between —200 deg. C. and —40 deg. C. practically no other life is possible unless it be some low vegetable forms and plant spores. At about —40 deg. C. the higher order of animal life takes its permanent abode upon earth. Antarctic explorers find the emperor penguin living comfortably in large flocks where, as Amundsen recorded, the temperature never rose higher than —5 deg. C. and where it often remains below —40 deg. C.

At 37 deg. C., the blood heat of warm blooded animals, life upon this earth—and I believe throughout the universe—teems. But ascend only 63 deg. C., or a little over 1 per cent of the temperature of the sun's surface, and water boils and all life, including the hardy bacilli, is destroyed. Since the earth as a whole has probably never been colder than it is at present, it is worthy of remark that in the several millions of years that life has been upon its surface the temperature cannot have changed so much as 2 per cent of the temperature of the surface of the sun. It would take but a trifling irregularity in the customary course of the solar system—as the falling of a considerable mass into the sun—to raise the temperature of our earth some 60 deg. C. In this event all protoplasm—the life stuff—would be cooked and two of the three kingdoms on earth, the animal, vegetable, and mineral, would cease to exist.

In the range 100 deg. C. to about 525 deg. C. matter can only be inorganic, and it is not self-luminous. If it is to be seen, it must be illuminated by light from an independent source cast upon it. But Draper has shown that at about a temperature of 525 deg. C. matter of all kinds begins to furnish a faint red glow. The activity of the motion of its particles becomes so great that the ether disturbances produced are able to affect our eyes and as the temperature steadily rises this first faint red glow becomes stronger; orange, yellow, green, blue, indigo and violet rays are successively added with increasing elevation of temperature, until finally the dazzling blue is reached which is found at the temperature of the positive crater of the arc lamp, a temperature which must be attributed some threefold to the surface of the blue stars.

It may be said that below —40 deg. C. matter reveals only faint indications of the life within it which at the absolute zero passes into complete death; that from —40 deg. C. to 100 deg. C. it exhibits an abundant visible life seen in the activity of the protoplasm which it produces, that from 100 deg. C. to 525 deg. C. the life in matter, though not visible to the eye, is to be conjectured from its mass movements and phenomena of contraction and expansion and that above this temperature the life in matter reveals itself with ever increasing visibility until eyes are blinded with the radiant energy which its vibrating particles give rise to.

At about 1000 deg. C. we find at least twenty-seven out of some fifty known metals are molten and flow like mercury. Here chemical activities are immensely increased, which changes the identity of most all familiar compounds. Our common experience of the chemical properties of bodies and elements avails us little in predicting the chemical reactions which will take place. It thus happens that physicists unfamiliar with high temperature work can make little use of their experience acquired at ordinary temperatures in predicting the nature of the phenomena which, under given conditions, may be expected at this elevated temperature. It is for this reason that even at this moderately high temperature investigation has become a specialty.

At 1550 deg. C. gas-thermometry ends. When the Carnegie Institution at Washington started its investigations the gas-thermometer scale had only been extended, with any pretense at precision, to 1100 deg. C. The recent gain of 450 deg. is largely due to the splendid work of Dr. Arthur L. Day, the director of the Geophysical Laboratory. At 1755 deg. C. platinum, the metal par excellence for measuring temperature, has itself become a liquid. As thermo-couples for high temperature work have always been made of this metal in combination with platinum alloyed with rhodium or iridium, thermo-couples thermometry must end at this temperature unless some heretofore untried metals of still higher melting point be used for the purpose. It is not impossible that molybdenum-tungsten thermo-couples properly protected in an atmosphere of hydrogen might be used under certain circumstances to temperatures up to their exalted melting points.

At 2000 deg. C. almost all substances known to us will be plastic, gaseous or molten. The physical properties of matter at this temperature are but vaguely comprehended. Certainly most familiar properties have gone. All magnetism of matter was left far behind at about 800 deg. C. At this teperature all matter is conducting and there are no more insulators of electricity. If at 2000 deg. C. we are to have electric currents they can only be produced as eddy currents—for no insulators can be found to lead the electric current into directed paths. Ascend another 700° or 800° and all matter, in ordinary atmosphere, will have entered into new chemical combinations, have become liquid or vaporized. It will possess but four or five of the many familiar properties of matter we study and about which we consider we know so much. Hardness, porosity, tensile strength, ductility, elasticity, stability of form, magnetism, color, etc., are all gone. Density, expansibility, thermal and electrical conductivity are profoundly modified. Even the air surrounding such matter has become a conductor due to the thermions which the glowing matter freely emits in abundance.

Two fundamental properties remain, however, constant and unmodified. These two properties are inertia and weight. The kinetic energy of a unit mass of matter moving with a given velocity is just the same at a temperature of 2000 deg. as it is at the temperature of the room, while the earth will attract this matter with the same force whatever its temperature. The surface tension of molten metals persists up to their vaporization point. A portion of molten platinum will form into a liquid globule and roll like quicksilver, and even tungsten which resists before melting almost the highest temperatures we can produce on earth, will gather, when melted, into a bead. This persistence of surface tension strongly suggests that the ultimate particles of matter are attracted toward one another by the same force—gravitation—which draws all bodies—whatever be their temperature—with the one universal law discovered by Newton.

In an atmosphere of hydrogen three at least, and perhaps one or two more metals, recently studied in respect to their melting points, seem to resist fusion up to an elevation of temperature of about 3000 deg. C. Mr. Forsythe of the University of Wisconsin, finds the melting points of tungsten and tantalum to be in the neighborhood of this temperature and when they melt they form a well defined bead in contrast with carbon which has no true melting point, but at about 3700 deg. C. evaporates or sublimes.

Beyond the temperature range of the vaporization of carbon —and we have only reached a little over half way to the estimated temperature of the sun's surface—nothing whatever is known about the properties of matter beyond those which we can infer by studying the radiant energy which it gives off and from observing the manner in which it is acted upon by gravitation.

Our most extensive knowledge respecting the properties of matter is at the habitual temperature in which we live and try most of our laboratory experiments. The past history of physics is, in the main, a recital of the properties, the phenomena, and the laws of matter in the accidental and transitory range of temperature from melting ice to boiling water. If matter at the center of the sun is, as Arrhenius speculates, at the inconceivable temperature of 6,000,000 deg.—being 6000 deg. at its surface and increasing from the surface to the center about 9 deg. C. per kilometer—then the petty range of temperature in which we study matter is but about 1/60,000 of the total range of temperature in which the matter of our solar system exists.

If in our chart we let the height of the straight line represent temperature elevation and if we represent, by distances measured to the right of this line, the number of facts and laws of matter about which we have gathered true experimental evidence, we obtain a curved line which incloses an area that represents, in a conjectural way, the real extent of what we know about matter. Thus, starting at —273 deg. C. or at the absolute zero, we have no experimental facts whatever and the line inclosing our area must begin at the bottom of the line of temperature. With a small rise of temperature our knowledge of the physics of matter increases rapidly. A number of facts are known at the temperature of liquid air but it is at about 20 deg. C., at which temperature most laboratory experiments are tried, that our knowledge is a maximum. It then begins to fall off, slowly at first then very rapidly, until at 2000 deg. C. there are known relatively but very few facts and laws. Above this temperature our knowledge is very slight, being confined chiefly to radiation phenomena and the laws which govern the gravitation of matter.

This area, enclosed between the temperature scale and the limiting line of knowledge, may be called the *Region of Experimental Evidence.* It is the region in which our knowledge of matter rests upon the sure basis of observed facts and carefully made measurements. All outside of this area belongs to the field of imagination and speculation. It may properly be called the *Region of Pure Surmise.* The first region is large compared with that—shown inclosed in dotted line—which the philosophers of antiquity could have drawn to represent the knowledge of their day. But the second, the Region of Pure Surmise, extends beyond all assignable limits.

It is the inheritance and the pride of our generation that we can claim so great an extension from the region of the unknown. By the application of the scientific method, the invention of instruments, and the cooperation of many investigators, the insignificant area which may be assigned to the ancients, in a few generations, has been immensely enlarged. But we cannot rest satisfied, for the craving of intellectual man is to ever explore. Nevertheless, in this exploration we should seek intellectual efficiency quite as much as we strive for commercial efficiency.

To enlarge the region of experimental evidence our explorations should be directed where results will follow in greatest abundance for the efforts put forth—and, we should add, where the knowledge gathered promises to have an immediate or early application to the use and comfort of mankind in general. A glance at the shape of the area of experimental knowledge will show that it needs to be squared up in the temperature-range from 100 deg. C. to 2000 deg. C. Here lies the opportunity of the ambitious investigator to gather precise experimental knowledge of the properties of matter, now totally lacking, at temperatures which we can produce, control, and use industrially.

When the properties of matter are known in this region as they are now known between 0 deg. and 100 deg. C. we may expect industrial uses of the properties of matter of vast and undreamed of service to man.

But the labors of a single individual are brief and very small. Even the well directed and long life of a talented investigator can only put, as it were, a fringe of differential breadth upon the margin of knowledge which is grounded securely upon experiment. But though the extension is slight the intellectual pastime which accompanies the effort is delightful. To accomplish as much as possible in a life time we should give careful heed to plans, methods, and equipment. A canvass of these leads me to believe that it is far more efficient for individuals to examine, study and measure a few important properties of many substances over a considerable range of temperature than to try to do the same for many properties of a few substances. In the former case the same general equipment of apparatus and the experimental experience acquired will be of service, whereas in the latter case many kinds of apparatus, a wider knowledge and a greater expense would be needed to accomplish an equal result.

Of the many properties of matter which deserve investigation, between room temperature and 2000 deg. C., the electrical conduction of matter is a problem which is at once definite and important. As the conduction of matter has interested me, I may be allowed to very briefly consider it here. In the region of temperature at which air is liquid, all bodies are divisible, very sharply, into conductors and insulators. At this temperature the resistivity of all the pure metals is extremely low, the curves all pointing toward zero resistivity at the absolute zero of temperature. The resistivity of the alloys is also low though not so low as that of the pure metals, and the curves do not point toward zero resistivity but above this value at the absolute zero of temperature. The ordinary insulators, on the other hand, are much more perfect insulators at very low temperatures than they are at room temperatures. Ice for example is an excellent insulator long before reaching the temperature of liquid air. The dielectric properties of the insulators, including ice, are extremely good at low temperatures. By good, it is meant that they show very little energy loss per cycle per cubic centimeter per volt when tested with alternating current. It is in fact a safe prediction to state that at the temperature of liquid air all dielectrics, as mica, glass, hard rubber, celluloid, fiber, etc., will not only show an extremely high resistivity but also very little dielectric loss or electric absorption when used in a condenser.

As the temperature rises the so-called insulators diminish in resistivity. Thus Somerville, who has investigated the variation in resistance of glass, porcelain, and quartz, states that these substances begin to decrease in resistance at a very definite temperature and fall rapidly, so that in the small range of temperature from about 500 deg. to 1000 deg. C. the resistance may fall to 1/10 or less of its value at the lower temperature. Also some rods of pottery which measured 10,000,000 ohms at about 550 deg. C. measured only 15,000 ohms at 1100 deg. C. The course of the resistance curve with rise of temperature of an insulator is most familiar in the case of the Nernst glower, which is a good insulator cold and a very good conductor when white hot. The pure metals, and for the most part the alloys, on the other hand, steadily rise in resistivity as the temperature is increased from the lowest attainable to their melting points. At the moment the metals melt they take, as it were, a leap in resistivity. Thus I have found, myself, the ratio of the resistivity after fusion to the resistivity before fusion to be: 1.45 for sodium, 1.52 for potassium, 2.28 for aluminum, roughly 2.5 for copper, 1.98 for cadmium, while investigations, now under way, indicate similar ratios for other metals. Other investigators find the ratio for tin 2.38, for zinc 2.1, for cadmium 2.3 and for lead 1.9. Two German investigators, J. Koenigsberger and K. Schilling, have made a thorough investigation of such half metals as silicon and titanium, and

various oxides and sulphides of the metals. They found in general that the resistivity of these at first decreases, until a minimum is reached, and then continues to increase up to the highest temperature reached in their experiments, which was about 900 degs. C.

It is highly probable that at very high temperatures there ceases to be any distinction whatever between insulators and conductors. Electric conduction is now recognized to be of two kinds: electronic, or conduction by the passage of electrons, in which no chemical decomposition is produced, or counter e.m.fs. developed, and electrolytic conduction, in which there is chemical decomposition which at room temperatures obeys the law of Faraday. As the temperature is elevated there is good evidence to show that in many substances both kinds of conduction can be taking place at the same time, and it is not known if all conduction may not be electrolytic in all compounds at elevated temperatures, and if so whether or not Faraday's law is obeyed.

Though we may already trace, in general outline, the progress in these modifications in the electrical properties of matter as the temperature is elevated beyond 1000 deg. C. we have little exact data, or anything which deserves the name of precise measurement. The experimental difficulties are great, but great also is the need of precise information. We want it to reduce to a more exact science electric furnace practice and electrometallurgical operations. Quite recently Mr. L. Saunders has made a most commendable effort to determine the temperatures in the interior of a silicon carbide furnace, and has found the decomposition temperature of silicon carbide to be in the neighborhood of 2240 deg. C. But we want this information for, what in my judgment, is a far more important purpose, which is, to give an enlargement to our vision of the cosmos in which we dwell as men and not as mere money accumulating machines. For processes and machines should serve the spirit of man—the last and highest product of evolution—and this spirit must not be sacrificed to its servants.

The goal is to ever extend the region of *experimental evidence* and take a little more from the unlimited region of *pure surmise*. Every one that labors with earnest endeavor and honesty of purpose to improve apparatus, to perfect processes, to build machines, or to study pure science, in laboratory or field, is taking his mite, in the ceaseless conquest, from the region of pure surmise.

Palmer Physical Laboratory,
Princeton, N. J.

Chilean Production of Nitrate.—The production during 1911 exceeded that of any previous year, reaching 54,784,271 quintals (Spanish quintal = 101.41 lb.). The price fell as low as $1.66 gold per quintal in March, but advanced to $1.94 in October. New works of a capacity of 18,000,000 per annum were begun last year and will be completed this year. Authority has been granted by the government to put more nitrate land on the market. Nitrate constitutes about 80 per cent of the exports of Chile, and supplies about 60 per cent of the revenue of the government.

Flexibility in wire rope requires relatively small individual wires which do not possess the wearing qualities of ropes having larger outer wires made of higher carbon steel. When such flexible ropes are used on single rope tramways, the spans are limited to 600 ft. in length, with loads of 600 lb. and grades of 1 in 3.

Aerial tramways, if longer than 3½ or 4 miles, are made in sections, shunting the buckets from one to the other. The long cable way in the Argentine Republic, designed to bring ore to Chilecito, is 22 miles long, with a fall of 11,500 ft., and is in eight sections. It carries 40 tons per hour, using buckets of ½ ton capacity.

The Concentration of Carnotite Ores, and Some Similar Ores.

By Siegfried Fischer

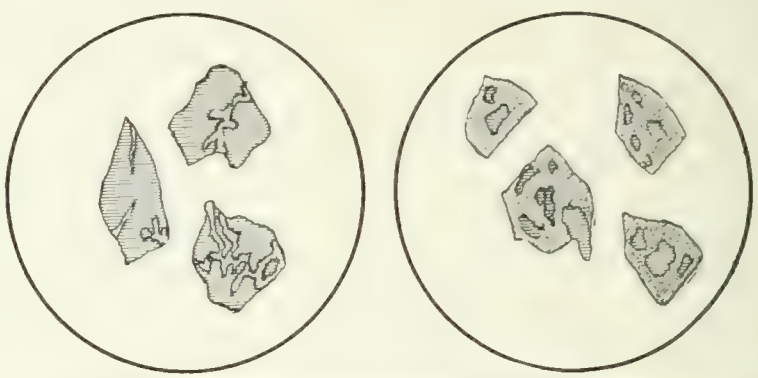
Introduction.

The carnotite ores have recently attracted considerable attention in the commercial world, for the reason that they contain uranium and vanadium salts. It is a well known fact that all the uranium minerals contain a greater or less amount of radium, and it is due to this element that carnotite is such a high priced ore. Its vanadium content has not been given much consideration on account of there being no commercial process at hand for the economical handling of this valuable element in this form. There is, however, a process known abroad, by which the radium is obtained.

Mr. W. F. Bleecker, in his recent articles published in Metallurgical and Chemical Engineering,[1] has discussed in detail the present status of the extraction of vanadium from carnotite ores, so that I may omit anything in this line. There has, however, been some recent work done, but I am not at liberty to discuss it.

Carnotite.

Literally speaking, carnotite is a new mineral, and not much is known about it. There are quite a few theories as to its chemical composition, but they are not definite. We know, however, that carnotite is a mixture of vanadium and uranium salts; that it usually occurs as an impregnation in some other mineral, such as sandstone, quartzite, coal, etc., and that according to its depth of color, it is richer or poorer in uranium or vanadium.



FIGS. 1 AND 2. MICROPHOTOGRAPHS OF MEDIUM RICH AND VERY RICH ORES

After having subjected 12 different samples to a minute microscopical examination, the author drew the conclusion that carnotite is a coating on the various mother materials; that each sand grain bears the carnotite as a coating, and that according to the richness of the ore, the coating will be thicker or thinner, more compact or spread. Fig. 1 shows a medium rich ore, and Fig. 2 a very rich one, as they appear under the microscope. The dotted portion represents sandstone, and the ruled areas indicate carnotite. On all the grains we notice some particles of carnotite.

This alone, however, would not be sufficient proof for assuming carnotite to be a coating, and another means had to be sought for to verify the microscopical examination. This was done in the following way: The samples of ore were subjected to grinding under slight pressure. Then by treating this ground material with water the carnotite was removed as suspended slime. By testing each treatment it was found that, on dissolving the particles suspended in the water, and testing the solution so obtained for vanadium, it showed a very strong reaction for this element. On testing the residue left for vanadium it showed only minute traces. The tailings were then dried and again examined under a microscope. The grains of the mother mineral were, practically speaking, free from the

[1] Dec., 1910, April and October, 1911

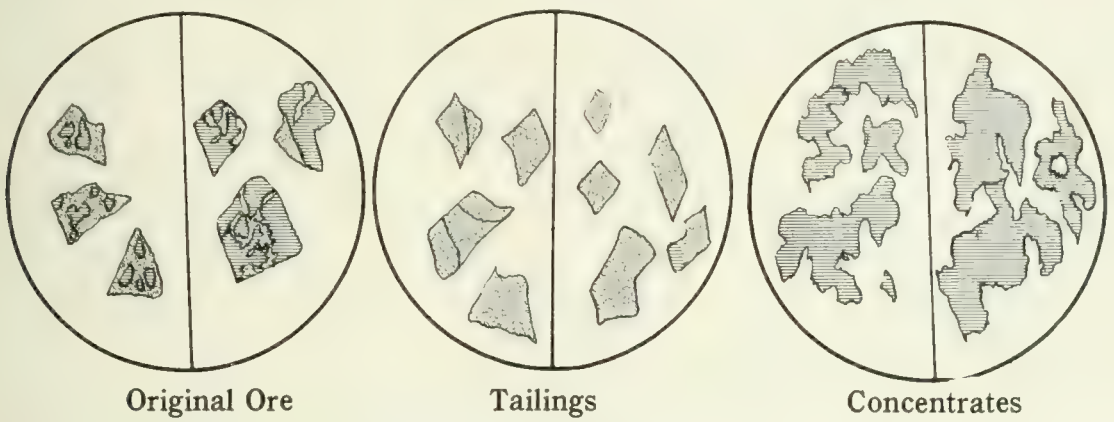
yellow coating. Figs. 3, 4 and 5 show successively the original ore, the concentrated material and the tailing of a medium and a rich carnotite ore. Each ore and its products appear in corresponding halves of the drawings.

Some numerical data will make this clearer: While all of the particles of the original ore showed the carnotite coating, very few of the grains showed a yellow color after grinding. In one case only 3 particles out of 53 in the field of vision showed a slight trace of yellow. In another case, out of 64 particles only 5 showed indications of yellow.

These two tests prove conclusively that carnotite is only a coating or impregnation on the mother mineral, and indicate the fundamental principle upon which the patent for a process for the concentration of carnotite and similar ores is based. This, however, will be discussed later.

Concentration.

At the present time practically all carnotite ore is shipped in its crude form; that is, as it is obtained from the mine. This causes a large and useless expense, in that a large amount of material has to be shipped for which not only no financial return is obtained, but for which freight has to be paid. This is the gangue; and if we consider that an ore carrying 4 per cent. vanadium and 5 per cent. uranium is a good commercial ore, we realize what a thorough and economical concentration process means in the carnotite industry.



FIGS. 3, 4 AND 5.—RESULTS OF CONCENTRATION.

Treatment: A general outline of the treatment will be in place. After grinding the ore, as much of the carnotite as possible is removed as slime suspended in water. Then the tailings are subjected to grinding and again slimed. This is repeated until the tailings show no reaction for vanadium or only minute traces. In this crude way three treatments are usually sufficient to remove all the carnotite from the gangue mineral. Then the original ore, the concentrates, and the tailings are subjected to a minute microscopical examination, and also tested for vanadium and radium.

The following are some of the results obtained:

Sample No. 1: 200 gms. of ore treated, yielded 127 gms. tailing and 73 gms. concentrate. Equal amounts were used for the vanadium tests and subjected to exactly the same treatment. The concentrate was found to contain practically all the vanadium, while the tailing showed only a trace. The concentration ratio was practically 3:1.

Sample No. 2: Carnotite from the J. Mackay Mine No. 2, Rio Blanco Co., Colo. Same treatment. 61 gms. Original ore yielded 19 gms. concentrate and 42 gms. tailing. The concentrate contained practically all the vanadium, and tailing only a trace. Concentration ratio nearly 3:1.

Sample No. 3: Carnotite from near Greenriver, Utah. Same treatment. 100 gms. original ore yielded 30 gms. concentrate and 70 gms. tailing. The concentrate contained nearly all the vanadium, while tailing showed only a trace. Concentration ratio, 3:1.

These are only a few of the results, but they will make clear the efficiency of the concentration.

The vanadium test is the best criterion for the efficiency of the concentration, for as soon as the tailing shows practically no reaction for vanadium one can be assured that no uranium or radium is left in the tailings. Tests have proved this point.

Another important factor is the mesh to which the ore is ground. The finer the mesh, the more rockslime will the concentrate contain. I will cite two examples:

Fifty gms. of ore that passed through an 80-mesh sieve gave 39.5 gms. concentrate and 10.5 gms. tailing.

Fifty gms. of same ore that passed through a 60-mesh sieve gave: concentrate, 18.5 gms., and tailing, 31.5 gms.

The concentration ratio in the first case is practically 5:4. In the second, nearly 3:1.

The cause of this is, that the carnotite coating is only on the outside of each grain, and not inside. Consequently, if the mesh is finer than the grain the chances for the increase of rockslime in the concentration product are correspondingly greater. It is essential, therefore, in the successful concentration of said ores, to bear this in mind, as it not only enables one to obtain more satisfactory results, but effects also a saving of money and time.

The Principle of the Process of Concentration is as follows: Carnotite being a coating, the principle is in direct connection with this fact. First, remove the coating by abrasion. This may be accomplished by the rubbing against one another of the grains of the mother mineral, or by machinery, or both. The pressure used to cause the abrasion should be slight, because if too high, the pressure will be sufficient to grind the ore to a finer mesh and so increase the rockslime in the concentrate.

Second, suspend the carnotite in water by slow motion. Draw off water plus the concentrate; collect, and free from as much moisture as possible.

Finally, dry the concentrate by suitable means. The concentrate is then ready for shipment or for further treatment.

Without abrasion it is impossible to concentrate ores of this type. Grinding alone is practically useless as a means of concentration, for the reason already mentioned, namely, the increase of rockslime introduced by too fine grinding. The grinding would have to be exceedingly fine, so fine in fact, that it would hardly pay. But grinding and abrasion combined give the desired results cheaply.

Process: While a combination of various machines will give the same results, the underlying principle for the combination is the same. I will, therefore, simply explain one in detail, the one which accompanies the patent application.

The ore is dumped on a grizzly as it comes from the mine. The finer material drops on a belt-conveyor and goes directly to the ore bin. The coarse material passes through a crusher before being received in the ore bin. From here the ore passes through three sets of rolls. The ground material then enters a Dorr classifier, where the abrasion and suspension of the carnotite take place. The metal shoes which actually are used to convey the tailing out of the classifier, in this case serve also as the desired means of abrasion. The slow motion of the rabbles will give sufficient movement to the solution to suspend the valuable slime. At one end of the classifier the solu-

tion carrying the concentrate enters a Dorr slime thickener, where the slime is settled and freed from part of its moisture. It is then sent to a rotary dryer, and finally to storage bins. If re-treatment is necessary, suitable arrangements are made as shown in diagram.

The process is continuous, and demands little attention and labor. But, as mentioned before, this is only one arrangement

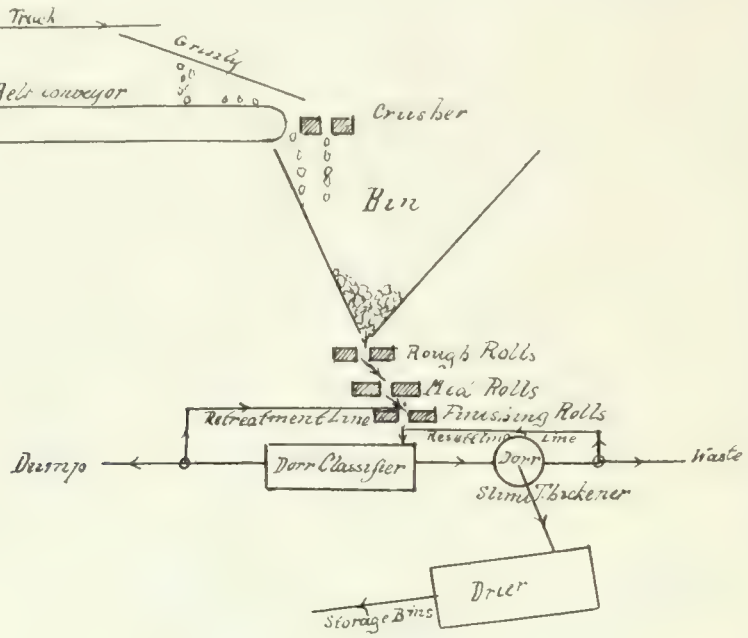


FIG. 6.—DIAGRAM OF PROCESS.

of the many embodying the principle. Fig. 6 gives a diagram of the process.

To make the Dorr classifier work the scrapers will have to have the shape shown in Fig. 7; they must also be adjustable, so that the pressure may be changed by raising or lowering.

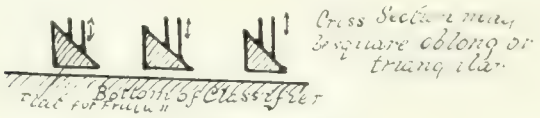

FIG. 7 —SCRAPERS.

The regulation of the pressure for causing the necessary abrasion can be determined in the laboratory while making the tests deciding the mesh.

Mesh Tests: These tests should be made for the different ores, as they give an easy means of obtaining the most desirable results. First notice the structure of the ore, then grind to as near the size of the grain as possible. Then weigh out a definite amount of the sample and put it in a mortar. Wash out all the carnotite possible and rub the remaining material with a pestle; wash again and repeat the operation until the tailing shows no reaction for vanadium, or only a slight trace. Usually three treatments were found to be sufficient. Weigh concentrates and tailing. Until one has obtained a little practice it is best to try 3 or 4 different meshes on the ore. The results should be tabulated, and I would recommend the following scheme:

NO. OF SAMPLE.		DATE.
Amount Taken.	Wt. of Conc.	Wt. of Tail.
Mesh.	No. of Treat.	Time.
PRESSURE:		CONCENTRATION RATIO:
VANADIUM TEST:		SIGNATURE:
MICROSCOPICAL TEST:		
RADIUM TEST: Orig.		
Concent.		
Tail.		

Naturally, the tailing and concentrate should be examined for vanadium and radium, and the results recorded in a similar fashion.

These tests are simple and require very little time. Furthermore, the chemical analysis of the original ore and of the concentrates should be made, but that is self-evident, as that is done in all metallurgical processes.

There is no need of my entering upon the hydrogen peroxide test for vanadium, as it is well known; also the microscopical test, which already has been described.

Radium Test: The best test, to my knowledge, is the test by means of the electrometer. It is comparatively quick and gives fairly accurate results. Precautions must be taken, however, first, that the instrument is free from any radio-active material, and secondly, that small enough amounts are used for the analysis; for it is a well known fact that materials exposed to radium will themselves emanate radio-active rays, and these rays will effect the discharging of the instrument. It is due to this that the above mentioned precautions must be regarded. If small enough amounts are taken this error may be reduced considerably. For emanation does not necessarily mean the presence of the element radium itself; and this latter statement holds true for the tailings.

A test, which in its way is useful, is the exposing of volumetrically equal amounts of the original ore, the concentrates and the tailings to photographic plates, for the same length of time. This is done in the following way: The plates are first packed in black paper, so that no light can reach them. The amount of each material is measured and put into a small box. On top of the plate a flat metallic object is placed, and this covered by the box containing the material. After exposure the plates are developed and printed. According to the intensity of the picture produced, one may judge as to where most of the radium is to be found. This, of course, is no quantitative determination, but simply serves as a verification to the electrometer in a general way.

Figs. 8, 9, 10, 11, 12 and 13 are photographs obtained in this manner. The exposure lasted for 73.5 hours. The first three show the results obtained from an ore containing approximately 4.5 per cent. uranium. The last three show the results of a very rich ore, of which, unfortunately, I have no quantitative analysis. But, nevertheless, it shows again that the radium is in the concentration product.

All the tests combined prove definitely that all, or practically all, of the valuable mineral is obtained in the process of concentration.

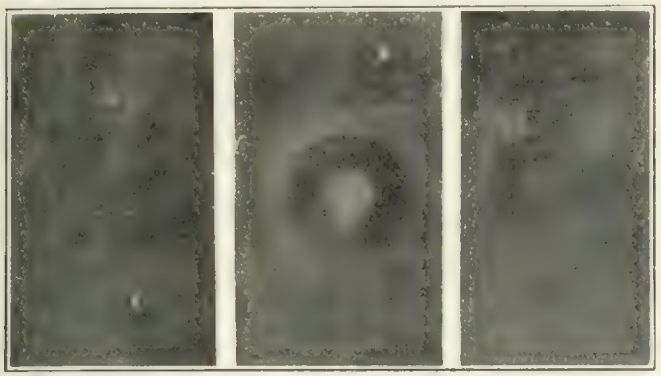
By these tests we also demonstrated that all of the valuable materials are contained in the concentrate, and that the undesirable elements are, if not entirely removed, reduced to a minimum. The concentrate is, therefore, in the best commercial form for shipment, and if a practical process be found for the extraction of the vanadium, the ore could not be in better form. For any chemical process at the present time is handicapped by the large amount of chemicals used for the extraction, due mostly to the fact that the gangue materials consume a large percentage and will give no financial returns.

The concentration will yield over 90 per cent. recovery.

Other materials besides carnotite have been successfully concentrated. Various sandstones carrying only vanadium as a coating have been treated with similar results. The abrasion principle is essential here as with the carnotite. In fact all ores carrying valuable mineral as a coating will bear the same treatment. Some ores naturally will have to undergo more than one treatment, but the cheapness of the process makes this only a very small factor.

The Value of the Process.

In considering the commercial side of the process, I will use the data obtained from a firm shipping a carnotite ore worth $200 a ton. We will also use the minimum values for the cost and freight. The same ore was concentrated by the above



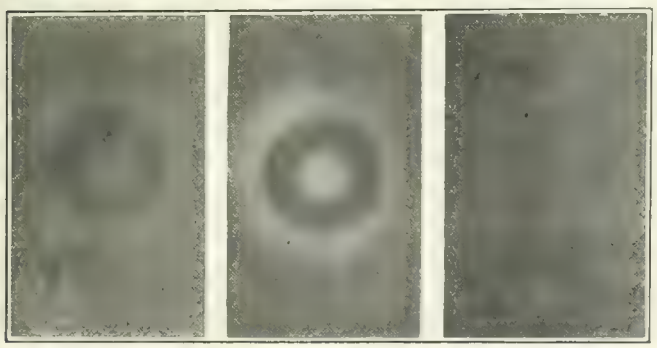
ORIGINAL ORE CONCENTRATE TAILING

FIGS. 8, 9, 10. PHOTOGRAPHS SHOWING THE CONCENTRATION OF RADIUM CONTENTS IN UTAH CARNOTITE.

process, and not having any definite figures we will assume the maximum cost for its production.

Value per ton of original ore	$200.00
Cost of production per ton	.20
Freight per ton (to Europe)	20.00
Actual value per ton	179.80
Value per ton of concentrate (ratio 3:1)	600.00
Cost of production per ton (maximum)	10.00
Freight (to Europe)	25.00
Actual value per ton	565.00
100 tons @ $179.80 (original)	17,980.00
100 tons @ $565 (concentrate)	56,500.00

The gain, without any doubt, is noticeable and even should



ORIGINAL ORE CONCENTRATE TAILING

the cost of production exceed the figures given, which is not likely, the profit is still enormous.

Golden, Colo.

The Upward Concentration of Kish by Flotation.

BY HENRY M. HOWE.

In an extremely interesting and valuable article Dr. Paul Goerens[1] informs us that the so-called primary graphite "is distributed very evenly (durchaus gleichmässig verteilt ist)" in a remarkable specimen of cast iron made and cooled slowly in the electric furnace, and containing about 7.5 per cent of carbon, of which about 6.5 per cent existed as graphite. The prominent facts are (1) that much of this graphite existed in extremely large flakes; (2) that he calls these "primary graphite"; (3) that he indicates that they form at the liquidus BD; and (4) that his diagram Fig. 1 suggests that kish is identical with primary graphite. From these facts one might well believe that these great flakes are identical in origin with kish.

But one immediately asks how it is possible that true kish should be distributed evenly throughout the interior of a mass of cast iron. The solidification of such a mass of cast iron, of

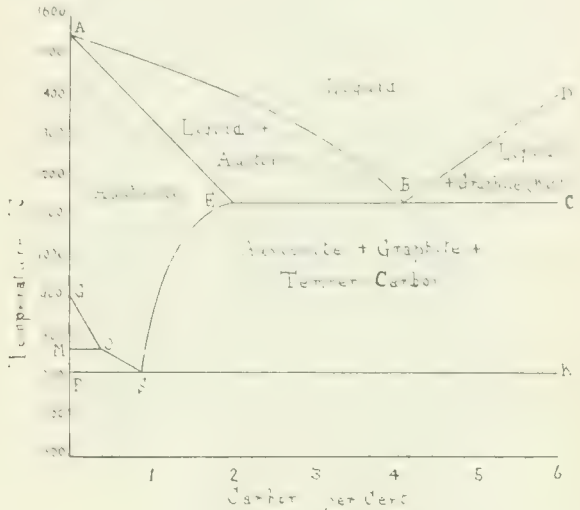

FIG. 1. CARBON-IRON DIAGRAM (GOERENS).

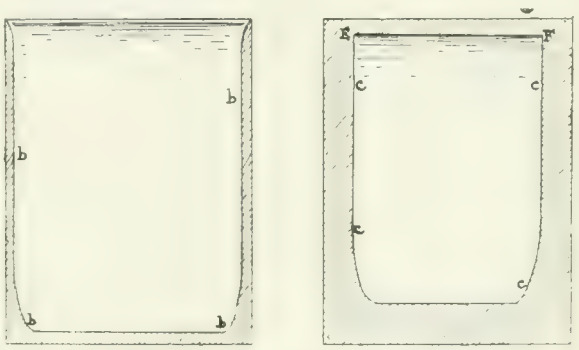
course, takes place progressively from without inward as sketched in Figs. 2 and 3. It is perfectly familiar to us that, while some kinds of cast iron are molten as in Fig. 2, flakes of kish do escape from the upper surface, which would appear to indicate that they have risen to that upper surface from some lower position, either from the molten iron, or, as is more probable, from that submerged layer *bbbb* which at the moment is solidifying, and is therefore at the shore line between the already solidified part and the still molten interior. To be more exact, we should naturally suppose that this throwing off of kish occurs in those layers which at the moment are either at the liquidus itself or between the liquidus and the eutectic freezing point.

If this natural conception of the origin of kish is true, then it is very hard to understand why there should not be a concen-



FIGS. 2 AND 3. CONJECTURED COURSE OF SOLIDIFICATION OF A CAST IRON INGOT.

tration of kish in the upper part of the mass. We should naturally suppose that the course of events which led the solidifying layers *bbbb* in Fig. 2 to expel kish which rises to the surface and escapes into the air before the upper surface crusts over, would also continue at the shore layer *cccc*, Fig. 3, after that upper surface has crusted over. And if they did so continue, then it would be inevitable that those flakes which have risen and would have escaped if the upper surface had remained

[1] Metallurgie, 1907, 4, p. 137.

molten, must be caught and concentrated in the upper part of the casting at the line *AB* by the crust which has now formed across the upper surface.

Moreover, this condition of affairs ought to continue as the upper surface grows thicker and thicker. As the crust which forms on the top of the molten mass gradually thickens by the

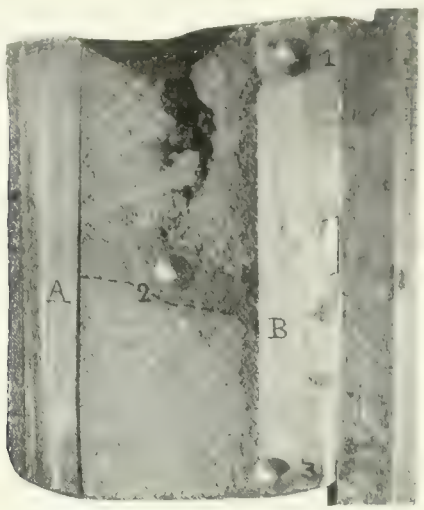


FIG. 4. INGOT OF KISH-BEARING CAST IRON IN WHICH THE UPWARD CONCENTRATION OF KISH WAS FOUND.

solidification of fresh layers on its lower side, each layer as it solidifies should catch some of the upward-rising kish, and in that way should become enriched in graphite at the expense of the layers *cccc,* which are below the molten part.

A very valuable paper by Mr. J. E. Johnson, Jr.,[2] indicated that there is such concentration of kish in the upper part of castings made directly from the blast furnace. Mr. Johnson says, "Whereas, if the metal is allowed to cool to some extent before pouring, graphite begins to form within it, and separates out at eddies and high points of the mold, with objectionable results."

Mr. T. D. West informs me that in his practice in making ingot molds with cast iron direct from the blast furnace, bottom cast, and thereby probably nearly freed from mechanically entrained kish, about half a peck (say, 270 cu. in.) of kish would rise to the top of 3-ton casting and have to be scraped off. Indeed, he found it necessary to have the molds open at the top in order that he might be able thus to remove the kish from the top of the casting.[3]

It is true that in none of these cases does attention seem to have been directed to the special point before us, whether within the solid metal the large flakes assumed to represent kish are distributed evenly. From the fact that in Mr. West's case this rising of kish seems clearly to have continued after the solidification of part of the iron had begun, we infer that it is extremely probable that kish evolved still later would be caught in the upper part of the casting. But to change a probability into a certainty I asked Mr. Edward B. Cook, manager of the Warwick Iron & Steel Company, Pottstown, Pa., to make for me a casting from pig-iron running from one of his furnaces at a time when that furnace was making kish-bearing iron. To that end I sent him a steel mold 6 in. in diameter and 8 in. high, consisting of a piece of common steel tubing closed at the bottom with a steel cap.

This casting when broken open did not show clearly to the naked eye any marks of upward concentration of graphite, although there was a sharp line of demarkation running across it as shown at *AB* in Fig. 4. But chemical analyses of borings taken at the points 1, 2 and 3 showed that there was a very great upward concentration. There is about 1.1 per cent more graphite at the top than near the bottom. The graphite content as determined by Messrs. Booth, Garrett, and Blair was as follows:

	Graphitic carbon.
1. "Top"	3.700 per cent.
	3.682 per cent.
2. "Below pipe"	2.748 per cent.
3. "Bottom"	2.506 per cent.
	2.582 per cent.

Flotation or Segregation.

If this concentration of graphite in the upper part of the casting simply represented the common course of segregation, by which the most fusible matter concentrates in the last freezing part, then the enrichment ought to be most marked in that last freezing part, which, as experience indicates, is usually just below the bottom of the pipe. But if that concentration represents in large part the entanglement of upward swimming kish expelled from the submerged solidifying layers, *bbbb* or *cccc,* then the enrichment in graphite ought to be greater at the top of the ingot than at the bottom of the pipe, and this we find to be the case.

We see that there is, as might be expected, a slight enrichment in graphite just below the pipe, but it is very slight. On the other hand, there is an enormous enrichment at the top of the ingot. This is not the last solidifying part, and therefore the enrichment here must necessarily represent the flotation of kish and its entanglement in the solidifying upper layers, as distinguished from the progressive concentration in the last freezing region by normal segregation.

From Ruff's analysis[4] of his experiments I believe that this kish is not primary graphite, but the product of the graphitization of cementite. The most natural supposition is that this cementite is primary. It is very probable that these graphite flakes are not pseudomorphs after primary cementite, because their strong curvature is so very unlike the usual striking blade-straightness of primary cementite crystals. They certainly seem to be idiomorphic. Their idiomorphism contains a strong suggestion that they have formed direct from the molten, or in other words that each particle of carbon between the instant when it precipitates in the form of primary cementite and the almost immediately following instant when it had graphitized and joined the particles of graphite which had previously assembled, has redissolved in the molten metal and re-precipitated from it, forming an idiomorphic crystal with these previously assembled particles. It is true that the time available is extremely brief; yet it may suffice. Thus we know that, whereas in Ruff's relatively rapid coolings in which he quenched molten cast iron in iced water, the graphitization of the cementite went very far; yet in Hanemann's experiments[5] which differed from Ruff's chiefly in having a still faster rate of solidification, the cementite often escaped graphitization and apparently nearly completely, and was retained in very large part in the form of crystals of primary and eutectic cementite, often of extraordinary beauty. That Hanemann's rapidity of cooling was in fact much greater than Ruff's is seen not only from his thus retaining the cementite ungraphitized, but from an inspection of his conditions. Ruff's molten iron was thrown into the water while still remaining in its crucible, and therefore was exposed to the cooling water only on its upper surface, and even this would necessarily be protected from the water by the envelope of ill-conducting vapor which surrounds a metal quenched in almost any liquid. Hanemann poured his molten metal into a narrow metal mould, so that there was direct contact between molten metal and solid metal, with excellent opportunity for rapid transfer of heat from the small quantity of molten metal to the large mass of the cold and rapidly conducting mould.

Dry Cells—Their Uses and Testing

THREE years ago (December, 1909, vol. VII, p. 501), we made the following remarks: "The dry cell industry in this country has now an annual output of some 40,000,000 cells and is still continually growing. But the general lack of exact knowledge about the dry cell is appalling, while the usual methods of rating dry cells reminds one at best of kindergarten methods for making electricity easy." These remarks were made on the occasion of the appointment of a Committee on Dry Cell Tests by the American Electrochemical Society and we expressed the hope that through the work of this committee the deplorable situation would be effectively changed.

This committee presented at the recent Boston meeting of the American Electrochemical Society a preliminary report, which, while only tentative, deserves fullest publicity so as to bring out intelligent discussion.

Tentative Report of American Electrochemical Society Committee on Dry Cell Tests

The committee consisted of Prof. C. F. BURGESS, chairman, and Dr. J. W. BROWN, Mr. F. H. LOVERIDGE, and Dr. C. H. SHARP.

The report divides dry cell tests into three main groups: (1) tests to determine whether or not a cell is in good condition before being placed in service; (2) tests to determine the actual or comparative service capacity of cells, and (3) tests to determine the rate of deterioration of cells on open circuit.

(1.) Tests to Determine the Condition of a Cell Before Use

I. Electromotive Force.[1]—The electromotive force of a cell may be read by connecting a voltmeter directly across the terminals. In new cells of various types the electromotive force may vary from 1.5 to 1.6 volts. If a cell of the type now in general use gives an e.m.f. five or more hundredths less than 1.5 volts it is an almost certain indication either of serious deterioration due to age, or of the external short-circuiting of the cell, or of some defect such as an internal short-circuit, which will soon render the cell unfit for service.

It is seldom necessary to measure the open-circuit voltage of cells, since they are seldom deficient in this respect. It is a test which may be considered as secondary in nature, and should be applied when it is suspected that the cells are below standard, for example, when cells are received with wet jackets, when the terminals are corroded, when the electrolyte leaks from under the seal, or when the cells are abnormally low in short-circuit current.

An accurate or carefully calibrated voltmeter should be used, the resistance of which is sufficiently high to render the current flow through it inappreciable. A two-scale Weston instrument of 300 ohms resistance with 3-volt maximum deflection and 1500 ohms with 15 volts maximum deflection has been found very satisfactory for both cells and batteries. Cheap pocket instruments are often so inaccurate as to make their indications of open circuit voltage worse than useless.

The effect of temperature on electromotive force is very slight, amounting to only a few hundredths of a volt between all ordinary temperature ranges. The voltage returns to normal with the temperature.

II. Short-circuit Current.—The short-circuit current of a cell may be obtained by connecting an ammeter directly across the terminals of the cell.

The short-circuit current of a cell is of value only when coupled with a familiarity with the brand of cell in question. If the reading is normal for that brand of cell, it is reasonably certain that the particular cell is in good condition, and that it will probably give as good service as others of the same make. This applies only to cells of the same brand and make. That the short-circuit current of a cell of a new and unfamiliar brand is as high as that of another brand is no indication whatever of the equality of the service capacities of the two cells.[2] The short-circuit current bears no relationship to service, and when measured without reference to temperature or other conditions may be entirely meaningless and misleading.

The ammeter for reading short-circuit current should be deadbeat, and with its leads should have a resistance of 0.01 ohm, to within 0.002 ohm. Two 30-inch lengths of No. 12 lamp-cord make very convenient leads. The maximum swing of the needle should be taken as the short-circuit current of the cell.

The ammeter should be connected across the brass terminals of the electrodes. Low readings are apt to be obtained if the ammeter is applied to the carbon electrode directly.

In order to avoid high contact resistance, the terminals of the cells and of the ammeter leads should be brightened. It has been found very convenient to fit the ammeter leads with small terminals of lead. The contact on the cell terminals is greatly improved, and with such leads it is unnecessary to brighten the contacts.

For accurate measurement of the short-circuit current of a new cell, cheap instruments of the pocket type should be avoided.[3]

The effect of temperature on the short-circuit current[4] is quite pronounced. Between 10 and 80 degrees centigrade, the amperage of cells is raised on an average of about 1 ampere for each 10 degrees centigrade rise in temperature. This value varies considerably with different cells, and is somewhat greater at the lower (colder) end of the scale and less at the higher. At very low temperatures the effect is very pronounced, and it is often noted that cells received in extremely cold weather read but one or two amperes. On bringing them to room temperature, however, the short-circuit current becomes normal and the cell is not impaired by the freezing.

III. Internal Resistance.[5]—This value is usually determined by applying the formula:

$$\text{Int. Res.} = \frac{V - V'}{C}$$

where V is the open circuit voltage of the cell, V' the closed circuit voltage, and C the current drain to which the cell is subjected in order to make the determination.

The above formula gives a compound value, composed partly of the sum of the resistances of the various parts of the cell, and partly of the resultant of the various electromotive forces in operation during the action of the cell. The value obtained varies with the current flowing, the age of the cell, and the temperature. For these reasons the committee advises against the use of this test. It indicates nothing in regard to the service capacity, nor does it give an exact value of the actual internal resistance of the cell.

(2.) Service Capacity Tests—General Discussion

Requirements for a satisfactory test:—In general there are but two reasons for desiring a service test upon dry cells:

[1] Trans. Amer. Electrochem. Soc., vol. 16, p. 103 (1909); vol. 17, p. 345 (1910).

[2] Trans. Amer. Electrochem. Soc., vol. 13, p. 178 (1908); vol. 16, p. 110 (1909); vol. 17, p. 346 (1910); vol. 19, p. 33 (1911).

[3] Trans. Amer. Electrochem. Soc., vol. 16, p. 117 (1909).

[4] Trans. Amer. Electrochem. Soc., vol. 17, p. 356 (1910); vol. 19, p. 37 (1911).

[5] Trans. Amer. Electrochem. Soc., vol. 17, p. 348 (1910).

1. To ascertain what life may be obtained from a brand of cells in a certain service.

2. To ascertain which one of several brands will give the longest life in that particular service.

With the former object in view the knowledge is best obtained by actual use of the cells in connection with the appliance. In some cases this is the only feasible way in which the definite information sought can be obtained. The great majority of tests are carried on, however, with the second object in view, viz., the comparison of two or more brands of cells for use in a particular service. Where the amount of testing is large, it is impossible, even were it expedient, to use the actual appliances for testing cells, and it becomes necessary to devise special testing methods and apparatus such that results obtained therefrom shall be comparable to the results obtained from the cells when placed in actual service. This is the one necessary condition which dry cell tests must fulfil.

There have been tests devised which seek to go further and make the operating conditions not only comparable, but as similar as may be to the operating conditions of the service for which the test is intended. Upon this point there is some diversity of opinion. Some authorities claim that a test is of greater value and is more reliable the more nearly the conditions of test approach those of service, and, following out these claims, have devised certain tests which are rendered quite complicated, requiring much attention and apparatus for their continuance, by the introduction into the method of some of the irregularities to be expected in service. It is questionable, however, if results of greater meaning are obtained from such strict adherence to service conditions. At best, such a test is but an approach to actual service, which must be continually varying from time to time and from locality to locality. Again, the apparatus necessary to carry on an irregular, intermittent test is very complicated and requires much careful attention. This feature limits its use to the large consumers and manufacturers.

Testing cells in series.—It has been suggested that cells of various makes be tested by connecting them in series and discharging them simultaneously through any suitable resistance, thereby assuring that the cells are discharged at the same rate and under identical conditions. There are several objections to this method[6] and the committee therefore advises against the testing of cells in this manner.

Judging Results.—In interpreting the results obtained from a test of various grades of cells, the committee cautions against drawing definite conclusions from the outcome of a single test or of a small number of tests. When the matter of choosing a brand is of much importance, it is necessary to run a series of tests over a period of six months or a year. In this way a very good idea may be obtained of the average service results which may be expected.

In the following table are given the results of ten monthly tests completed during 1910 on two brands of dry cells. The values represent the length of service given:

Tests.	1	2	3	4	5	6	7	8	9	10	Ave.
Brand A	42	35	38	33	60	45	48	35	66	48	45.0
Brand B	30	37	24	25	27	40	48	42	40	40	35.3

It is very evident from a comparison of the averages of these tests that Brand A is much superior to Brand B, yet had the consumer only the results from tests 2 or 8, he would have undoubtedly arrived at a very erroneous conclusion regarding the real merits of the two brands.

Service Tests Recommended

I. Telephone Service:[7] Discharge three cells, connected in series, through 20 ohms resistance for a period of two minutes, each hour, during 24 hours per day and seven days per week, until the closed circuit voltage of the battery at the end of a period of contact falls to 2.8 volts.

The following readings are taken:

1. Initial open circuit voltage of the battery.
2. Initial closed circuit voltage of the battery.
3. Closed circuit voltage at the end of the first discharged period.
4. Closed circuit voltage at the end of a discharged period after three days, and weekly thereafter.

Report the results as the number of days during which the closed circuit voltage remains above the limiting value of 2.8 volts.

Notes.—Fig. 1 shows in diagrammatic form a very convenient and inexpensive method of carrying on this test.

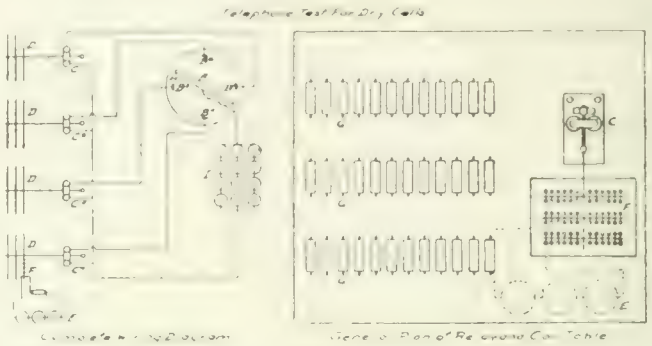

FIG. 1. DRY CELL TEST FOR TELEPHONE SERVICE.

The left hand portion indicates the apparatus necessary and its arrangement. The hand of the clock A revolves once per hour, closing, by means of a suitable contact H, the circuit of the battery I in turn through the contacts B_1, B_2, B_3 and B_4, on the face of the clock. This current magnetizes in turn the cores of the relays C_1, C_2, C_3 and C_4, causing the extended armature arms D to fall, bringing the inverted U shaped fingers F into mercury cups, to which the terminals of the individual test circuits are connected. Each contact plate B is of such length that two minutes are required for the passage of the contact H.

At the right of the figure is shown one testing unit, consisting of the relay C, the mercury cups into which dip the contact fingers F, and the arrangement of the 20-ohm resistance coils G.

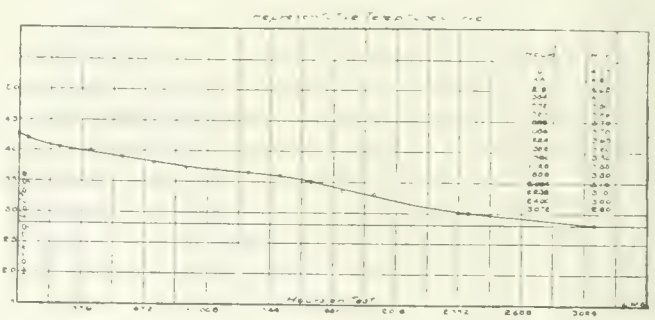

FIG. 2 REPRESENTATIVE DRY CELL DISCHARGE CURVE FOR TELEPHONE SERVICE TEST.

The batteries E, are stored under the table on which the various parts are fixed. One complete test battery circuit is indicated by the dotted lines.

Fig. 2 shows a representative discharge curve obtained from a battery of three 2½ x 6 inch (6 x 15 cm.) cells of a well known brand. The curve passes through the values of the closed circuit voltage at the ends of the contact periods.

The test should be conducted in a dry place, and normal room temperature should be maintained as closely as possible.

II. Ignition Service: Discharge six cells connected in series through 16 ohms resistance for two periods of one hour each

[6] Trans. Amer. Electrochem. Soc., vol. 19, p. [illegible] (1911).

[7] Trans. Amer. Electrochem. Soc., vol. 17, p. 358 (1910); vol. 19, p.41 (1911).

per day, seven days per week. The periods should be eleven hours apart, but in cases where the circuits are not automatically controlled, the first and the last hour in the working day may be chosen for the discharge periods and the discharge omitted on Sunday, without materially affecting the results.

The following readings are taken:

1. The initial open circuit voltage and short-circuit current of the battery.

2. The initial closed circuit or working voltage, and the initial impulse of current which the battery is capable of forcing through a 0.5-ohm coil connected in series with an ammeter, and in parallel with the 16-ohm coil.

3. Closed circuit voltage and impulse current through the 0.5-ohm coil at the end of the first period of closure, at the end of the sixth period, at the end of the twelfth period and after every twelfth period thereafter.

The test is considered completed when the impulse current at the end of a period falls below four amperes. Report the results as the number of hours of actual discharge to the limiting value of impulse current.

Fig. 3 shows diagrammatically the arrangement for a single test.

When the number of tests is not large the circuits may easily be closed by hand. When a great many tests are to be made,

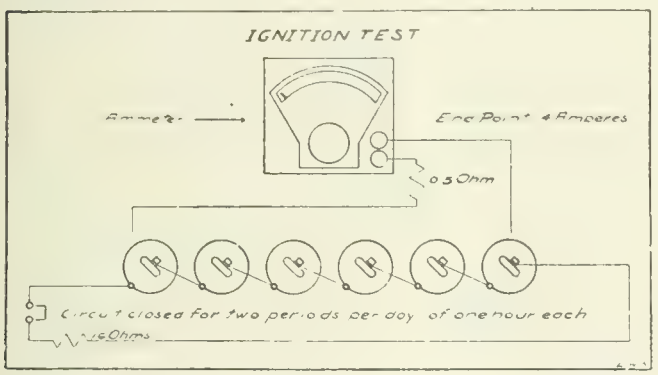

FIG. 3. DRY CELL TEST FOR IGNITION SERVICE.

it is convenient to arrange a clock-operated automatic circuit closing device.

By varying the length or number of discharge periods, the test may be made representative of any special cases of ignition. For a good comparison of the fitness of various cells for general ignition service, however, the test as given above is to be recommended.

Particular care should be taken to keep the temperature of ignition test batteries as nearly constant as possible, as the service obtainable is greatly influenced by this factor, as shown by the following table, in which are given the averages of five separate tests conducted at 5, 25, 35, 45, 55, 65 and 75 degrees centigrade.

Temperature	5°	25°	35°	45°	55°	65°	75°
Hours service	31.9	46.3	50.4	46.2	35.6	29.3	26.6

The reasons for the adoption of the various constants of this test, viz., number of cells, resistance in main circuit, end point, and resistance in ammeter circuit, is fully described in the Trans. Amer. Electrochem, Soc., vol. 13, p. 178 (1908); vol. 17, p. 361 (1910); vol. 19, p. 43 (1911).

III. Flash-light Batteries: Discharge the battery to be tested through a resistance of four ohms for every cell in series, viz., eight ohms for a two-cell battery and 12 ohms for a three-cell battery, for a period of five minutes once each day until the closed circuit voltage at the end of a discharge period falls to 0.75 volt per cell, viz., 1.5 volts for a two-cell and 2.25 volts for a three-cell battery.

The following readings are taken:

1. Initial open-circuit voltage and short-circuit current.

2. Initial closed-circuit, or working voltage.

3. Closed-circuit voltage at the end of the first, third and seventh periods of closure, and after each seventh period thereafter.

Report the results as the number of minutes during which the battery was discharged through the resistance to the given end point.

In case the circuits are not operated mechanically, the results are not materially changed if the batteries are discharged only on working days.

Four ohms per cell is chosen for the resistance in circuit, since the tungsten bulbs generally used with a three-cell battery have a resistance of approximately 12 ohms.

Miscellaneous Services: In addition to the telephone and ignition services, which are by far the most important services in which dry cells are used, there are numerous other services, among which may be mentioned the operation of automobile horns, sewing machine motors, small fans, toys, massage vibrators, cigar lighters, bells, buzzers, etc. In the aggregate these miscellaneous services consume enormous numbers of cells, but they are so numerous, and there are such variable conditions prevailing in each kind of service, that it would be useless to attempt to develop standard tests covering them.

It is not difficult for anyone particularly interested in any special service to arrange a suitable test for himself. Care should be taken to make the conditions of test, viz., number of cells, resistance in circuit, period of drain, etc., approximate those of the service in question.

(3.) Rate of Deterioration on Open Circuit

The voltage and short-circuit current of the cells for test are read initially in order to insure that the cells are in good condition. The cells are then stored in a dry place of normal room temperature.

The following readings are taken:

1. Initial voltage and short-circuit current.

2. Short-circuit current at the end of four weeks, eight weeks and each eight weeks thereafter.

3. Voltage at the end of six months.

The cells are kept on the shelf until the short-circuit current has fallen below 10 amperes. This point is arbitrarily chosen, as it represents a point below which it would be difficult to market the cell. For practical purposes, the results are expressed as the number of months during which the short-circuit current remains above this cut-off point. Much more meaning, however, is attached to the rate at which the current falls, generally reported as the drop in amperage for a given period expressed as a percentage of the initial amperage. This is especially true when investigation of the quality of cells is the object. For practical purposes, however, the first rating given, i. e., months to 10 amperes, is perhaps preferable.

The results from this test are largely indicative of increase in internal resistance, and bear no definite relation to the service which the cells may give. However, this information, coupled with familiarity with a brand of cells, becomes a very good indication of its quality. It also serves to indicate any serious defects of manufacture.

The ammeter for reading short-circuit current should be dead-beat, and with its leads should have a resistance of 0.01 ohm. Two 30-inch lengths of No. 12 lamp cord make very convenient leads.

Particular attention should be given to the temperature at which cells are stored, as the rate of deterioration is influenced to a marked degree by the temperature of the cells.[8]

The ideal method for an open-circuit deterioration test would be the determination of the decrease of service capacity due to storage over definite periods. This practice, however, would entail much labor and expense when the amount of testing to be done is large.

[8] Trans. Amer. Electrochem. Soc., vol. 17, p. 357 (1910); vol. 19, p. 50 (1911).

Finally the committee discusses the *adaptability of these tests to the needs of the various classes of consumers.*

First the *small users,* the number of which is legion, cannot conduct any kind of service test. The only safe course for him is to purchase a reputable brand of cell and perhaps to read the short-circuit current of every cell purchased thereafter to see whether the reading is normal and the cell in good condition.

The class of *"small dealer"* comprises those dealers who may dispose of from a few hundred to a thousand or more cells per year. The dealer is particularly interested in keeping the quality of his stock up to the standard. As cells are received, a representative sample, e. g., 10 per cent. chosen at random throughout the lot, should be read with a reliable make of ammeter. If the readings are normal it would scarcely profit to make further tests. For his protection all cells should be read with the ammeter before being delivered to customers.

The *jobber* buys and sells dry cells largely by barrel lots, and in many cases conducts no tests whatever. If he is desirous of keeping his quality strictly up to standard it would be well to open several barrels in each shipment and test with an ammeter a dozen cells chosen at random throughout the barrel. If the large jobber wishes to carry the best grade of cell for any service, it would probably pay him to conduct the recommended telephone and ignition tests on a small scale. The consumer, however, has more interest in the service to be obtained from cells than has the jobber, but, as noted above, the small average number purchased by the consumer prohibits tests of any magnitude. Therefore if the jobber takes up dry cell testing seriously, it would be with the ultimate aim of protecting and building up the reputation of the small consumer.

The *small telephone company,* consuming say less than ten barrels of cells per year, could install a standard telephone test of small capacity by fitting suitable electrical contacts on a clock and connecting these with a telegraph relay in such a way as to cause the latter to open and close the dry-cell circuits. The Committee advises that such a test be maintained by each company and that periodical tests (at least four per year) be made on the shipment of cells received and also on small lots of other brands purchased from time to time for the purpose of test. The small company should also test a representative sample (say 10 per cent.) of all consignments received, with a good ammeter.

The *large telephone company,* using many barrels of cells per year, can well afford to install an apparatus for carrying on the test suggested in this report. The Committee advises that a battery of three cells from each consignment received be placed upon the telephone test. It, however, considers two such tests per month as a safe maximum number of tests. In addition the short-circuit current and open-circuit voltage should be read upon a representative sample of all cells received. It would be profitable for the large telephone company to conduct regular telephone tests, not only upon the batteries used with their equipment, but also batteries composed of the different makes of cells, in order to compare their relative merits on telephone service.

To the *gas engine manufacturer* it is important that the batteries furnished with his engine be the best cells obtainable from an ignition standpoint. As the apparatus necessary for carrying on the ignition test is quite inexpensive, and as the test requires very little attention, the manufacturer of such engines purchasing a considerable number of cells should conduct the ignition test not only as a check upon the cells he is receiving, but as a basis for judging the merits of the different grades of ignition cells which are available at that time on the market.

An ignition test upon six cells from every fifth barrel received with a maximum of two tests for a single consignment of cells, would probably be sufficient. Before being sent out with an engine the short-circuit current on all cells should be read and those reading abnormally low (e. g., 5 amperes or more below the average for the brand and grade) should be rejected.

Short-Circuit Current and Deterioration of Dry Cells

At the Boston meeting of the Electrochemical Society another interesting paper on dry cell performance was presented by Mr. Carl Hambuechen, of the Northern Chemical Engineering Laboratories of Madison, Wis.

Mr. Hambuechen, who has made since 1908 several thousand dry-cell tests on all kinds of commercial brands, points out that there are three important characteristics of dry cells by which merit is judged, these being commonly designated as the "flash" or "short-circuit current," the "shelf life" and the watt-hour output or "service capacity." The first is of the least importance and the last is the most important, as determining the actual merits of the product, but as to the frequency of use, this order is reversed, and it is by the flash test that the largest proportion of dry cells sold are judged.

Now because the short-circuit current test is in such universal use (the average user choosing that cell which gives the highest short-circuit current), the dry-cell manufacturer is naturally subject to the temptation to turn out a product giving a high short-circuit current, regardless of other probably far more desirable properties.

Mr. Hambuechen's observations make it certain that there has been a tendency in recent years to construct dry cells so

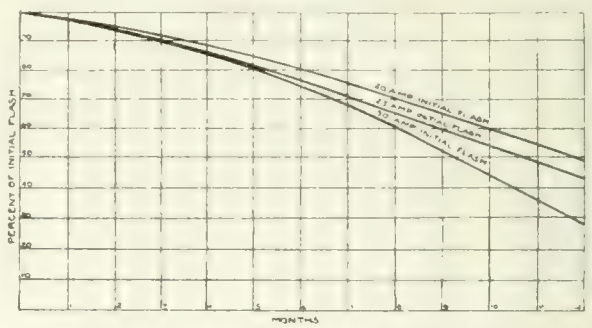

FIG. 4. NORMAL DETERIORATION CURVES

as to give a higher and higher short-circuit current. In 1899 the flash test or initial amperage of commercial American dry cells varied between two and ten amperes. There has been a gradual upward tendency since that time, and this upper tendency is still continuing. Since 1908 the initial amperage of the ignition-type cell has been raised from 20 to over 30 amperes, while with the telephone-type cell the amperage has been raised from 15 to nearly 30 amperes. There are various methods by which the initial amperage may be increased, including the use of graphite and higher conductive carbon, the increase in the percentage of this material with a corresponding decrease in the manganese and other constituents, by the use of various chemicals which increase the activity, by the use of thinner and more porous lining for the cells, and by the density and hardness of tamp, etc.

The question naturally presents itself as to whether in the attainment of a high flash some of the other desirable characteristics may not be sacrificed, and from the author's observation it appears that during the past three years there has been little, if any, improvement in the cell durability or shelf-wear or in the watt-hour capacity; in fact, there is some evidence that these important qualities have been sacrificed in the attainment of high amperage.

Interesting in this connection, as well as interesting in itself, is the question: "What is the rate of normal shelf-deterioration for a standard well-made cell under normal temperature conditions?"

This question is answered in Mr. Hambuechen's curves of Fig. 4, which show the normal deterioration of the more prominent types of cells on the market during the past year.

It is noteworthy that cells made with higher initial amperage show a more rapid deterioration than those giving initially a lower flash test as indicated by the three curves for cells having initially 20, 25 and 30 amperes respectively. It has been pointed out by Messrs. Pritz and Ordway that the falling off in flash tests does not by any means indicate a corresponding reduction in useful service capacity, and the author confirms these observations. Nevertheless, it is desirable that cells be improved for shelf wear, and the above curves indicate that marked opportunity for improvement exists.

British Comparative Dry Cell Tests

Finally an abstract will be given of a recent Faraday Society paper of Mr. S. W. MELSOM, of the (British) National Physical Laboratory, entitled "Dry batteries; the relation between the incidence of the discharge and the relative capacity of cells of different manufacture."

Owing to the absence of agreement as to the method of testing likely to give the best comparative results, it was felt desirable, before settling on a definite test for use in the National Physical Laboratory, to make a comparison between results obtained with a number of the tests in general use and those obtained by a test, the conditions of which approximated as nearly as possible to actual working conditions. The cells subjected to the various tests were selected not in order to ascertain which type of cell is the best when taken into practical use, but with a view to determining the most suitable method of testing dry cells. The four types chosen for the purpose of the investigation were, therefore, those which previous tests had indicated as widely different.

The size of cell employed was that most generally used for telephone work in England, the dimensions over all being 7 in. by 2½ in. by 2½ in. Sixty cells of the requisite size of each of the four types were supplied by the manufacturers, and four cells of each make were selected at random for each of the discharges mentioned. It was evident from the close agreement between the individual cells in each group that this number could be taken as fairly representative of the type. The four makes of cells are designated as A, B, C and D respectively.

The following series of seven tests were taken as being representative of those in general use:

Test 1 (discharge for 5 minutes per hour through a resistance of 50 ohms per cell) represents as nearly as possible the working conditions of a cell on a telephone circuit. The information on which this test is based was supplied by the National Telephone Co., i. e., two cells working on a circuit, the resistance of which is about 100 ohms and the average discharge five minutes per hour. Measurements were made by the National Telephone Co., and it was found that the minimum current with which a telephone microphone would work was 0.018 ampere, and the discharge of the cells was, therefore, considered to be completed when the voltage had fallen to 0.9 volt at the end of any period of discharge.

Test 2 was a discharge for five minutes per hour through a resistance of 1 ohm.

Test 3 was specified by the National Telephone Co., the cells in this case being discharged continuously for six hours per day through a resistance of 5 ohms, resting the other 18 hours. The discharge in this case was considered to be complete when the voltage of each cell, taken after the period of rest, had fallen to 0.9 volt, when discharged for two minutes through a resistance of 50 ohms.

Test 4 was the test formerly specified by the British Post Office. Each cell was discharged continuously at a constant current (in this case 20 milliamperes) until the e. m. f. observed immediately after the current was switched off, had fallen to one volt.

Test 5 is the test most favored by British manufacturers, each cell being discharged continuously through a resistance of 10 ohms. This test is largely used, but the various users are seldom agreed as to the point at which the discharge should be considered complete. Three complete discharges were made under these conditions; one immediately after the cells were received, one after six months' storage, and another after the cells had been stored for 12 months.

In test 6 each cell was discharged through a resistance of 100 ohms, the discharge being considered to be complete when the voltage had fallen to 0.9 volt per cell.

Test 7 is one of the tests used by the (British) War Office, and consists in observing the voltage of the cell when it is discharged continuously through a resistance of 500 ohms.

Results of the Tests.—The volt-hours, ampere-hours and watt-hours given by each cell (the result in each case being the mean of four cells), and, in addition, the relative value of each set of cells, taking for this purpose the output of cells

TABLE I.—Relative Capacity of the Cells at Various Rates of Discharge (The values are in watt-hours, except where otherwise stated.)

No.		Cells. A.	B.	C.	D.
1	5 mins. an hour on 50 ohms.	100	93	83	28
	5 mins. an hour on 1 ohm. Initial	100	59	43	7
2	After 6 months' storage	100	58	50	–
	After 12 months' storage	100	53	42	
3	6 hours per day on 5 ohms— Mean of V B and V E curves	100	50	50	35
4	Continuous at 20 milliamperes— Initial ampere-hours	100	43	36	30
	Initial watt hours	100	45	40	29
	After 8 months' storage, watt hours	100	50	45	5
5	Continuous on 10 ohms— Initial to 0.7 volt	100	75	53	60
	Initial to 0.5 volt.	100	76	55	60
	After 6 months' storage, to 0.7 volt	100	59	44	28
	After 12 months' storage	100	67	50	2
6	Continuous on 100 ohms	100	68	51	35
7	Continuous on 500 ohms— To 1.3 volt.	100	102	87	10
	To end [illegible] 118 weeks	100	94		

TABLE II.—Relation between Incidence of Discharge and Capacity. (The capacity in each case is given in watt-hours.)

Test No.	Cells. A.	B	C.	D.
1	43	40	36	12
2	44	26	19	3
3	126	63	63	46
4	105	47	42	31
5	64	49	35	38
6	107	73	55	38
7	79	66		

A as 100, are given in the paper in form of curves. A summary of the relative values is given in Table I, which is herewith reproduced. It will be seen that the order of merit was the same throughout, but the relative capacity varied considerably. The reason for this is apparently due to different methods of manufacture.

Capacity at Various Rates of Discharge.—In order to determine accurately the capacity of dry cells at various rates of discharge, it would be necessary to fix upon a point at which the discharge should be considered to be complete, at each of the various rates. This point should, of course, be based upon the relation of the fall in voltage to the current which is drawn from the cells. In the present work the limit was, in most cases, that specified by the various users of cells. Therefore the summary of results, given in Table II, must be taken only as an approximation.

The differences are, however, in some cases so large that the effect of stopping the discharge at a slightly higher or lower point on the curve would not seriously affect them. For the purpose of comparison we might dismiss cells D, that type

being so different from the others, especially in its keeping properties. On the intermittent discharge (No. 1) all the cells gave a lower capacity than when discharged continuously at about the same current; this result is remarkable, inasmuch as the cells A, B and C, tested by the continuous discharges, showed little or no deterioration after 12 months' storage.

Conclusions.—In view of the great difference between the relative results of different makes of cells under the various conditions of discharge, and also as to the relation between the incidence of the discharge and the capacity, it seems obvious that, with the exception of No. 1, none of the methods of test investigated can be relied on to give even an approximation of the relative capacity of dry cells or of the output which may be obtained under working conditions. What may be called a "rough idea" of the relative value might, perhaps, be obtained for telephonic purposes from the results of a continuous discharge through a resistance of 100 ohms, but for a really correct comparison the test should approximate as nearly as possible to working conditions.

The author has not made a large number of tests on the larger types of dry cell, such as are used for ignition purposes, but from the results obtained with those that have been tested there seems every reason to believe that the conclusions arrived at as a result of this investigation would apply also to them; the rate of discharge being, of course, in proportion to the size of the cell.

A standard test of this sort, although it would of necessity take a considerable time and might at first sight be considered laborious, would eventually show distinctly which brand of cell is the best suited to the requirements, and would give a very fair approximation of the cost of the energy used. Moreover, satisfactory mechanical arrangements can readily be made for switching the cells off and on, and it is only necessary then to take readings of the voltage about once a week, at, or near, the end of a discharge period. The observations of voltage on open circuit and of internal resistance—at best somewhat indefinite, and always difficult to interpret—would not be required; the process of recording observations would, therefore, be much simplified.

Condensers and Condensation for Vacuum Plants.

By B. Viola, M. E.,
Member American Society of Mechanical Engineers.

The condensation of vapors may be carried out in two different ways, viz., by dry surface-condensation or by wet injection-condensation, according to whether the vapor comes in contact with the cooling water only indirectly by means of a dry cooling surface or directly without intervening plates.

Dry condensation is commonly employed in steam engine plants in order to keep the feed water free from impurities or salts; wet condensation is generally used where cold water (seldom cold air) may be directly injected into the condenser without disadvantage.

Another distinction is made between direct-current and counter-current condensers, according to whether the cooling water and the steam or vapor move in the same or in opposite directions. In either case the steam or vapor is deprived of the latent heat by which it was produced, and it is precipitated once more as water in the form of drops, while simultaneously the pressure exerted by the steam disappears and a vacuum is produced.

Wet condensation is the kind chiefly used in vacuum plants. The cooling surface here is the surface of the cooling liquid while flowing off. The steam, being brought into contact with this cooling surface, will condense, reducing its volume and pressure. According to the ability of the cooling water to consume heat, a certain quantity of steam can be condensed continuously per unit of time and surface.

If a vacuum pan is connected with a condenser, the reduction of pressure in the condenser will communicate itself to the steam space in consequence of the tendency toward equalization of pressures in communicating rooms, and the difference of pressure between boiling surface and condensation surface will be only the amount of pressure required for overcoming the resistance of friction of steam and gases during their motion. These resistances are very different, according to the construction of the condensers and the shape and dimensions of the connecting pipes.

In order to maintain a constant pressure in the vacuum pan, it is not merely sufficient to condense the vapors. With the cooling water a vast amount of atmospheric air and carbonic acid is introduced continuously into the apparatus. Besides, the alkaline earths dissolved in the water can produce gases which will become noticeable at higher temperatures. Even in the evaporator gases, carbonic acid, etc., are produced. All the gases set free from the cooling water have a motion opposite

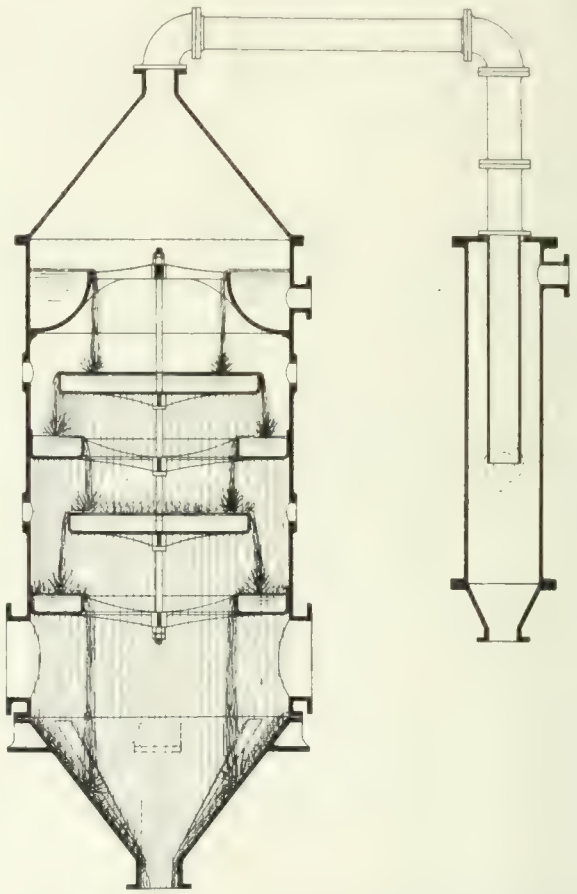

FIG. 71.—CROSS-SECTION OF COUNTER-CURRENT CONDENSER.

to that of the steam; they penetrate the latter, mix with the gases coming from the evaporator and alter their own motion only in the upper part of the condenser, or at the air-pump connection.

If the gases were not allowed to escape from the condenser they would soon fill the room of the vacuum pan to such an extent that in spite of good condensation the pressure would be considerably increased. They would also follow the pitch to the cooling surface, taking up the volume formerly occupied by the condensed steam, would delay the cooling of the steam, and finally stop condensation altogether. To avoid this, an air pump is attached to the upper part of every counter-current condenser in order to take care of these gases.

The cooling water gives off the absorbed air upon entering the condenser in the same proportion as the pressure is reduced. The air is, therefore, carried off by the air pump from the upper part of the condenser at the lowest temperature, never reaching the lower part of the condenser and only promoting the condensation of the vapors in the upper part.

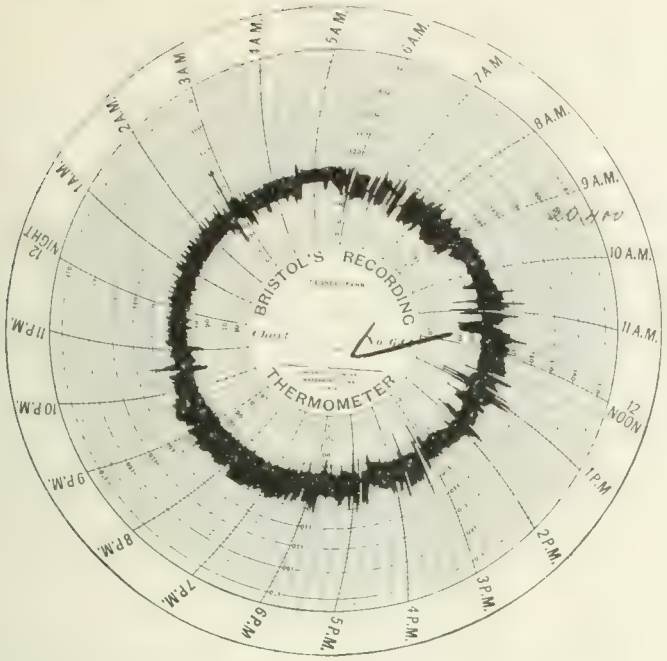

FIG. 73 TEMPERATURE CHART OF CONDENSE WATER WITH AUTOMATIC REGULATION.

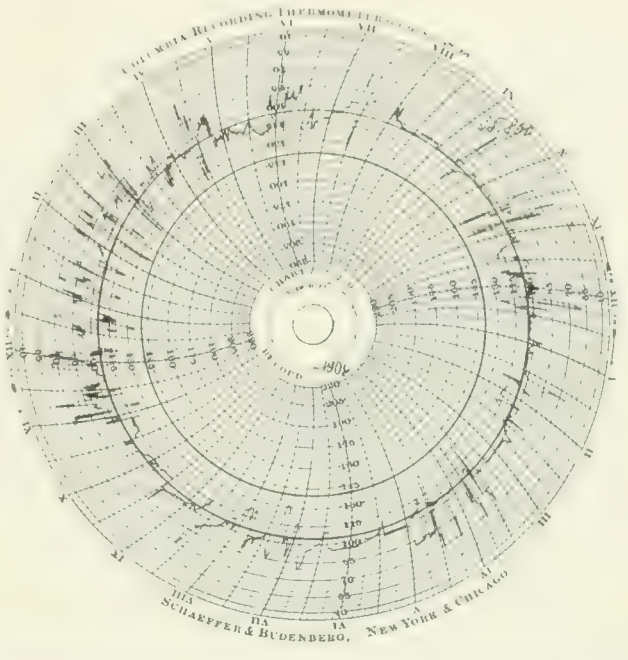

FIG. 72 TEMPERATURE CHART OF CONDENSE WATER WITH HAND REGULATION.

It is generally known that 0.07 is the proportion of air in the water in a wet condenser, including that passing through leaky joints.

We therefore see how important it is never to inject any more water than the vapors require for their condensation.

In practice it is very often found that by an incorrect working of the vacuum, or of the condensing plant, the injection of cooling water is increased. Such a faulty operation is indicated by various symptoms, but most strikingly by the temperature of the condensed water. If the flow of cooling water is too rapid the work of the air pump is immediately made more difficult, since a great deal more air is to be removed. If the air pump is accurately proportioned according to the size of the plant, it will now be unable to accomplish the work. If it is larger, the work is done at the expense of more steam. If a wet-air pump is employed it is called upon to remove more air and water. Moreover, the excessive injection of water will cause a higher pressure in the condenser.

Suppose the falling water to be a liquid cylinder, the outer surface or mantle of this cylinder will, upon entering into the hot steam, first take up the heat of the steam, while the interior parts remain cooler. If, owing to the great velocity of fall, the interior portions of the water column are unable to effect cooling as well as the exterior surface, the discharged water will be heated only to a moderate degree. But if an equalization of temperature can be brought about through the whole cylinder of water, while it is falling, the cooling power of the water is utilized to much better effect.

The finer the water can be subdivided in falling the more readily will the gases pass through it, and their resistance will be diminished as the surface increases.

The subdivision of the water brings about largely the escape of the air from the cooling water. But the division never is fine enough, hence in counter-current condensers the real counter-flow takes place only upon the surface where the water and steam are in contact. But the utilization of the cooling surface also depends on the time of contact; that is, on the time for which there is a maximum temperature difference between water and steam.

For the free fall of a body of water the time of falling t is equal to the velocity v, divided by the gravity g, or $t = v/g$. The height of the fall h expressed by the velocity is found from

$$v = \sqrt{2gh} \quad \text{or} \quad th = \frac{\sqrt{2gh}}{g} \cdot \frac{2}{g} \cdot \bar{h}$$

Applying this equation to condensation, we may say that the time th required for a fall from the height h increases proportionately to the square root of the height of the fall. But with the height of fall, the resistance in the condenser also increases.

We can divide the height of fall into n parts (for instance, by providing a series of basins or trays as will be described later on) and thus have:

$$h = n \times h/n.$$

The partial fall being h/n, and giving to the resistances the smallest value possible, and to the time of transferring heat in the condenser the highest value, we call the limit of the time of contact of water and heat $t(nh/n)$ and have this equation:

$$t(nh/n) = \sqrt{2h/g}.$$

From this we derive the proportion:

$$\frac{th}{t(nh/n)} = \frac{1}{\sqrt{n}}.$$

Then for every value of $n > 1$ we shall also have

$$t(nh/n) > th, \text{ and in general } t(nh/n) = \sqrt{n}\, th.$$

If we make n very large and h/n very small, we shall proportionately extend the time of contact between steam and water in the condenser.

$$\frac{h}{n} = \frac{gt^2}{2n^2}$$

It is necessary, however, that the partial fall h/n be not less than the value required by the amount of steam to be condensed.

From this calculation we see that the velocity of the water is governed by the height of fall and it is advisable to restrict this height in order to prevent friction resistance, if for no other reason. The smallest value of friction resistance corresponds to $h = o$, that is, the condition when steam and gases flow over standing water. Plants of such construction, however, would be too large. Moreover, water and gases being poor heat conductors when in a state of rest, it is necessary to provide for a certain degree of motion for the water in a condenser.

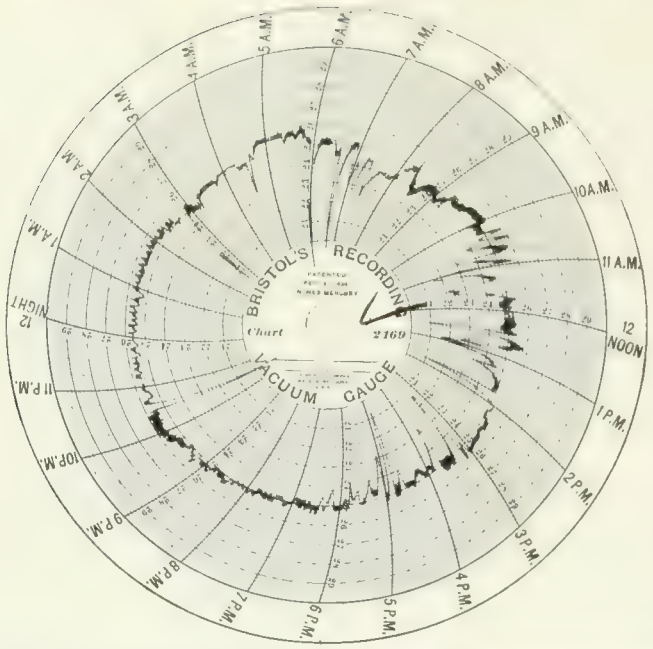

FIG. 74.—VACUUM CHART SHOWING CHANGES OF VACUUM DURING CHARGING OF TANKS.

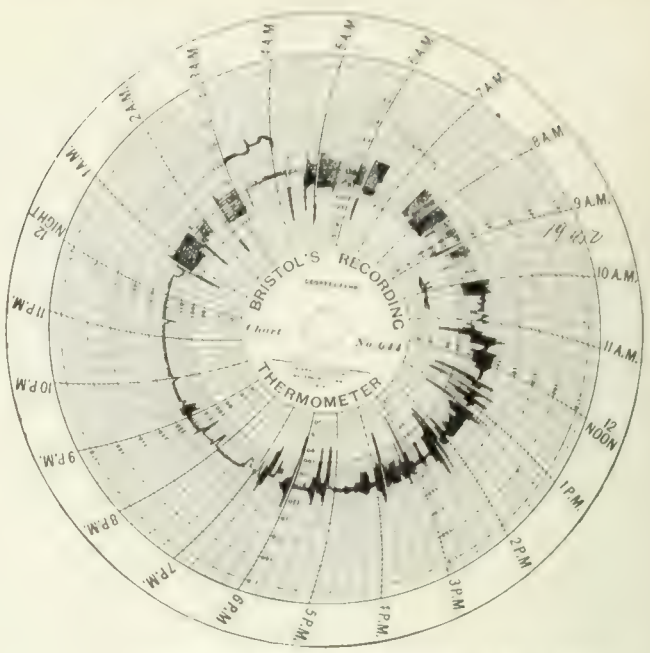

FIG. 75.—TEMPERATURE CHART OF CONDENSE WATER WITH AUTOMATIC REGULATION.

Further, the quantity of steam condensed per unit of time is directly proportional to the cooling surface and a division of the cooling water is therefore equivalent to an extension of the cooling surface.

Therefore, to heat the condenser water quickly to the necessary temperature by direct contact with steam, it is necessary,

1. That the surface of the cooling water be large;
2. That the cooling surface change quickly, and
3. That the time of contact between steam and water be as long as possible.

To fulfill these conditions, a concentric counter-current condenser such as that shown in Fig. 71 gives the best results. This condenser is designed for use in connection with two or more vacuum pans. By the addition of basins or trays the duration of the contact between water and steam is raised in the ratio of $\sqrt{n}$, resulting in an economy of water. Some water will accumulate in each of these trays temporarily and the temperature is, therefore, equalized at each stage. The fresh supply of water will sink to the bottom of the tray, forcing the lower stratum upward on account of the difference in temperature, and the warmer water will flow over from one tray to the next. The trays in this manner form zones with the desired small difference of temperature and constitute a graduated scale of temperatures from the temperature of the steam admission to that of the gas outlet.

The surface of condensation depends primarily on the size of the cooling-water cylinder when the depth of the trays is greater than zero. It may even be said that these moving water columns promote the cooling, and air and gases will pass at the surface of the trays even though they do not pass at the bottom. During the time the water remains in the trays it has a chance to take up more heat which is withdrawn from the steam. It is very important that enough water be permitted to flow to secure good results, but by providing the trays with spray holes the cooling effect of the water is considerably increased.

The work of the condenser varies with temperature, but in general it performs about 610 times the work of the air pump, volumetrically speaking. It is absolutely necessary to exhaust the air and gases to promote condensation, but the best air pump cannot do good work with a poor condenser, while a good condenser accomplishes at least fair results with an indifferent air pump.

As I have explained, it is very important that the correct quantity of water be used to condense a certain quantity of steam. This matter is neglected in most condensing plants and some kind of automatic device should be applied to regulate the flow of cooling water. Experience has shown that the amount of water should be from 20 to 40 times that of the steam to be condensed. This permits variations within very wide limits and in large condensing plants where immense quantities of cooling water are required some controlling device should be applied for economical reasons to prevent waste of water.

The first step is to decide at what temperature the water should be discharged from the condenser. This, of course, bears a certain relation to the steam to be condensed.

A record of experiments made and of results achieved with a condensing plant used in connection with vacuum pans, by the author, will now be given. I first applied a recording thermometer in the tail pipe of a concentric barometric condenser for the purpose of controlling the cooling water by hand operation of the inlet valve; but it was very difficult to convince the operator of the condenser that it was not necessary to let the cooling water run off cold, because it is generally believed the colder the water the higher the vacuum.

The variations of temperature with hand control can be seen in Fig. 72. After experimenting some time it was found very difficult to secure good results by hand regulation, because of the continuous changes which must be made to meet conditions as the number of pans connected to the condenser is increased or decreased. This led to the application of an automatic temperature controller in the tail pipe connected to the compressed-air inlet valve, and by this means it was found possible to feed the condenser approximately in proportion to the steam or vapor which had to be condensed. As a result the average temperature of the condense water was improved and the variations were reduced so as to be only slight.

The temperature of the condense water at a given time may be compared with the corresponding vacuum secured by automatic regulation. (Figs. 73 and 74.) By maintaining the temperature of the condense water nearly equal a very uniform vacuum was obtained except at periods when a new vacuum pan was charged.

The most striking changes will be noticed at 10:30 p. m.,

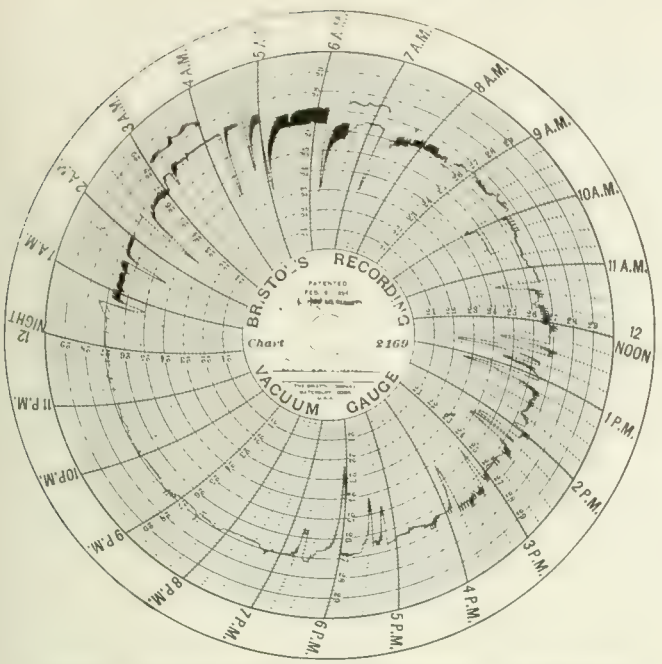

FIG. 76.—CHART SHOWING HIGH VACUUM WITH CONTROLLED COOLING WATER

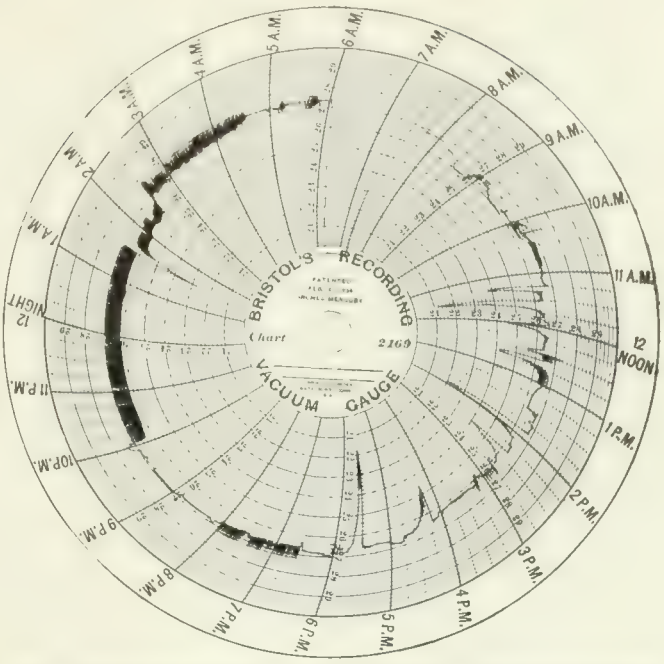

FIG. 77.—VACUUM CHART SHOWING DETAILS OF FLUCTUATIONS OF VACUUM.

2:45, and 6:00 a. m. in Fig. 74. At the same periods the controlling thermometer showed a considerable fall in temperature, due solely to the temperature of the air drawn in from a newly charged pan which was filled with air at the temperature of the operating room. The vacuum pump draws it into the condenser and as a consequence of this the vacuum drops until all the air is drawn out and the new pan reaches an equilibrium with the vacuum which the pump is able to keep up in connection with the other pans.

During this period of low vacuum the water is shut off by the controlling valve so that no cooling water whatever enters the condenser. Since the other pans are boiling, the temperature in the condenser increases until the water left in the trays is raised to the temperature limit, when the controlling valve opens and the cooling water is again admitted.

The fact that the higher vacuum is not obtained with an excess of cooling water can be seen from Figs. 73 and 74. Between 4:45 and 5:15 a. m., when according to the chart the lowest temperature was 110 deg. F. and the highest 120 deg. F., the corresponding vacuum was 25.8 inches. The charts shown in Figs. 75 and 76 show even higher vacuums with a temperature of 120 deg. F., the same vacuum pump and the same number of vacuum pans being used in each case.

On all the charts, especially on the temperature charts, most of the records are made up from lines going up and down from the lowest to the highest limit of temperatures, but these lines are so near to each other that it seems to be a continuous surface. The formation of these surfaces can be noticed on the vacuum chart No. 77. These variations are caused by the working of the controlling thermometer, which is always set to a certain highest temperature at which the condense water has to be discharged. After reaching that temperature the combination of the construction causes the opening of the water valve and as soon as the temperature falls, the feed valve gets closed partly so that the water inlet will be considerably diminished.

Doherty Patents on Gas Producer Operation Upheld in the Final Court.

The United States Circuit Court of Appeals for the First Circuit has handed down a decision sustaining the earlier decision of the United States Circuit Court for the district of Massachusetts in the case of the Combustion Utilities Corporation vs. the Worcester Gas Light Company.

The question at issue in both courts was the validity of the patents of Henry L. Doherty covering a means of controlling and regulating the temperature in gas producers. The defendant in the original suit claimed that Doherty's inventions were anticipated in the prior art and were therefore invalid. The trial of the case was held before Judge Brown in the United States Circuit Court of Massachusetts. The Doherty patents cover both an apparatus and a process, embracing the use of a part of the products of combustion in such a way as to restrain the temperature in the incandescent fuel bed in the producer below the point at which the ash can fuse or flux into a clinker. The result is a producer free from the troubles and expense attendant upon clinker in the furnace.

The original suit grew out of the installation of some gas benches for the Worcester Gas Light Company by a prominent builder, which were claimed to infringe the Doherty patents. Because of the importance of the questions at issue, the case commanded widespread attention. Judge Brown, in his decision, stated that "a very protracted and careful examination of the record convinces me that Doherty made a meritorious advance in the art; that he was the inventor both of an apparatus and a new process."

The Court of Appeals—the three justices unanimously concurring—sustains the decision of the lower court completely, making no exceptions whatever. And as this is the court of last resort the patents of Mr. Doherty are fully sustained.

A New Slime Density Table.

By H. B. Lowden

Slime density tables heretofore published have been prepared for use in special cases and are, therefore, not applicable to slimes in which the specific gravity of the solids differs from that for which the table was computed. Their value has been chiefly in indicating convenient forms in which the weight and volume relations may be tabulated for use in the control of the cyanide process. The writer, having experienced the need of a more generally applicable table in his work, has prepared one of considerable range with small intervals, which he feels may be useful to others.

The table is based on the percentage of solid in the slime,

opposite which is given the ratio of solid to liquid. The numbers heading the double columns following, are the specific gravities of the dry solid (that of water being taken as unity). The columns headed S. G. show the specific gravities of the slime, that of water being taken as 1000; that is, the figures show directly the weight of a liter of slime in grams. The columns headed Vol. show the number of cubic feet of the slime in one ton of 2000 pounds.

The specific gravities of solids chosen will probably cover the range of slimes ordinarily met with and the intervals are sufficiently small to admit of interpolation without appreciable error. The last column (4.50) is a hypothetical concentrate and is the specific gravity of a mixture of 80 per cent pyrite and 20 per cent quartz. The average specific gravity of working cyanide solutions is so small as to be negligible.

The table is convenient for ascertaining the amount of solid and of solution in slime pulps from the number of cubic feet, determined by rod or float, in the tank; and specific gravity of the slime, determined by taking the weight of a liter or by a specific gravity indicator in the tank. It is useful in calculations for ascertaining the amount of solution to be abstracted or added in thickening and diluting, for correcting the strength of the solutions, for checking tonnage and for other purposes.

Assume that in a plant in which the specific gravity of the solid is 2.7, a tank is shown, by the depth of pulp in it, to contain 3530 cubic feet of pulp, a liter of which weighs 1223 grams. From the table it is found that the specific gravity 1223 corresponds to 26.16 cubic feet per ton and to 29 per cent solid. The weight of pulp, therefore, is $3530 \div 26.16 = 135$ tons and the weight of solids $135 \times 0.29 = 39.15$ tons. The weight of solution is, by difference, 95.85 tons. If the solution titrates 1.05 pounds cyanide per ton and it is desired to bring the strength up to 2.5 pounds per ton, we have $2.5 - 1.05 = 1.45$ pounds cyanide to be added per ton. Therefore $95.85 \times 1.45 = 139$ pounds cyanide to be added to the tank.

The table is useful in determining the sizes of tanks necessary for any given capacities. Thus, if it is desired to agitate 50 tons of dry slime (specific gravity of solid 2.6) with three parts solution, the table shows this to contain 25 per cent solids and to have a volume of 27.08 cubic feet per ton: therefore $50 \div 0.25 = 200$ tons of slime $\times$ 27.08 = 5416 cubic feet, the required effective working capacity of the tank, to which an amount must be added to secure the desired height of curb above the charge.

*80% pyrite and 20% quartz.

Electric Steel Refining Before the American Iron and Steel Institute

THE general meeting of the American Iron & Steel Institute, held on May 17 and 18, was particularly successful and interesting on account of the careful balance struck between the different functions which the Institute strives to perform in its discussions of commercial problems, in its examination of technical matters, in its devotion to welfare work and the labor problem in general, and in the general social intercourse between its members, which has done so much to weld the constituents of the American iron and steel industry into a harmonious unit.

The morning session of May 17 was opened by an able address of the president, Judge E. H. Gary, on the general situation. The commercial side of the program was covered by an excellent paper by Mr. E. A. S. Clarke, president of the Lackawanna Steel Co., on "Contract Obligations," and by an interesting paper by Mr. Joseph G. Butler, Jr., vice-president of the Brier Hill Steel Co., on "Competition, Its Uses and Abuses." Both papers elicited considerable discussion.

The evening session, taking the form of a banquet at the Waldorf-Astoria, gave the opportunity for a discussion of welfare and safety work. Particularly notable were a paper by Dr. Thomas Darlington, on the enforcement of health laws, and an address by Mr. Raynal C. Bolling, on "Rendering Labor Safe."

The afternoon session of May 17 was devoted to technical papers. Mr. Julian Kennedy spoke on "Some Experiences in India," Dr. John S. Unger, of the Carnegie Steel Co., on "Metals and Alloys," Dr. A. S. Cushman on "Corrosion."

Of chief interest was, however, the paper by Mr. William R. Walker, of the U. S. Steel Corporation, on electric steel refining. This paper is here given in full, together with an account of the discussion which followed. We comment on the paper on our editorial pages.

The Electric Furnace as a Possible Means of Producing an Improved Quality of Steel.

By William R. Walker

United States Steel Corporation.

In the manufacture of steel by either the Bessemer or open hearth process, it is very difficult to remove the last traces of oxygen. In the basic Bessemer process, the overblown metal, which is an extreme case of oxidation, contains only .06 per cent of oxygen.* Oxygen in combination with carbon (carbon monoxide), silicon, iron, aluminum and manganese, and also the combinations of silicates with these oxides, are very deleterious in steel.

My investigations lead me to believe that in the manufacture of steel for the so-called heavy products and steel that is produced in large quantities, a combination of either the acid or basic Bessemer converter and the electric furnace will take a very prominent place. With this combination it is possible to produce steel extremely low in oxygen and other impurities at a cost that will not be prohibitive.

At the present time there are over 70 electric furnaces of various types producing electric steel in Europe and America. These range in capacity from 1 to 15 tons. There is now under construction in Germany a furnace of 25 tons' capacity. A number of these furnaces are competing successfully with crucibles in the manufacture of very high grade steel.

Generally speaking, electric furnaces may be divided into two groups:

First, induction furnaces, in which the heat is supplied by a current induced in the bath.

Second, arc furnaces, in which the arc is struck, either between an electrode and the metal in the bath, or between two or more electrodes so as to heat the metal only by radiation from the arc.

In operating the electric furnace at the present time, the most prominent methods or combinations are as follows:

1. Oxidation of silicon, carbon and manganese in an acid lined Bessemer converter and removing the phosphorus in the basic lined electric furnace with an oxidizing slag and then recarburizing and with the aid of manganese and carbon and a new reducing slag removing oxygen and sulphur and dead melting as in the crucible process.

2. Removal of silicon, carbon, manganese and phosphorus in a basic lined Bessemer converter and further removing phosphorus (if desired) in the basic lined electric furnace with an oxidizing slag, and then with the aid of manganese and carbon and a new reducing slag removing oxygen and sulphur and dead melting as in the crucible process.

3. Removal of silicon, carbon, manganese and phosphorus in the basic open hearth furnace and then recarburizing and in the basic lined electric furnace with the aid of manganese and carbon and a new reducing slag removing oxygen and sulphur and dead melting as in the crucible process.

4. Melting of cold scrap of inferior quality in a basic lined electric furnace; removing phosphorus with an oxidizing slag and then recarburizing and with the aid of manganese and carbon and with a new reducing slag removing oxygen and sulphur and dead melting as in the crucible process.

5. Melting high grade materials in the electric furnace and dead melting as in the crucible process.

The phosphorus is removed in the basic electric furnace in the same manner as in the basic open hearth furnace—that is, by the use of lime and oxide of iron—and the resulting slag containing the phosphorus is removed and a new slag formed consisting of burnt lime and fluor spar; and when the slag is melted, coke dust is added, which, coming in contact with the lime in the slag and the electric arc, produces carbide of calcium. The free carbon and possibly the carbide of calcium in the slag, with the aid of carbon and manganese in the bath, eliminate the oxygen from the steel.

As compared with the Bessemer and basic open hearth processes, the electric has the following advantages:

1. The more complete removal of oxygen.

2. The absence of oxides caused by the additions, such as silicon, manganese, etc.

3. The production of electric steel ingots of eight tons in weight and smaller that are practically free from segregation.

4. Reduction of sulphur to .005 per cent, if desired.

5. Reduction of phosphorus to .005 per cent, as in the basic open hearth process, but with the complete removal of oxygen.

As evidence of the reducing properties of the slag in the basic electric furnace, it has been found that if oxide of manganese and oxide of iron are thrown on the molten slag, the oxides are reduced to the metallic state and the reduced metal goes into the bath. Blown metal from the acid Bessemer converter, containing only .10 per cent to .20 per cent manganese, has been completely deoxidized in the electric furnace without addition of manganese or aluminum, the usual amount of silicon being added in the steel ladle. Rails made from this steel

* "The Non-Metallic Impurities in Steel" F. F. Low. "The Journal of the Iron & Steel Institute" Volume II Year 1907.

are now in service. The composition of one heat of this steel is as follows:

	Per Cent.
Carbon	.55
Manganese	.43
Sulphur	.017
Silicon	.19
Phosphorus	.022

These rails are comparatively soft, but are showing superior wearing qualities compared with the Bessemer rails in the same track and under the same service conditions.

Electric steel ingots crack much less in rolling than either Bessemer or basic open hearth steel. Cold electric steel ingots when heated and rolled into rails, roll extremely well.

At the present time there are approximately 5,600 tons of standard electric steel rails in service in the United States. These rails have been in the track about two years. During the past winter some of these rails have been subjected to very low temperatures—in some cases as low as 52° below zero, Fahrenheit, and are being exposed to all the possible conditions of severe service. It is too early to state much about the wearing qualities of these rails, but from present indications it would appear that rails made by the basic electric process can be made somewhat softer than by either the Bessemer or basic open hearth process and show highly satisfactory wearing qualities. Up to the present time we have not heard of any basic electric rails in use in this country being broken in service.

For experimental purposes, I have had made a small tonnage of electric steel rails, which have varied in analysis as follows:

	Per Cent.
Carbon	.50 to .75
Manganese	.13 to .80
Silicon	.10 to .40
Phosphorus	.02 to .06

On account of the wide variation in the chemical composition of this steel, it would in a paper of this nature and with the limited time at my disposal, be difficult, without going into considerable detail, to discuss the physical properties of these rails. It might be stated, however, that electric steel of a given tensile strength has a slightly greater amount of elongation than basic open hearth steel and that electric steel is somewhat denser than basic open hearth or Bessemer steel.

With the electric furnace, it is possible to produce steel, which when magnified one thousand diameters, shows no oxides or slag enclosures.

As high grade electric steel can be produced at a lower cost than crucible steel, there has been a gradual increase in the production of electric steel for certain purposes where crucible steel was formerly employed and where it has been demonstrated electric steel can be successfully used. This increased production has not been so marked where the object has been the improvement of steel entering into products manufactured in large quantities where the expense involved for experimental work is very great and where of necessity it takes several years to demonstrate if rails and other products made by the electric process are superior to those made by either the Bessemer or open hearth process. From present indications, it would seem probable that there will be a decided increase in the production of electric steel for these products in the near future.

Discussion.

Mr. Walker's paper elicited quite an interesting discussion, in which Mr. T. W. Robinson, vice-president of the Illinois Steel Co., and Mr. Eugene B. Clark, of the American Sintering Co., participated.

The secretary read a communicated discussion by Mr. S. T. Wellman, of the Wellman-Seaver-Morgan Co., and formerly of the famous Otis Steel Co.

Electric Steel for Rails.

Mr. S. T. Wellman's communicated discussion was as follows:

"I have been very much interested in reading Mr. Walker's paper. It confirms my own observations as to the new method of refining steel and making an article that is of the very highest quality in every respect.

"We have heard a great deal in years gone by of the necessity, if high-class steel was wanted, of melting it in a reducing atmosphere, but this has never been possible in the furnaces which we had at our command because with the reducing atmosphere there came reduction of temperature too low for the proper melting of the steel, but with the electric furnace all these conditions are changed, and we can get the highest temperature known in the arts without the presence of any free oxygen whatever.

"The electrical furnace makes possible the production of ideal steel for any purpose whatever, whether it be the softest steel used for high-grade sheets or plates, medium steel for axles and shafts, rail steel, or any of the numerous grades of ordinary tool steel, or for high-speed alloy tool steel, or projectile steel.

"I think that the most important use that electrically refined steel can be put to is the manufacture of rail steel. The railroads of this country have been learning some very costly lessons during the past few months as regards steel rail specifications, and it would seem that now they should be ready to buy the best and safest rail that can be made without regard to a slightly higher price or possibly a little more rapid wear.

"Rails made from electrically refined steel seem to me to offer the very best solution to the problem, for the following reasons:

"1. An ingot is produced which from all the evidence we have is almost perfect in structure. There is almost an absolute freedom from blow-holes which is caused by the freedom of liquid steel from oxides and gases of all kinds; but, what is most important, ingots as large as eight tons, as mentioned by Mr. Walker, can be made which are practically free from segretion. Mr. Walker's statements in regard to this confirm my own observations.

"2. The ingot can be made practically free from phosphorus and sulphur, and on account of its freedom from oxides and gases little or no manganese is necessary in the steel; thus the steelmaker is able to make the ideal steel which is absolutely free from deleterious impurities, and contains nothing but iron and the carbon to give it the necessary hardness for wear. It will probably be found that on account of its greater density not as much carbon will be necessary to give it good wearing qualities, as is the case in ordinary Bessemer or open hearth steel.

"3. On account of its freedom from oxides and gases, there is almost perfect freedom from cracking in rolling. This must make a better rail on account of more perfect surface and freedom from little imperfections which start the wear and are also good starting places for cracks.

"4. The most valuable peculiarity in electrical steel seems to me to be its freedom from segregation. Most, if not all, the failure of rails during the last winter have been practically on account of bad defects caused by piped ingots, the defects from which were not discovered in the blooms nor in the finished rails.

"I think it more than likely that it may be found that the best rail steel if made from the electrical furnace can be made by making small additions of some of the numerous metals used as alloys, like chromium, titanium, nickel, vanadium or tungsten. The effect of these different metals on steel is not yet generally understood, but it offers a very attractive field for study and experiment. From my own observations, I think that a small percentage of chromium, not to exceed 0.25 per cent and a very much smaller amount of titanium would have a very good effect on the density of the rail, and would at the same time toughen and strengthen the steel.

"Some of the gentlemen present may say to me, as my friend, Captain William R. Jones, did to William A. Sweet when he came down to Pittsburgh many years ago to the meeting of one

of the engineering societies to tell them how to make good rails. Said Captain Bill 'What do you know about making rails? You never made any,' which would be a good criticism of anything I might say about this subject, so I will stop right here."

Electric Steel Furnace Experience at South Chicago.

Mr. T. W. ROBINSON, vice-president of the Illinois Steel Co., referred to the fact that three years ago the 15-ton basic lined Heroult furnace erected at the South Chicago works of the Illinois Steel Company* made its first heat. At that time it was the largest electric furnace in existence, and none of greater capacity has as yet been put into operation, although there are several 20 or 25 ton furnaces in Europe now under construction.

"The application of electricity to the manufacture of steel is, commercially speaking, a new process, and the installation at South Chicago was a new adaptation of this new process. Our purpose was to demonstrate whether it was feasible to successfully operate a large electric furnace and make electric steel in large tonnages. At the time the South Chicago furnace was started, the electric furnaces used in the manufacture of steel here and abroad were small, running from a ton or less to five tons in capacity. The aim in their development was largely to find a cheaper process than the crucible process. Our aim was to command a superior steel, and if possible at a cost that would permit of its use in such products as rails. Our problems, mechanical, metallurgical and otherwise, proved many, and our experience soon demonstrated that the conditions surrounding the successful operation of a large electric furnace were in many respects entirely different from those involved in the use of smaller units. In illustration, the demands of a 15-ton electric furnace proved to be far in advance of the art of manufacturing electrodes. Our necessities represented a requirement that the electrode manufacturers of America and Europe had not been called upon to meet, and it took much time and money before there was finally accomplished the 20-inch round amorphous carbon electrode that is now being used at South Chicago." . . .

"While in the application of the electric furnace to the metallurgy of steel there is usually embodied the preliminary removal of impurities by oxidation, the thermal and chemical conditions that obtain are unusually favorable to the final purification of the metal. Although it has proved perfectly feasible to make steel of superior quality from even low grade cold material, the usual practice at South Chicago is to refine in the electric furnace full-blown metal from the Bessemer converter.

"While the electric furnace at South Chicago has probably operated on a greater variety of products than any other furnace in the world, especial attention has been given to the production of electric steel for rails. As Mr. Walker has stated, the results have been most promising.

"The steel in teeming lies much more quietly than is ordinarily the case with open hearth or Bessemer. The ingots when split show a very solid metal, with a remarkable freedom from blowholes. The pipe, unless filled, is as deep as with open hearth or Bessemer steel. Segregation is at a minimum, and the steel is exceptionally homogeneous. Chemically speaking, almost any result within reasonable limits can be obtained. Physically, the metal is more dense than either open hearth or Bessemer. In its ultimate strength and elongation for the same carbon there is but little difference between electric and open hearth in the higher carbons. In the lower carbons, electric steel has a tendency to a higher tensile and a possibly somewhat lower elongation.

"Many etched sections of rails indicate that the steel from the electric furnace is peculiarly uniform in structure, and it appears to be exceptionally free from oxide and slag enclosures as partially determined by microscopic examination. In fact, such superiority as electric steel may have, probably largely lies in its relative freedom from oxygen.

"How much there may be in the theory advanced by some that the characteristics of electric steel are partially due to the influence of the peculiar thermal conditions upon its molecular structure, I cannot say. Certain indications, however, point to there being more in this hypothesis than is generally recognized.

"As Mr. Walker has stated, we have thus far received no report of any breakage from the 5,600 tons of standard steel rails that we have shipped. Some of these rails have been in track for two and a half years or more. Some of the first rails that we produced were intentionally made upon the soft side, running as low as 0.55 in carbon. Our later electric rails, of which the laboratory results would indicate a relatively better wearing quality, have been made ten or more points higher in carbon.

"I recognize that on account of the comparatively short time that the electric rail has been in service, any statement in respect to its comparative quality is open to question. Of course, the final verdict on the merits of any steel must be in that metallurgical court of last resort—result in service. But whatever may be the verdict, American steel practice and the public must be the gainers from the extensive work that has been done in the endeavor to produce, through the electric furnace, a rail of superior quality."

Various Types and Applications of Electric Steel Furnaces.

Mr. EUGENE B. CLARK, of the American Sintering Co., referred to the hypothesis that the heat treatment of molten steel may have an effect upon its subsequent quality. "If this is so, the type of electric furnace in which the steel is refined must be taken into consideration, for the method of the application of heat to the molten steel differs considerably in the different types of furnaces."

Mr. Clark briefly sketched the relative advantages and disadvantages of induction furnaces and arc furnaces, both of the submerged arc type and of the surface arc type. "The submerged arc furnace is more extravagant of electrodes but less severe on linings than is the surface arc type, but on the other hand the heat is localized under the electrode in the former case and distributed over the whole bath in the latter case. What influence, if any, this heat distribution has upon the quality of steel is open to argument, and no effort is intended here to venture an opinion, but certainly this subject is of sufficient interest to warrant study. There are few cases when a steel manufacturer has tried more than one type of furnace."

Mr. Clark referred briefly to the production of high-grade steel in the electric furnace in competition with the crucible process and pointed out that "for certain foundry operations electrically refined steel is especially adapted. Small steel castings require a very hot metal and one free from slags and gases. The baby Bessemer gives a hot steel but one which runs high in oxides and often high in sulphur, so castings are apt to have blowholes and cracks. High manganese and high carbon contents are required to give sound castings, so annealing generally is necessary. The electric furnace obviates these objections by giving a metal at once hot enough to pour into thin molds, and still perfectly free from slags and gases. Metal of exactly the required composition may be obtained, and alloys of any desired analysis may be formed." Mr. Clark explained finally why electric heat must always be relatively expensive.

The **Joseph Dixon Crucible Co.** of Jersey City, N. J., has recently issued pamphlets on lubrication and especially on the use of Ticonderoga flake graphite as a lubricant. Reference is made to a statement by Prof. Goss to this effect: "The tests show that with no other lubrication than flake graphite the journal and brass may be run together for hours at a time, heating up to a high temperature, and this may be done repeatedly, and yet the rubbing surfaces of the bearings remain unscored. As a protection against abrasion of rubbing surfaces, I know of nothing that can equal the record of flake graphite."

* For illustrated description of this furnace see this journal, vol. VIII, p. 179 (April, 1910).

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Filtering Furnace Gases.—Various means have been proposed to purify furnace gases where they are used for heating purposes or for the driving of gas engines. Water sprays and centrifugal force have been used in wet processes, and metallic screen filters have been proposed for dry filtration. According to the specifications of a patent granted to Friedrich Müller, Otto Johannsen and Peter Pape, of Brebach-on-the-Saar, Ger-

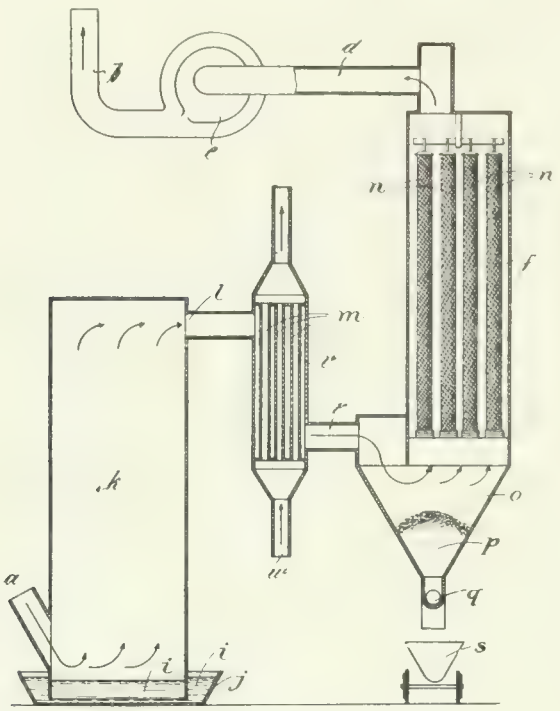

FIG. 1.—FILTERING FURNACE GASES.

many, there are serious objections to the use of these methods, and they propose a new scheme which they claim is an improvement on old methods.

The improved process admits of the use of fibrous material of animal or vegetable origin for filters, provided the temperature and moisture content of the furnace gases is closely regulated. They claim that foreign matter can be eliminated so that the gases will contain only 5 mg of such substances per cubic meter of gas. It is essential that the filter should not be subjected to variations in temperature, and, therefore, the gases are first cooled to the dew point. But as the dew point of the gases is usually higher than atmospheric temperature, it is not advisable to pass the gases directly to the filters without first slightly raising their temperature, in order that the filters shall not become clogged by water and solids which would be deposited at the dew point of the gas. Therefore a restricted heating process is introduced, after cooling to the dew point, before the gases are filtered. The reheating must be sufficient to raise the gas temperature about 20 deg. C. above its dew point. In order further to protect the filters from destruction by dry heat, the gases are damped in the cooling process, by allowing them to come in contact with a surface of water in the cooler.

In Fig. 1 is shown apparatus for cooling, reheating and filtering furnace gases according to the present invention. The cooler *k* is shown in a vessel of water, the latter forming a seal against the escape of the gases. The reheater is shown at *v*, and the filter at *f*. A fan *e* serves to draw the gases through the apparatus and deliver them by *b* to the point of application. Accumulated dust is removed through the hopper *o*. The path of the gas is from *a* through the cooler, reheater and filter to *b*.

The inventors give examples of conditions in German works, one of which is presented herewith, viz., the Halberger foundry.

Coke used per ton of pig iron, about 1300 kg.

Ore yielding about 31 per cent pig iron, 3230 kg.

Water contained in coke, 8-9 per cent. Water contained in ore, 8-10 per cent.

Gas evolved from coke, about 4 cu. m. per kg.

Water contained in charge, 1,300 kg. coke × 9 per cent + 3230 kg. ore × 10 per cent = 440 kg.

Gas evolved, 1300 × 4 = 5200 cu. m.

Moisture in gas, $\frac{440{,}000}{5200} = 85$ gr. per cu. m.

Dew point, 50°C. This gas would be reheated to about 70°C. before filtering. (1,022,496, Apr. 9, 1912.)

Gold and Silver.

Aeration in Cyanidation.—In our issue for April, 1912, page 203, Mr. Louis Cohen presented some miscellaneous cyanide experiments. One of the experiments dealt with the value of aeration of sand charges, alternating percolation with aeration. The results obtained showed the greater value of an intermittent process as compared with one of continuous leaching. As a result of these experiments, Mr. Cohen and Mr. John Gross, both of Denver, Colo., designed and patented an apparatus for carrying out their ideas on alternate leaching and aeration in comparatively thin beds of sand. The apparatus is shown in Fig. 5.

It consists of a circular tank having an annular filter bed on which the sand charge is deposited in a uniform manner by a rotating distributer. While the sand pulp is being distributed on the bed, the solution is drawn through the filter by means of a vacuum pump, and when the bed has been built up to the required thickness, the flow of pulp is turned off. Following this a flow of cyanide solution is allowed to pass over the charge from the rotating distributer, the vacuum being still in effect. In this manner fresh solution is passed through the charge at intervals determined by the speed of rotation of the distributer, and during these intervals air is drawn through the charge, thus effecting an alternating leaching and aeration. When extraction has been completed by this means, a wash of water may be applied to remove the remaining cyanide solution, and finally the extracted charge may be sluiced out of the tank, through an annular opening at the center of the tank bottom. By means of an adjustable plow and water pipe attached to the arm of the distributer (not shown in the cut), the sluicing of the charge is facilitated.

In Fig. 5 the source of ore pulp is shown at 30, the pulp being received in a bowl attached to the central shaft at 29, and distributed by the pipe 34 and apron 35 to the distributing rolls 37. A pipe for conducting cyanide solution to the charge is shown at 31. The distributer travels on wheels running on annular tracks as shown. (1,021,248, March 26, 1912.)

Filter Press Indicator.—For the purpose of enabling an operator to know the thickness of cake being deposited on a filter leaf in the enclosed type of slime filters, Mr. David J. Kelly, of Salt Lake City, Utah, has invented the indicator described herewith and illustrated in Fig. 6. The figure shows diagrammatically a drum containing filter leaves on which a slime cake may be made to form by forcing slime pulp into the drum, the liquid portion being removed through the filtering medium and the pipes *m*. As the operation is not visible to the eye of the operator, an indicator has been devised to show the amount of slime deposited, and thereby the point at which filtration should stop. The indicator consists of a small filter leaf *a*, similar in construction to the large leaves, connected by pipes *d* with a head *c*. On the opposite side of the head *c* is a float *b*. The filter and float being thus at opposite ends of a pivoted connection, they are free to turn about the pivot which consists of a pipe *f* extending through

the drum at *e*. To the outer portion of this pivot pipe is fixed an arm or pointer *g*, upon which is mounted an adjustable weight *j*. A graduated quadrant is placed as shown. The pivot pipe *f* may have a flexible attachment to direct the solution flowing from the small filter to any desirable place.

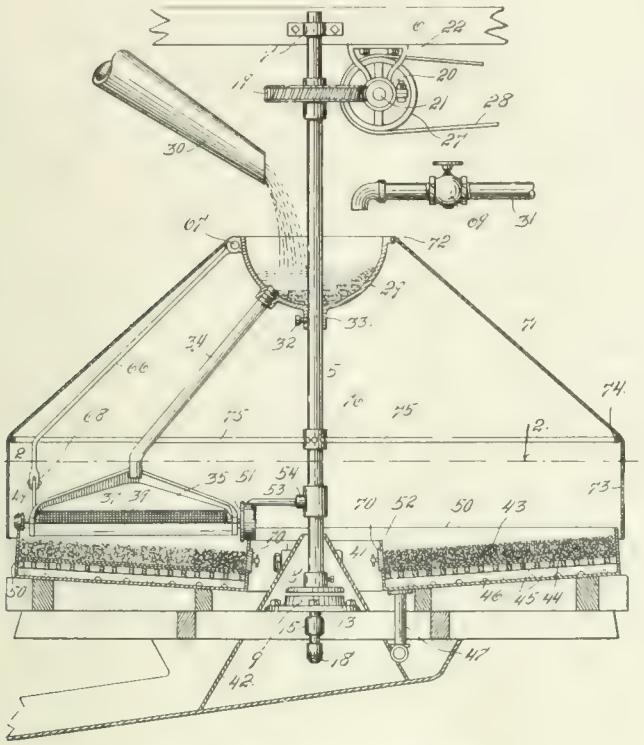

FIG. 5.—AERATION IN CYANIDATION.

It will be apparent from this description that when the drum is filled with slime pulp and cakes begin to form on the large leaves, a similar cake will form on the small leaf *a*; and as the cake continues to form, the leaf will sink by reason of its increased weight, and cause the pointer on the outside to register the thickness of the accumulated cake. The float is so proportioned as to neutralize the effect of the force of buoyancy on the cake, being made to correspond relatively to the cubical contents of the cake and the distance from the fulcrum.

While the invention is described in connection with a pressure filter, it is apparent that it can be applied to vacuum filters by connecting the flexible connection *i* with a suitable branch of the suction line connecting with the main filters. (1,024,082, Apr. 23, 1912.)

Lead and Copper.

Sintering Machine.—The sintering machines devised by Dwight and Lloyd have been constructed on the down-draft principle, as described and illustrated in our issue for February, 1912, page 87. In a patent recently granted to ARTHUR S. DWIGHT, of New York, a modification of the "straight-line" down-draft machine is proposed, in which an upward draft may be employed. The ore is deposited on an endless moving grate as in the down-draft machine, but the igniter is below the grate instead of above it, and the ore bed is held in the desired state of quiescence by means of a second endless moving grating in contact with the upper surface of the bed of ore. Upper and lower "wind boxes" house that part of the grate in which combustion and sintering is taking place, and a fan is provided to force air through the bed, or a suction fan may be used to draw the air in the desired direction. The invention may be applied also to stationary grates, with a perforated grate resting on the ore to prevent it from being disturbed by the blast. (1,021,509, Mar. 26, 1912.)

Alloys.

Substitute for Brass.—Mr. Louis Gross of Homestead, Pa., has been granted letters patent on a composition of matter made from 3 lbs. copper, 1½ oz. ash or clinker, and 1½ oz. borax.

The copper is heated to about 1000°F., when the powdered clinker and borax are added. The mass is then heated to about 1975°F., and afterward cast into molds. The cinder or clinker contains about 35 to 40 per cent metallic constituents, the effect of which is to harden the copper and make it a suitable substitute for brass. (1,023,642, Apr. 16, 1912.)

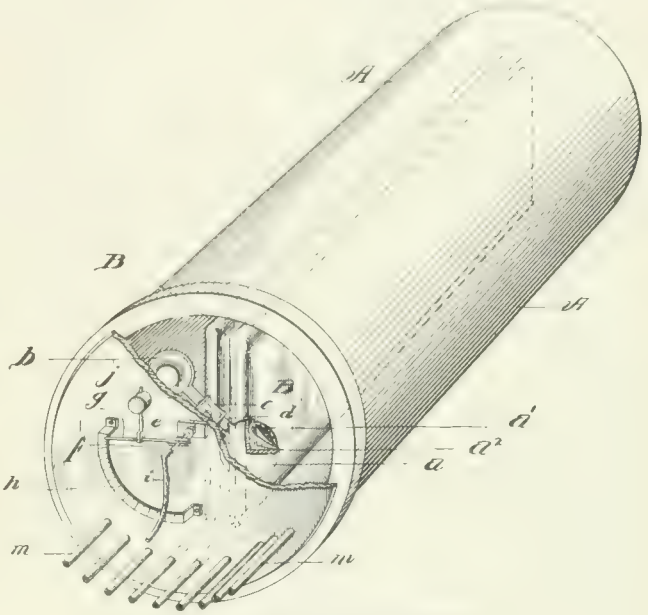

FIG. 3.—FILTER PRESS INDICATOR.

Pyrophoric Alloys.—Ferdinand Krieger, of Berlin, Germany, has compounded a new alloy of manganese and antimony which has pyrophoric properties. It is claimed that the formation of the spark is better than in the case of cerous iron, in that it gives a long flame instead of a cluster of sparks. Further, the new alloy is said not to disintegrate under the influence of the air. The alloys must contain more than 10 per cent each of manganese and antimony, and a good effect may be obtained by adding certain metals, such as chromium up to 20 per cent, but better less than 10 per cent; titanium up to 15 per cent, but better less than 8 per cent. A little magnesium or aluminium may be added to facilitate the process of alloying. (1,023,661, Apr. 16, 1912.)

The rare metals of the cerium group are used for a similar purpose by AUGUST LESMÜLLER, of Munich, Germany. Instead of using iron, nickel, etc., as hardening metals, he prefers to use silicon, titanium or boron, as these give harder alloys which are more economical in use. The amount of hard metal added must be within the following limits: Silicon, 1.8 to 14 per cent; boron, 1.2 to 8 per cent; titanium, 1.5 to 19 per cent. The more of these metals added to the cerium metals, the harder the alloy will be. (1,023,208, Apr. 16, 1912.)

Synopsis of Current Literature

Gold and Silver.

Testing Zinc Dust.—The growing use of zinc dust in the precipitation of cyanide solutions makes it desirable to have certain definite standard tests which may be applied to determine its fitness for metallurgical work. In the *Journal* of the Chem. Met. & Min. Soc. of S. Africa, for February, 1912, Mr. W. J. SHARWOOD, of the Homestake Mining Company, Lead, S. D., publishes some notes on testing zinc dust, and brings out the principal qualities which the material should have. These may be summarized as follows:

It should be dry and fine, nearly all—say, 95 per cent—should pass a 200-mesh screen, while very little—say not over 1 per cent or 2 per cent—should remain on a 100-mesh screen, and none on 50 or 60 mesh. It should not show signs of caking, or contain lumps which do not break up readily when shaken on a screen. An ash-gray color is more favorable than a decidedly blue or white, but color cannot be taken as an absolute criterion. The presence of a little lead—say, 2 per cent to 3 per cent—is an advantage. Laboratory tests with pure zinc, and with alloys containing up to 5 per cent lead, in the same state of subdivision, have invariably shown more rapid and more nearly complete precipitation in the case of the alloy. The presence of a little zinc oxide is not detrimental, although it diminishes the quantity of zinc metal present. Attempts to remove the oxide usually result in removing more or less zinc and sometimes in the destruction of the finest particles. No injurious effect has been traced to any cadmium present. The samples which have been tested and proved satisfactory have shown from 85 per cent to over 95 per cent metallic zinc, most of them containing over 90 per cent.

Typical Analyses of Zinc Dust

Number and Source	Metallic Zinc	Zinc Oxide	Lead	Iron, Cadmium, Carbon and Insoluble
1 Belgian	91.50	Little	0.5	
2 Belgian	88.74	6.60	2.5	2.1
3 Belgian	79.16	11.26	1.9	7.2
4 Average Belgian	84.50	9.3	1.6	4.0
5 Silesian	84.50	4.9	4.3	6.2
6 Silesian	88.50	7.4	2.0	
7 Silesian	...	88.2	4.0	3.0 (SO_3 4.1)
8 American	29.60	57.5	Trace	Insol. 9.6
9 American, good quality	96.00	.....	..	..
10 European, imported, good	90.90	4.0	2.7	.
11 European, imported, fair	85.00	....	2.0	
12 European, imported, fair	94.60	3.7	0.2	Iron 0.3
13 Used at Deloro, Canada	...	3 to 5	1.74	.

Various authorities give the specific gravity of zinc as from 6.85 to 7.21; of zinc oxide from 5.6 to 5.78, and zinc carbonate 4.3 to 4.5. Samples of zinc dust have given results from 6.82 to about 7.0, while the material itself weighs from about 2 to 2.5 grains per cc, or about 120 to 155 lb. per cubic foot. No connection has been shown between the apparent density and the quality, but at least one "heavy" sample was found unsatisfactory.

It is highly desirable to avoid contact with moisture or moist air in the transportation and storage of zinc dust. In a shipment of casks of dust imported into Montana the percentage of zinc oxide varied in different casks and in different parts of the same cask. Portions near the staves of a cask assayed 10 per cent more oxide than a portion in the middle, and a lumpy portion from the bottom of one cask showed 39 per cent oxide.

Chemical Examination: Determination of Lead.—Moisten 10 grains dust with water, then add 200 cc water and stir well. Add 10 cc strong sulphuric acid, stir well and cover. Warm to 60 or 70 deg. C. and stir frequently. If action is slow at start, add one drop of very dilute platinic chloride. When it becomes slow add 10 cc more sulphuric acid and continue warming until nearly all zinc is dissolved. Decant solution onto a filter, wash by decantation several times with water, and pass through filter. Wash residue from filter back into the beaker and dissolve with a little nitric acid; wash into a casserole, add 5 to 6 cc strong sulphuric acid and evaporate to dense fumes. Finish the determination in the usual manner, titrating with ammonium molybdate solution.

Estimation of Zinc Oxide in Zinc Dust.—Solution required: 250 cc. water, 70 grains ammonium chloride, and 150 cc strong ammonia water. One gram of dust is shaken in a stout test tube with 25 cc of the prepared solution, using a piece of soft rubber packing as a stopper held in place by the thumb. Shake well for exactly 5 minutes, and throw the mixture onto a filter, washing well with hot water. Dilute the filtrate with hot water to about 100 cc, add a drop of phenolphthalein, neutralize with HCl and then add 5 cc HCl in excess. Heat to 80 deg. C., and titrate with standard ferrocyanide. Zinc found in solution × 1.245 = zinc oxide in 1 gram. The error due to solution of metallic zinc is negligible if only five minutes contact is allowed. Carbonate of zinc dissolves in the same way as the oxide.

Estimation of Total Zinc.—One gram of the dust is dissolved in dilute HCl and made up to 200 or 250 cc, from which 50 cc is taken for analysis. Add to this portion 5 cc strong HCl, and about 2 gr. ammonium chloride, dilute to about 200 cc and titrate with standard ferrocyanide in the usual manner.

Estimation of Metallic Zinc in Zinc Dust.—A number of methods can be applied for this determination.

I. Take the difference between the total zinc and the zinc as oxide.

II. Reduction of chromic acid by subjecting the dust to the action of potassium bichromate acidified with sulphuric acid. The bichromate should be in considerable excess of the calculated amount for the zinc used. The residual chromic acid is determined by titrating an amount equal to that originally taken, and the solution after the zinc has acted, either:

1. By means of KI, titrating the liberated iodine with thiosulphate, or

2. By means of a standardized solution of ferrous sulphate, or

3. By adding an excess of standardized ferrous sulphate, and completing titration with standard bichromate.

III. Reduction of ferric chloride or sulphate, and titration of the ferrous salt with standard permanganate or bichromate.

IV. Reduction by zinc dust of a solution of iodine in potassium iodide, titrating the residual iodine with thiosulphate. This has given good results only on small quantities, say, 0.1 or 0.2 g.

Following are results obtained by these methods on a sample of zinc dust:

I. Metallic zinc by difference, 78.7 per cent. II. Metallic zinc by reduction of bichromate, (3) 79.6 per cent. III. Metallic zinc by reduction of ferric alum, 77.1 per cent. Whatever *reduction* method is used, the metallic zinc can be calculated thus: 1 cc N/10 standard solution = 0.00327 g zinc.

Determination of Precipitating Efficiency.—A solution of potassium silver cyanide is prepared by dissolving 10 gr. AgCN and 5 gr. "99 per cent" KCN in a little water, and diluting to 1000 cc. It is then adjusted by a little more AgCN or KCN until the solution shows from 0.12 per cent to 0.15 per cent *free* KCN by titration with standard $AgNO_3$, using a 10 cc or 20 cc sample with the addition of 1 cc 2 per cent KI and a slight excess of ammonia to give a sharp end-point.

Weigh out 0.5 g zinc dust, mix with a few cc water and then pour in 250 cc of the prepared solution, stirring vigorously. Continue stirring for five minutes and see that all lumps are broken. Stir every ten minutes for about two hours, then filter, wash the precipitate thoroughly, sprinkle with test lead, wrap the paper carefully around the mass, and scorify carefully with about 20 g test lead. Scorify for five minutes and then cupel at low temperature. Milligrams of silver obtained from 0.5 g zinc × 0.0606 = percentage precipitating efficiency. This test gives conditions similar to those obtaining in practice. Satisfactory samples of dust usually show an efficiency of between 40 per cent and 60 per cent, and sometimes as low as 35 per cent—100 per cent being the standard calculated for the complete replacement of pure zinc by silver.

Mechanical Tests—Sizing Test.—Good samples of dust will show 95 to 98 per cent or more passing a 200-mesh screen, and not more than 1 per cent on 100 mesh.

Elutriation Test.—For the purpose of further studying the physical characteristics of the dust, it may be elutriated by a current of water of definite velocity causing the finest portion of the dust to be carried away from the coarsest. On examination under a microscope the latter will be found to be composed

of impurities, round particles or aggregates of zinc, and feathery or fern-like aggregates.

Surface Exposed by Zinc Dust.—The efficiency of this precipitant is due to the large surface exposed. To calculate the exposed surface we may use the formula $\frac{2304}{gd}$, which expresses the total surface exposed by 1 ton (2000 lb.) of any material in uniform grains—either cubes or spheres—when g is the specific gravity of the material and d is the length of a side of a cube or the diameter of a sphere expressed in inches. The specific gravity of zinc being nearly 7, and assuming the material to be in the form of spheres of d inch diameter, we have, square feet of surface exposed by 1 lb. zinc dust $= \frac{0.165}{d}$

Thus the portion which will just pass a 200-mesh screen, $d = 0.003$ in., will expose only 55 sq. ft. per pound, while the material averaging only 0.0001 in. in diameter—which constitutes a considerable portion of the whole,—exposes 1650 sq. ft. per pound. It is interesting to compare this with zinc shavings, which expose from 45.8 to 84.3 sq. ft. per pound, according to the size of the shaving.

Air-Lifting of Slime Pulp.—The ordinary air-lift has much to recommend it as a means of handling slime pulp, especially in those cases where aeration is a benefit. In the *Mining Magazine* (London) for April, 1912, Mr. A. W. ALLEN presents some considerations of this device.

In the erection or working of an air-lift the following errors should be avoided:

1. Insufficient or excessive ratio of submergence to lift.
2. Lack of precautions providing for the intimate mixture of air and pulp at the lift intake.
3. The use of bends or elbows in the discharge pipe.
4. Unnecessary air pressure.
5. Excessive volume of air.
6. High velocity in the rising main.

When the submergence of the lift pipe in the pulp is insufficient to satisfy an efficient ratio, an excess of air will be necessary to perform the work. With an unnecessary submergence the air pressure required rises above the economical limit. Various ratios are in practice, but it has been shown by a number of investigators and operators that a submergence of from one and three-quarter times to twice the required lift is most efficient. When possible the depth of submergence should be maintained at a constart level, in order to keep the conditions favorable to efficient working.

Efficiency is largely dependent on the intimacy of the mixture of air and pulp at the beginning of lifting. The best arrangement to secure this effect is to have the air pipe perforated with a number of holes which are surrounded by a sleeve of rubber hose. A single air jet will suffice for lift pipes up to 6 in. diameter, but in larger installations it will be necessary to distribute the air over as large an area as possible.

The air pressure required to start the lift will depend on the submergence and the specific gravity of the pulp. If H is the submergence in feet, and S the specific gravity, then, theoretical gage pressure would be $0.434 \times H \times S$ pounds per square inch. In practice an increase of from 10 to 15 per cent will be found necessary.

The volume of air required per unit volume of fluid lifted is proportional to the height of the lift. In Professor Josse's tests, at Charlottenburg, an efficiency of 4.9 per cent of the indicated work in the compressor cylinder was obtained with a submergence ratio of 2:1, lifting 24.6 ft. by the use of compressed air at equivalent atmospheric volume of one and three-quarter times the volume of water lifted. At Preesal, Lancashire, Kelly obtained an efficiency of 38 per cent, lifting 113 ft with the use of a free volume of air in the ratio of 4.5 to 1 of water.

As shown above, the gage pressure necessary to work an air-lift is dependent on the submergence and the specific gravity of the pulp. The required pressure is, therefore, independent of altitude, and air-lifting is as economical at altitude as at sea-level; an extra cost for compression being balanced by the increased expansibility of the air when compressed. E. A. Rix gives the ratio of the volume of free air to volume of water as follows:

Height of lift, ft.	Volume of free air, cu. ft.	Volume of water, cu. ft.
20	1.5 to 2.0	1
20 to 50	2.0 to 3.0	1
50 to 100	3.0 to 4.0	1

It is generally conceded that the velocity of the mixture in the rising main should be as low as possible. As a rough guide it may be taken that the area of the lift pipe in square inches should not be much less than one half the number of cubic feet of pulp required to be lifted per minute. With pipes of constant diameter the velocity in the rising main increases from the base to the top, and under normal conditions the expansion of the air is responsible for doubling the initial velocity. An increase in the area of the rising main to counteract this increasing velocity has been suggested, and while it would be impracticable in most cases, it would seem that in Pachuca tanks an increase in area of central tube from bottom to top would obviate an unnecessary discharge velocity, insuring a better mixture of air and pulp, and allowing quieter conditions at the discharge.

The **Calumet & Hecla Co.**, of Michigan, will regrind the copper tailings previously discharged into Lake Linden by Hardinge regrinding mills. The plant will consist of two units, each unit containing thirty-two 8 ft. diameter Hardinge conical pebble mills.

The oxalate-permanganate method for the determination of copper associated with cadmium, arsenic, iron or lead, consists in precipitating copper as oxalate by adding 2 grains of oxalic acid to 55 c.c., or 4 grains oxalic acid to 100 c.c. of a 50 per cent acetic acid solution of a copper salt containing 5 to 10 per cent nitric acid. The copper oxalate is decomposed by H_2SO_4, and titrated with $KMnO_4$. H. L. Ward (Amer. Jnl. Sci., May, 1912), gives results obtained in a long series of experiments, and concludes that the method may be used with satisfactory results.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in February, 1912, was 67. The total quantity of ore milled during that period was 2,026,140 tons. There were 10,016 stamps in operation, with an average duty of 8.06 tons per 24 hours. Tube mills in commission numbered 263. The yield for the month was 703,866 fine ounces gold.

The American Zinc, Lead & Smelting Company is constructing a zinc smelter at Hillsboro, Ill., with a complete sulphuric acid plant, where they expect to treat 30,000 tons of ore per annum. The plant will be in operation some time this year. The development of the company's Tennessee property has progressed so far as to warrant the construction of a mill, and an increase in capital stock from 150,000 to 300,000 shares has been proposed to meet the financial demands for these new improvements.

Chilean Production of Nitrate.—The production during 1911 exceeded that of any previous year, reaching 54,784,271 quintals (Spanish quintal = 101.41 lb.). The price fell as low as $1.66 gold per quintal in March, but advanced to $1.94 in October. New works of a capacity of 18,000,000 per annum were begun last year and will be completed this year. Authority has been granted by the government to put more nitrate land on the market. Nitrate constitutes about 80 per cent of the exports of Chile, and supplies about 60 per cent of the revenue of the government.

Heavy-Duty Crushing Rolls.

Automatic Lateral Adjustment

By S. W. Traylor.

The movement for good roads throughout all countries has in the last five years trebled the demand for stone crushing machinery, and the enormous increase in the use of concrete, calling for great quantities of crushed stone, has greatly increased machinery requirements.

So great has become the demand for crushed stone that the finer or "sand" product used in all concrete and in road building, has been difficult to obtain of suitable character in many localities.

It has been found generally more satisfactory, and sometimes most advisable, to use the fines or sands made by the general stone crushing plants.

It is usually necessary, however, to have more fines than are made ordinarily in stone crushing, and for this purpose suitable crushers or fine grinding machines have been sought. There are a great variety of such machines on the market, among which are the ball mills, the swing hammer mills, the so-called disc crushers, and others, none of which, however, have been entirely satisfactory for one reason or another, but mainly because of the great expense in the matter of upkeep.

It has long been recognized that the crushing roll would be admirably suited for fine grinding, being unquestionably the cheapest machine in up-keep, if the tires could be prevented from corrugating and made to wear down smoothly, as the corrugation of the tires greatly decreases the capacity of the mill and affects the uniformity of the size of the product, and if not remedied by removing the tire and turning it down soon incapacitates the roll entirely. The time lost in removing the tires for turning down or truing, as well as the loss of the metal in so doing, greatly shortening the life of the tire, makes the ordinary roll anything but satisfactory for such purposes.

Certain manufacturers, however, have given a great deal of thought and attention to the general improvement in the design and construction of rolls in the last few years, and it is believed that the modern roll described below, is thoroughly dependable for fine grinding to 16-mesh.

Modern rolls have also been greatly desired by the large metallurgical companies, especially for concentrating plants where medium or preliminary fine grinding is necessary, and it is a well known fact that a roll makes a more satisfactory product for successful concentration than any other style of pulverizing mill. The trouble has been, however, that most users of rolls have attempted to obtain a product much finer than was practicable to secure from the machine, as it is not practicable, from an economical standpoint, to attempt to grind finer than 16 mesh or 1 mm with a roll.

The improvements in the construction of the modern roll make it entirely safe to consider the use of rolls as a matter of economy, and where properly used and where the product is properly prepared before delivery to the rolls, they will grind down to 16 mesh, on the average run of ore or rock, at a less cost per ton than any other method.

To do this, however, the normal capacity of the roll must be maintained, and it is necessary that it be equipped with the automatic lateral adjusting mechanism, which will positively prevent the corrugating of the tires. This gives to the roll its full capacity at all times, and a roll so equipped will grind just as thoroughly when the tire is half worn down as when it is first placed in commission, and without its having been removed and turned down.

The working out of this automatic adjusting device has made it possible and practicable to increase the width of the face of the rolls, as with this arrangement there is no difficulty in preventing corrugation of the tire up to a width of 20 inches, and it is entirely possible to increase the width even beyond this.

Moreover, in fine grinding practice with rolls, there is no question but that a roll operated at a low peripheral speed will give far better results than a roll running at a high speed; and if the width of the face can be increased, the speed of the roll may be reduced and still maintain the capacity. A slow running roll is unquestionably more desirable from the standpoint of up-keep, as there is far less shock or jar on the bearings, frame and the machine generally than would be the case at a high speed. It is true that a roll running at a low speed requires more horsepower to operate the machine, but the horsepower per ton of product will be found to be very much less, as a slow running roll will produce from 25 to 40 per cent more fines than one with a high peripheral speed, and the economy is therefore apparent.

A careful study of the following description, with the accompanying cuts, of the automatic lateral adjustment will be of general interest, but of particular advantage to those who may be concerned with this important problem of fine grinding.

It will be noted that there is mounted on the end of the so-called stationary shaft a sleeve *F*, the shaft having been turned with flanges corresponding to the recesses in the sleeve. At the bottom of the sleeve is provided a U-shaped opening, through which passes an eccentric shaft *D*. The end of the roll shaft is turned down to receive an oil tempered forged steel worm wheel *A;* this worm wheel meshes into a gear *B*, which is operated as the shaft rotates, and on the shaft on which *B* is fixed, as shown in the plan *X*, there is provided a pinion gear, *H*1, which meshes into the large gear wheel *C*1 mounted on the end of the eccentric shaft D.

Through this system of back gears, the eccentric shaft *D* makes one complete revolution to every 120 revolutions of the roll shaft, giving a slow reciprocating motion to the stationary roll, thus continually changing laterally the relation of the wearing faces of the roll tires.

Without the lateral adjustment the two tires would present exactly the same faces to each other at all times, and in running in this same position continually the roll tires would soon corrugate. To prevent this corrugation with the ordinary hand adjustment requires constant and careful attention on the part of the operator to see that the rolls are often and regularly shifted, and the greatest attention must be given to the feed of the roll.

With this automatic adjustment no particular attention is required. It is possible to utilize from 85 to 90 per cent of the steel in the tire for crushing purposes, and at all times the roll maintains its normal capacity.

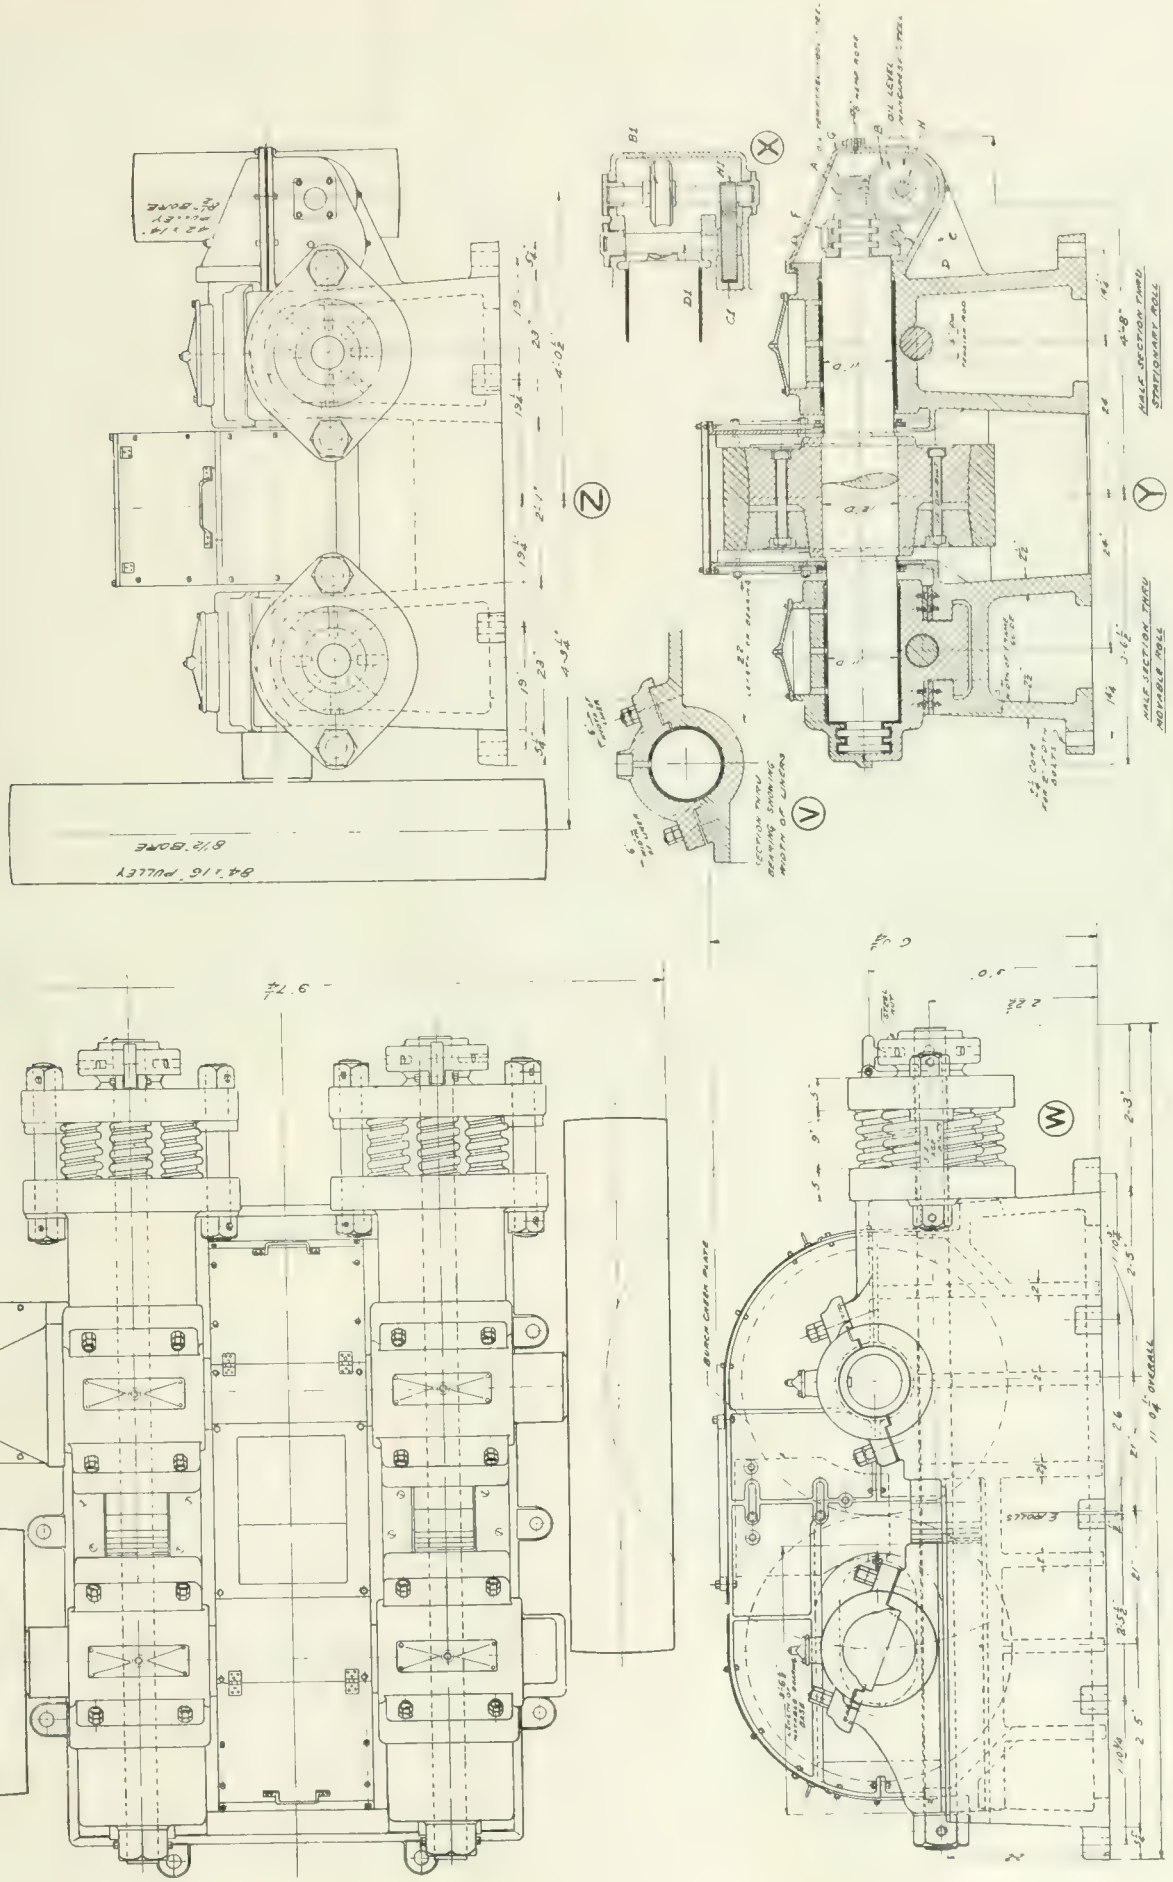
It will be noted that the lateral adjusting mechanism is completely housed, making it positively dust proof. The housing, being kept filled with oil, insures perfect lubrication of all the gears and reduces the wear to a minimum.

Cut *Z* shows the end elevation of the roll, and cut *W* the side elevation. Cut *V* shows the section through one of the bearings, which are of very heavy construction, machine finished, with ample width for liners, packed in the ends and protected at the upper side by a projecting lip, and are dust proof.

Attention is also called to the fact that there are no collars of any sort on the roll shafts, which have been found to be a great nuisance, as they are difficult to hold securely to the shaft and become dangerous. This feature alone, in the machine herein described, will be found of value and considered of importance by the practical operator.

It will be noted also that all moving parts, such as the guides shown in the section, cut *Y*, are faced with oil hardened machine steel, this being a point that usually shows heavy wear in rolls subjected to continuous hard use.

The cuts here shown represent a roll 42 inches in diameter by 16-in. face, which is the heaviest machine of this size that has ever been built. This roll is intended for especially heavy service, where fine grinding is required, with very large capacity. In fact, this roll has, easily, 50 per cent greater capacity



HALF SECTION THRU STATIONARY ROLL
HALF SECTION THRU MOVABLE ROLL
SECTION THRU BEARING SHOWING METHOD OF ADJUSTING
BENCH CASTING PLATE
8'-0" OVERALL

HEAVY-DUTY CRUSHING ROLLS.

than rolls of similar diameter and width of standard construction. The weight of this machine is 53,000 lb., while the standard roll of the same size weighs 28,000 to 36,000 lb.

This particular roll was designed specially and is being built for use in connection with the large metallurgical plant of the Miami Copper Co. at Miami, Arizona.

By careful examination of these cuts, it will be noted that the greatest attention has been given to the matter of lubrication. Much consideration has also been given to the size of the roll shafts, tension rods, cage and heart bolts, as well as to the length of the base of the movable bearing, and by comparison with any standard roll, it will be seen that they have been greatly increased in size.

These machines are built by the Traylor Engineering & Manufacturing Company in three types, viz.: AA, A and B, the main difference being in the weight of the machine suitable for different classes of work and have been recently furnished to other large companies, among which are the St. Louis Smelting & Refining Co., the Butte & Superior Copper Co., the International Pavement Co., the Kennicott Mines Co., the Canada Iron Corporation and the Virginia Graphite Co.

Combined Potash Bulb and Drying Tube

BY GEORGE P. VANIER

The Arthur H. Thomas Company, of Philadelphia, has recently placed on the market a new combustion train with an electric furnace, the principal feature of which is the Vanier combined potash bulb and drying tube. Since the direct combustion of steels in oxygen has come into general use, chemists have been unable to find a potash bulb on the market suitable in every way for this method.

It is desirable to have a combined potash bulb and drying tube, the inlet and outlet of which can be closed to prevent diffusion of oxygen while weighing. They should allow the gases to pass through them rapidly without loss of CO_2 or moisture and should have a large absorbing capacity. Several months' exclusive use of the above combined potash bulbs and drying tube in a large steel works laboratory has shown them eminently suited for the work.

The advantages of these bulbs are:

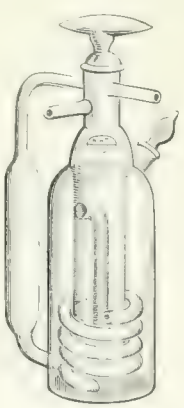
Their large capacity—six grams or more of CO_2 can be absorbed, thus enabling one to make 100 or more combustions without refilling.

When weighing with the bulbs filled with oxygen no rubber caps are necessary as the glass stopcock closes the inlet and outlet while weighing.

They are strong, compact and more easily handled and less liable to be broken than the ordinary bulbs with drying tube attached.

They present a smooth outer surface which is easily kept clean.

They present a minimum outer surface for moisture condensation.



VANIER POTASH BULB.

They are self-supporting and offer a firm base when placed on the balance pan for weighing.

As the drying tube is vertical and the moist gases pass in at the *bottom* the drying tube seldom stops up. As the solid caustic potash deliquesces it forms a pool and extra seal in the bottom of the drying tube.

Each bubble of gas comes in contact with a fresh portion of the KOH solution, and is in contact with the KOH solution while the bubble of gas passes through ten inches of glass spiral tube. The gases can be passed at a high rate without any fear of loss of CO_2 or moisture.

When the gases are passing through rapidly the action is perfectly quiet; there is no jumping or spraying of the solution.

To fill, remove stopper and glass stopcock. Fill drying tube to base of bulb with dry solid caustic potash (through 5 and on 10 mesh). Finish filling drying tube with dry caustic potash (through 10 and on 20 mesh). Place a small wad of cotton or glass wool on top. Through side stopper, with the aid of a small funnel, pour a solution of caustic potash (1 lb. caustic potash to 600 c.c. water) until it reaches the top of the coil. Grease and replace stopper and stopcock.

To empty, remove stopper, stopcock and wad of glass wool. Slip a piece of ¼-inch rubber tubing, about 10 inches long, over side tubulature. Turn bulbs upside down, holding in left hand, and with right hand grasp end of rubber tubing and hold end under a tap of running water, thus allowing bulbs to fill with water. Now lower end of rubber tubing, allowing water to run out. Repeat this operation of filling and emptying several times. Drain and dry, when bulbs will be ready for refilling. The bulbs charged weigh between 140 and 150 grams.

Pennsylvania Steel Co., Steelton, Pa.

Cement Grinding.

BY L. H. STURTEVANT

Increased competition in the cement business is causing the manufacturer to use every endeavor to reduce the cost of manufacture. Naturally one of the first matters to receive his attention is the grinding machinery, as this forms such an important part of a cement plant. Since, in fact, it often determines a profit or a loss to the whole business, it deserves most intelligent investigation.

Five important elements enter into the cost of grinding cement materials:

1—Cost of grinding machinery.
2—Power to operate.
3—Wear and tear (upkeep).
4—Production (output).
5—Continuous operation (absence of shut-downs).

In other words, the cost of producing finished cement per barrel per hour in the grinding mills covers all of these items and the cheapest method of producing this result is the aim of every cement manufacturer.

Large units have come to stay, for the cement business is one of large proportions and the use of many small individual machines is becoming obsolete, and rightly so, for who will install ten small grinders when two large ones will do the work?

It is acknowledged by experienced cement engineers that with any of the small machines now in use it requires from 6 to 10 horsepower per hour per barrel to reduce Portland cement clinker to a finish; that the wear and tear is from $800 to $1,800 per year per grinding mill (tube mills excepted).

The above figures are only for clinker. As to the cost of grinding limestone, coal, shale and clay, while the upkeep cost is not so great, yet the power is practically the same.

Now if a large unit can produce the same results with one-half the power and at one-half the cost for upkeep, one can readily appreciate the reason for its adoption.

The Sturtevant cement unit does all this, and more, for it opens up new possibilities for the cement manufacturer. It not only lessens materially the cost of his finished product, thus making large savings in all of his grinding departments, but lessens labor, cheapens buildings, because of the small space occupied for large outputs, simplifies and unifies the entire plant. It ensures continuous operation by practically eliminating breakdowns and by its few and accessible parts the time required for replacement is only a small fraction of that necessary with even the smallest machines.

This unit consists (as shown in Fig. 1) of a giant duplex ring-roll mill, an elevator, two Newaygo separators and one tube mill.

This is a simple, compact arrangement for clinker, limestone or coal, and has enormous capacity.

The giant ring-roll is used in combination with a tube mill for two reasons:

First—Because no single machine can do two kinds of work with equal efficiency; i.e., it is either better as a preliminary grinder than as a finisher, or vice versa.

No mill having internal screens can be as efficient as a mill that is free to grind and discharge its finished product the instant it is made.

It has proved a physical impossibility to make internal screens of sufficient size or give them proper vibration to handle the product of any good grinder. The result is that much of the sufficiently ground material cannot escape, which cushions and thus cripples the grinding action of the machine, lowering its efficiency and causing much useless wear and tear and bearing trouble due to excessive confined dust.

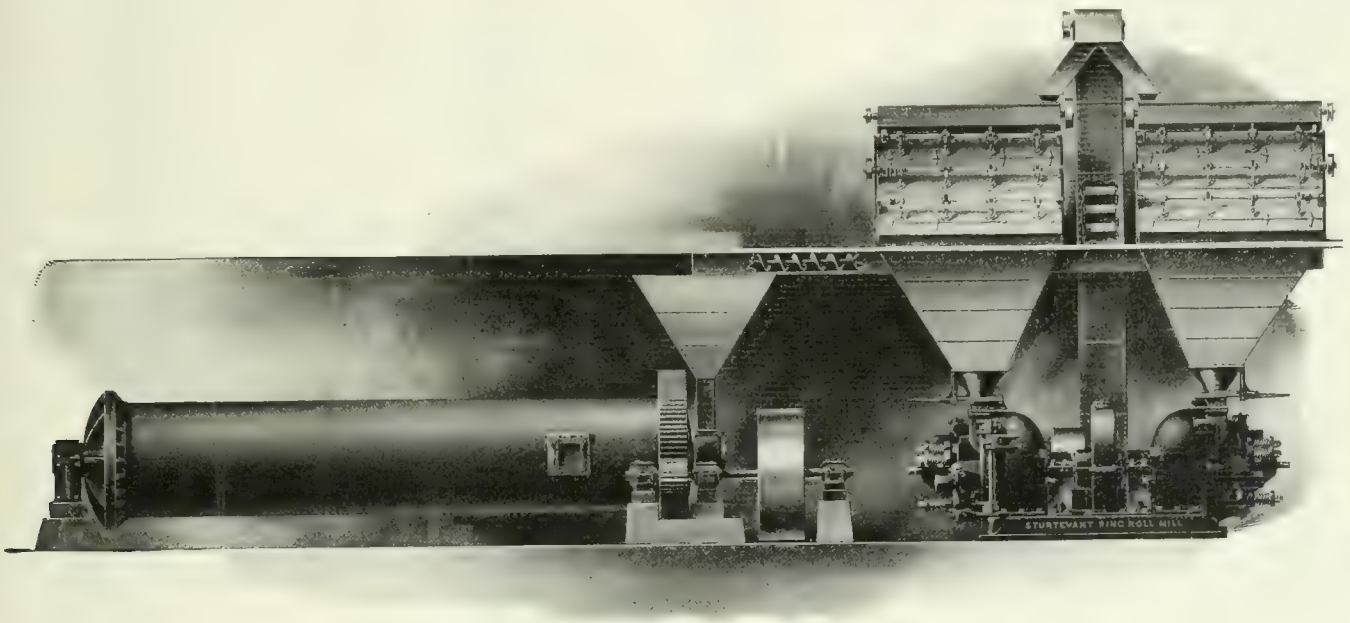
Properly used, the tube mill is a big unit with no small parts to give trouble—and it is a continuous operator.

Even the power is in its favor instead of against it, as most people think. Grinding with a 20-mesh feed, it does unquestionably take too much power for its output, i.e., 75 hp. is needed to drive a 5 x 22 mill to get from it only 12 to 15 barrels per hour (corresponding to approximately 7 hp. per barrel per hour).

But with that same 75 hp. and feeding the tube with 40-*mesh* clinker, we will get 30 *barrels per hour,* instead of 12 to 15 barrels, as before (that is now only approximately 2½ hp. per barrel per hour).

Now, again, taking the same mill, same power, and giving it an 80-mesh feed, the results will be a revelation. It now produces from 40 *to* 55 *barrels* per hour (or approximately 1½ hp. per barrel per hour).

Let us see next what can be expected from a unit, properly



CEMENT GRINDING UNIT.

By removing the screens from ball and other mills tests have proved the mill efficiency was increased by as much as 33 1-3 per cent.

Again, it is never economical to either screen or air-separate a finished product as fine as cement. It is too delicate an operation; it takes too much space and power, and it is complicated. Screening coarse material is easy, but with dust of cement fineness it is impractical on a large scale.

The ring-roll can finish, and some manufacturers would sell it for such work, but we would rather use it in just the place for which it is best adapted, and if there ever was an ideal preliminary grinder, the ring-roll is the machine.

On 20-mesh grinding, taking clinker 1½-in. size, its output is from 80 to 130 barrels per hour. On 40-mesh work, 60 to 80 barrels. On 80-mesh grinding, 40 to 60 barrels per hour. All of this is accomplished with 80 hp.

When a preliminary grinder will do such work as that why try to make it finish or do something that no grinder of its class should be asked to do, and hamper it with internal screens that hold in material already reduced, and clog and render the grinding members ineffective?

Second—Why do we recommend a tube mill as a finisher when we do not build them and have no interest whatever in tube mills?

Because the tube mill *properly used* is just as ideal a finisher as the ring-roll is as a preparatory grinder.

arranged, on a scientific basis, where screens are used, but in their proper place; and each machine operated in a highly specialized manner, never allowing either to do anything except *just that work for which its proved adaptability cannot be questioned.*

Plant:—

1—No. 2 Duplex ring-roll mill, taking 1½" to 2" clinker and grinding to 80-mesh. Capacity 40 to 60 barrels per hour. Power 80 to 90 hp.

2—No. 3 Newaygo screens. To take out the 80-mesh material from the ring-roll product. Comparatively coarse screening and 100 sq. ft. of efficiently vibrated 40-mesh wire cloth to do the work. Power 1 hp. each.

1—6 x 18 tube mill. To take the screened 80-mesh ground clinker from the ring-roll and Newaygo screens and reducing it to a finish, 98%, 100 and 85% 200-mesh. Capacity 40 to 60 barrels per hour. Power 75 to 85 hp.

Thus it will be seen we have a unit of 900 to 1500 barrels output per day, with a power expenditure of approximately 3½ hp. per barrel per hour.

This is the largest unit of its type and yet is as accessible and as elastic as any plant of small *individual* machines which is full of complications, and a complete machine shop is necessary to keep it going.

The above Sturtevant unit has been criticized by some men who have given the matter no thought, on the ground that it is

too big, too unwieldy. They say if something goes wrong the whole plant is shut down.

Let us see if this is true.

The ring-roll mill of duplex design has each half absolutely independent of the other—one half may be operated while the other half is at rest or is stopped for repairs. This feature enables the operator to reduce the workable size of the unit by half.

Again, what is there to get out of order or repair on the ring-roll? If we look it over, there are no scrapers, pushers, plows, guides, screens, shields, balls or other parts of a nature needing constant renewal as in other mills.

If we open the door, a matter of ten minutes, we will find a large ring or tire and three rolls, and that is all the parts we can find that come in grinding contact with the material being ground.

This explains why there is practically so little wear. Because there are no other parts in these mills that come in contact with any material to cause wear.

Is it likely that the upkeep can be much under these conditions?

Only the ring and three roll shells need to be looked after. These parts are *thick* and hard and last a long time, because the ring runs at only 64 revolutions per minute and the rolls have exactly the same surface speed, and when they need replacements it is the work of only *minutes* instead of hours to "open the door" and put new rolls on.

Ring-rolls are continuous runners.

Next, an elevator and two Newaygo screens are to be looked out for. But an elevator is needed in any case, usually *several*, plus conveyor systems that are needed for a multitude of small units; therefore, one elevator for a single great producer is not a complication.

Newaygo screens are continuous runners too, for while the small parts of one screen wear out, yet duplicate parts may be easily and cheaply kept on hand, so there is no delay in the whole system or stoppage, while necessary changes are made in one screen.

It is to be borne in mind that this is a comparatively *coarse screening system* and is therefore easy, for the separators have a great capacity on coarse work, and the *large wire* used for coarse screening renders them *durable*.

The tube mill is the only machine left and is too well known to require description. Everyone knows its interior parts consist of linings, replaceable once a season, and pebbles which may be replenished at intervals through the manhole. It is evident the tube mill is a continuous runner.

Shut-downs are expensive for a cement plant particularly, that ought to be relied on to operate continuously. This point is appreciated by every manufacturer. The Sturtevant unit is bound to be a continuous runner.

The cost of the Sturtevant unit is less than any other per barrel of production per hour, a whole lot cheaper.

The power is less, much less.

The upkeep is many thousands of dollars less, because it requires so few replacements.

Buildings are cheaper, for they may be smaller for a compact unit.

In fact, no feature of this plant can be mentioned that is not better in theory and in practice than any other.

Cement manufacturers are appreciating this fact and are keeping the Sturtevant Mill Co. of Boston, Mass., busy building ring-roll mills to meet the demand for big, economical grinding units.

The Colorado production of zinc now exceeds in value that of silver or of lead, and ranks next to gold. Improved methods of ore dressing are largely responsible for this condition. The value of the zinc output in 1910 was $3,366,437, while in 1911 it rose to $5,696,189. A further increase may be expected in 1912 owing to electrostatic methods of separation.

New Apparatus for Gas Analysis.

One of the most interesting papers presented before the Division of Industrial Chemists and Chemical Engineers at the Washington meeting of the American Chemical Society (December, 1911) dealt with some important improvements in apparatus for gas analysis, which combine in providing surprisingly greater convenience, portability, accuracy and rapidity and a minimum liability to breakage.

Mr. F. M. Williams, the author of that paper, is himself the originator of the new improved gas analysis apparatus, which he developed in his research and industrial laboratories in Watertown, N. Y. The paper is herewith given practically in full:

Probably the best known and most widely used apparatus for gas analysis is that of Orsat, or one of its many modified forms. The numerous modifications which have appeared from time to time bespeak a high tribute to the general utility of this instrument and also a keen desire to remedy its shortcomings.

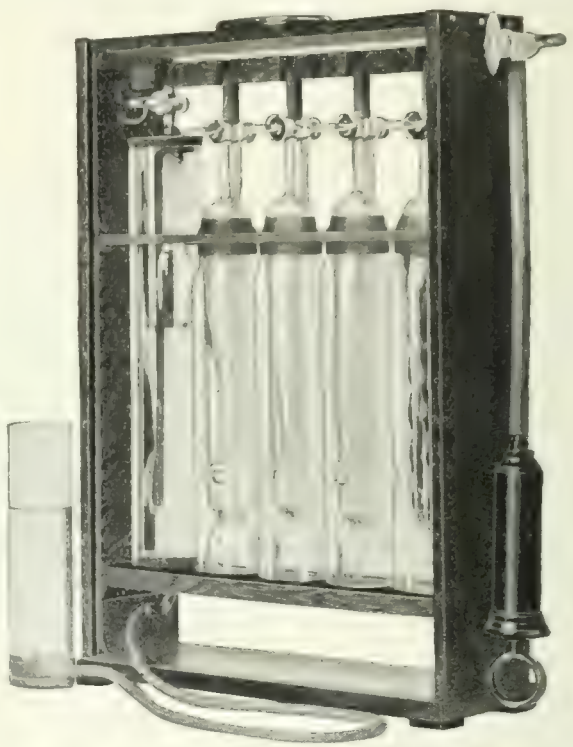


FIG. 1.—OUTSIDE VIEW OF GAS ANALYSIS APPARATUS.

The faults in the original Orsat apparatus may be briefly summarized as follows:

First, although portable, it is much too bulky. Mr. Williams has found that its size may be reduced nearly 50 per cent., still retaining the 100 cc. measuring burette and without impairing accuracy at any other point.

Second, the original form is awkward in manipulation, due to the position of the burette on the right-hand side, necessitating either left-handed manipulation or crossing the hands in the line of vision while operating.

Third, the design of its absorption pipettes with U-tube or gooseneck reservoir, is particularly fragile and liable to breakage at the bend, with the attendant unpleasant deluge of highly concentrated caustic solutions.

This form of pipette is difficult to wash and refill and is also slow in its absorption of gas.

In the modifications which Mr. Williams has developed the above noted objections have been overcome.

First, there is a marked reduction in size. Mr. Williams' model "A," arranged for the complete analysis of combustible gases, occupies a space of only 12 x 4 x 17½ inches, while the flue-gas apparatus, model "B," is only 9½ x 4 x 17½ inches.

The measuring burette is placed at the left side, allowing freedom of the right hand in manipulating stop-cocks, etc.

A special design of explosion burette is indicated in Fig. 2, with terminals permanently connected to binding-posts on outside of case. The bulb is placed lower upon the tube, permitting

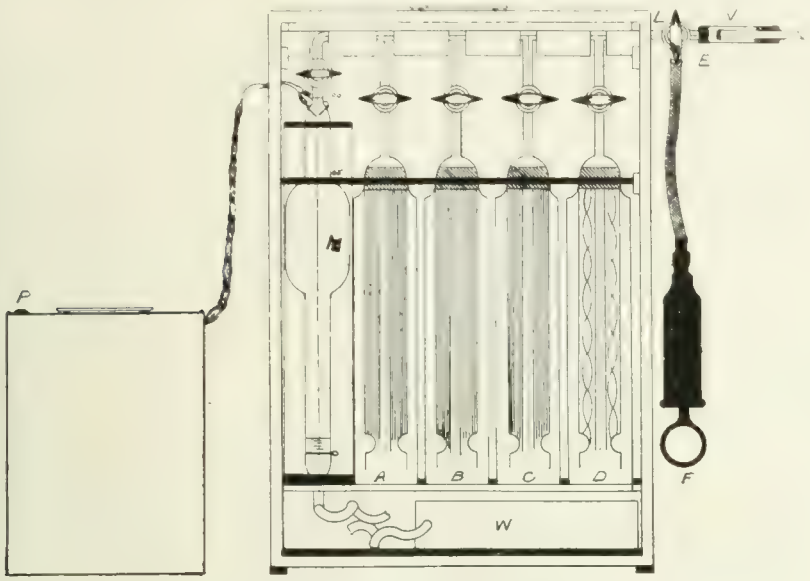

FIG. 2.—MODEL A GAS ANALYSIS APPARATUS FOR COMPLETE ANALYSIS OF COMBUSTIBLE GASES, CARBON DIOXIDE, ILLUMINANTS, OXYGEN, CARBON MONOXIDE, HYDROGEN, METHANE, AND NITROGEN.

15 cc. of clear graduation to be read on the small caliber of the burette above the swell.

The next point to be noted is the absorption pipette, of which two forms are shown, the simple and the bubbling, either form slipping interchangeably into the pipette jar or solution reservoir, with the closure at the top effected by an inexpensive rubber band.

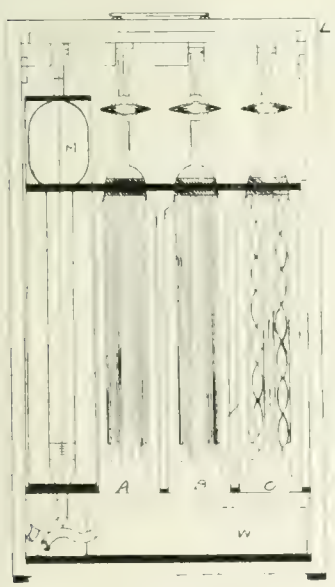

FIG. 3.—MODEL B FOR FLUE GAS ANALYSIS—CARBON DIOXIDE, OXYGEN, CARBON MONOXIDE.

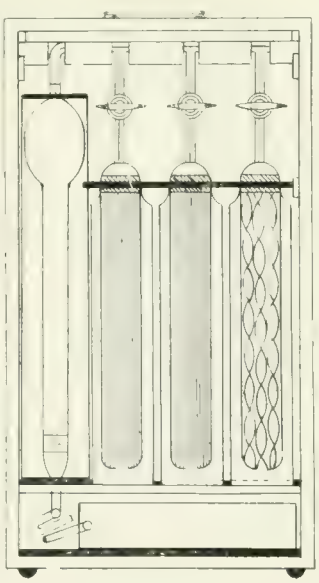

FIG. 4.—MODEL C FOR FLUE GAS ANALYSIS—CARBON DIOXIDE, OXYGEN, CARBON MONOXIDE.

Both forms are so constructed as to prevent the thin glass tubes from falling out when the pipette is removed from the jar.

The simple pipette needs little comment.

The bubbling pipette, which is exceedingly rapid in absorption, owes its high efficiency to the fact that the gas is not only caused to bubble through a long column of liquid, but the bubbles are also finely broken up by the thin glass tubes with which the pipette is filled and a large absorption area is presented by the wet surface of these tubes.

While the arrangement at the top of this pipette somewhat resembles that of Babb, this difference is to be noted—in the original Babb the long capillary tube which passes to the bottom of the pipette enters at the center or highest point while in the form here presented the long tube enters at the side, allowing the short capillary, through which the liquid is brought up to the reference mark, to be placed at the highest point, thereby completely removing bubbles from the surface of the liquid.

The mounting of the glassware in the case is such as to render all parts accessible and instantly removable for cleaning or recharging. The T's at the top are held in a channel piece, G, resting in saddles. The front-half of the cross-piece, H, is removable by lifting from the supporting saddles at the sides of the case.

The exposed portions of the inside of the case are rubber-covered.

The detachable three-way T stop-cock, with hard rubber pump and valves shown in Fig. 2, makes it possible to take a dry sample of gas directly from the source of supply, eliminating the inaccuracy and bother of collection over water, transference, etc.

After connection with supply the pump is operated, discarding the gas in the connecting line until the fresh sample is brought up to the apparatus, when by turning the stop-cock and

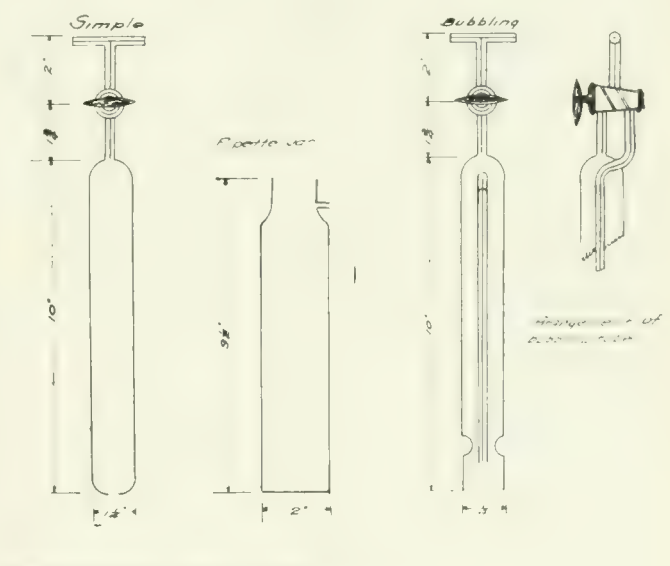

FIG. 5.—PIPETTE DETAILS.

lowering the water-level bottle the measured sample is taken directly into the burette.

This feature is especially advantageous in flue-gas analysis, when the apparatus may be permanently housed in the boiler-room with a line of piping running to the flues enabling an accurate determination of firing conditions to be quickly made at any time. The introduction of an aspirator tank into the line also enables an average sample to be taken covering any desired period of time. This method of control has some advan-

tages, at least, over a recording CO_2 instrument, in that its accuracy and adjustment are unquestionable and we are also able to determine carbon monoxide, which is sometimes an important factor.

Mr. Williams concluded his paper by the statement that years of experience with various kinds of gas apparatus warrants the statement that the form here described is without an equal in the combination of convenience, accuracy, rapidity and minimum liability to breakage.

Personal

Mr. Harold O. Bosworth, formerly of the Denver Fire Clay Company, and later manager of the assay department of the Mine & Smelter Supply Company, Denver, Colo., has gone to Allentown, Pa., where he will manage a concern manufacturing vitrified brick.

Mr. J. R. Finlay delivered the commencement address at the Missouri School of Mines, Rolla, Mo., May 31.

Dr. Hans Goldschmidt, the famous inventor of the electrolytic detinning process and of the thermit process, is at present in this country. He is accompanied by two of his daughters. He expects to return to Europe in the middle of June.

Mr. Victor G. Hills has returned to Denver after spending about one year in Nova Scotia, where he was engaged in the development of a tungsten property and the erection of a mill for the treatment of scheelite.

Mr. Joseph Hodgson, of Ishpeming, Mich., has been appointed superintendent of the Copper Queen mine, Bisbee, Ariz.

Messrs. L. D. Huntoon, B. Stoughton and A. H. Elliott have offices at 165 Broadway, New York, and will engage in practice as chemical, metallurgical and mining engineers.

Prof. W. S. Landis, associate professor of metallurgy, Lehigh University, and assistant secretary of the American Electrochemical Society, has resigned and taken the position of technologist to the American Cyanamid Company.

Mr. E. P. Mathewson, general manager of the Anaconda Copper Mining Company, was awarded a gold medal by the Institution of Mining and Metallurgy, London, in recognition of his eminent services in the advancement of metallurgy, and particularly the metallurgy of copper.

Mr. J. W. D. Moodie, formerly general manager of the Yampa Smelting Company, Utah, has resigned that position and accepted a similar position with the Brittania Copper Syndicate, Ltd., Brittania Beach, British Columbia.

Mr. John Jermain Porter has resigned from the University of Cincinnati and after June 1st will devote his entire time to consulting practice as metallurgical engineer. Mr. Porter will make his headquarters at Staunton, Va., and will give especial attention to improving the operating efficiency of blast furnace, foundry, coking and other processes. In this work he will be associated with Mr. Charles Catlett, Consulting Economic Geologist of Staunton, Va., whose strong connections with the Southern iron industry are well known.

Mr. E. P. Post, assistant in chemical department of the Carnegie Tech, Pittsburgh, has been appointed chief chemist of the Enameled Pipe & Engineering Company, Elyria, Ohio.

Mr. W. S. Quigley, who has been Vice-President and General Manager of the Rockwell Furnace Company, severed his connections with that company recently and has formed the Quigley Furnace & Foundry Company. Mr. Quigley has associated with him able furnace engineers with the intention of carrying on advanced ideas in furnace construction. The Quigley Furnace & Foundry Company is a Massachusetts corporation with a plant at Springfield, Mass. Ground has already been purchased for an enlargement of their plant.

Messrs. W. C. J. Rambo and L. G. E. Bignell have formed a partnership to engage in mining and metallurgical engineering. Their office is at 923 First National Bank Building, Denver, Col.

Messrs. Ricketts and Banks have removed their offices and laboratories to 80 Maiden Lane, New York.

Mr. G. A. Roush, a graduate of Indiana University and post-graduate in chemical engineering at the University of Wisconsin, has severed his connection with the West Virginia Agricultural Experiment Station, as research chemist, to accept the assistant professorship of metallurgy in Lehigh University, under Prof. Jos. W. Richards.

Mr. Fred G. Schenkel has associated himself with the sales force of the Treadwell Engineering Company, Easton, Pa., and will specialize their line of electric steel castings. Mr. Schenkel was formerly connected with the Hess Steel Casting Company.

Mr. R. J. Wysor has been appointed chief chemist of the Bethlehem Steel Company, succeeding Mr. Robert C. Kresge, resigned.

BOOK REVIEWS.

Laboratory Exercises in Physical Chemistry by **J. N. Pring,** D. Sc. 5 x 7½ inches (12½ x 19 cm.). 163 pages, 27 illustrations, Manchester, England: University Press.

Only the main topics are selected, and these particularly in the line of electrochemistry. The chapters are on molecular weight determinations, calorimetry, electrochemistry, electrolytic preparations and pyrometry. The book is elementary, for beginners, but appears well suited for this class. The calorimeter connections are rather crudely applied, and we wish our English friends would abandon the name voltameter for the instrument which measures coulombs and for which Theo. W. Richards has proposed the significant term "coulometer."

Aside from minor blemishes, it is a commendable book for the purpose intended.

Die elektrochemischen Verfahren der chemischen Gross-Industrie. Ihre Prinzipien und ihre Ausführung. Volume 2: Elektrolysen mit unlöslichen Anoden ohne Metallabscheidung. By Dr. **Jean Billiter.** 17 x 24 centimeters, 535 pages, 53 tables, 228 cuts. Price 28.50 marks. Halle: Wilhelm Knapp.

Volume 1, by the same author, covered the separation of metals from solutions and was reviewed (not very favorably) in this journal, September, 1909, page 414. Volume 3 is to be on the electrolysis of molten salts, and Vol. 4 on electric furnaces.

This volume covers a highly interesting and important field in a very satisfactory manner. The electrolysis of water is given 108 pages, while the electrolysis of alkali chloride solutions takes 322 pages, the bulk of the book. In this latest chapter the author is thoroughly at home, and moves systematically and thoroughly through the whole of this great subject, dividing it into (a) chlorine and alkali; (b) hypochlorite and electrical bleach; (c) electrolytic chlorates and perchlorates.

Everyone interested in these processes or industries should get this book.

A third chapter treats briefly of the electrolysis of bromide solutions.

An appendix of over 50 pages brings the various subjects treated in Volume 1 up to date, giving supplementary recent information on the electrolytic separation of copper, silver, gold, lead, zinc, tin, nickel, antimony and iron.

Without any question this is a praiseworthy book, written more carefully and with much better command of the subject matter than Vol. 1.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X — New York, July, 1912. — No. 7

Classification of Electric Furnaces.

What a man thinking of installing an electric furnace first asks for, in general, is a classification of electric furnaces into good and bad ones. When stripped of its flavor of morality, this means simply a distinction between commercially successful and unsuccessful furnaces. Yet a certain type of furnace may be eminently successful in practice for certain purposes and still prove unsuitable in other fields. Inversely the lack of success in one field does not prove that a new type of furnace will not find elsewhere its real field of usefulness. Hence it would seem that all that is needed and can be truthfully given is a statement of fact of success or lack of success in special well-defined cases. Of what use would any general classification of electric furnaces then be for practical, non-academical purposes?

Yet an unbiased classification is always useful, showing the casual interrelation of the various types. The distinction between arc and resistance furnaces is the natural one academically; it has proven good enough even commercially for patent lawyers and experts in long drawn-out suits concerning the difficile question whether a certain furnace was of the resistance or arc type.

Free from such ambiguity, yet not so very different in the last analysis, is a classification based not on the modus of producing the electrical heat but simply on the place where the heat is generated. We can distinguish three classes. First, in the one extreme case the charge is heated purely from the outside. Typical examples are the Stassano radiation arc furnace for steel refining and the Fitz Gerald-Thomson radiation resistor furnace for zinc smelting. In either furnace the heat is produced entirely outside of the charge under treatment and transferred to the charge by radiation.

The second class is the other extreme case in which the heat is produced entirely within the charge, where there is no heating from the outside whatsoever. This is the class of resistance furnaces either with terminals (electrodes) or without them (induction furnace), the charge itself forming the resistor in either case.

The third class comprises all those numerous cases in which there is heating of the charge both from the inside and the outside of the charge. This class comprises all combined arc and resistance furnaces. In some cases, like the Heroult steel furnace or even the Girod steel furnace, the effect of heating the charge from the outside by the arc is so predominant that the inside heating effect by resistance is practically negligible.

Now this classification may be carried a little further in a manner which is not uninteresting from a practical viewpoint. If we make the place of the heat generation the distinguishing feature we are led at once to the distinction between heating the charge from above, heating it from the sides, and heating it from below. All arc furnaces necessarily employ heating from the top. Heating from the bottom or from the sides is possible only in resistance furnaces. Heating from the bottom is

employed, for instance, in the Hering pinch furnace and in the Nathusius steel furnace. Typical examples of heating the charge from the sides are the Acheson furnaces, while in steel refining it is only in the Röchling-Rodenhauser furnace that heating from the sides is employed. There is nothing revolutionary about this whole classification, but it may not be unsuitable for practical discussions.

The Ultimate Objects of Engineering Education.

The ultimate object of all education is to make men. That this remains true even in these days of far-reaching specialization is impressively brought out in two commencement addresses, published in this issue—one delivered last year by Mr. David H. Browne, at Queens University, the other last month by Mr. William L. Saunders at the Colorado School of Mines.

Mr. Browne's address was originally intended as a forcible "answer to Mr. Crane," but in the conclusion of his speech the able metallurgist of the Copper Cliff smelter gives a wonderfully inspiring and clear-cut positive statement of what more than anything else the university or college graduate should take along with him into life—culture, friendship, inspiration.

One single phase of this trio was the subject of Mr. Saunders' not less able address dealing with "culture in the education of engineers." There is too marked a tendency on the part of engineering students to devote their time to what they regard as the "practical" part of their course. Too often they fail to see the value of culture, and neglect the study of subjects which make a well-developed and normal man. They fail to "acquaint themselves with the best that has been known and said in the world." They do not develop habits of good speaking and correct writing, and consequently neglect the only means of communicating their ideas in a pleasing and effective manner.

We may less stress for a moment on one single point on which too little stress is generally laid—the value of good technical writing, the ability to express concisely our ideas or the results of our observations. Engineering is a profession of precision, and the tools of expression used in conveying engineering knowledge must be appropriately chosen and accurately used. Under any other conditions an attempt at technical writing becomes abortive, for the reader may be left in doubt just when he should be accurately and adequately informed. Hence laxity in technical expression is sometimes worse than useless—it may be misleading.

The Michigan College of Mines has made a commendable beginning toward educating its students in the art of English expression. Colorado has been doing something along this line, and at the last meeting of the board of trustees additional appropriation was made to extend the facilities for teaching English composition. Other institutions doubtless are considering this work, and we hope that the next few years will see a wide extension of instruction in English composition in our technical schools.

Some Aspects of the Steel Production Rate.

Two or three months ago the production of steel in the United States reached a new record rate, a fact which is of profound significance. General business conditions in the United States are not particularly good, if one make a composite of the views expressed by various authorities. We must not, of course, take such a composite view too seriously, particularly if we desire to use it for comparison with the situation in the steel industry, for it requires little penetration to observe that these views as to the state of general business are derived more from a contemplation of the profits involved than from a measure of the volume of trade. For the steel industry, it is distinctly in tonnage, and emphatically not in profits, that a new record rate has been reached. The earnings are regarded as quite unsatisfactory. As to the state of general business, it may be observed that commodity prices are practically at the highest average upon record and that labor is very scarce. Possibly these elements exist contemporaneously with poor, or but moderately good business, but if so they are keeping very strange company.

The external relations of the high rate of steel production, however, are mentioned only en passant; it is the internal relations which we particularly desire to consider. To define the position first, it may be observed that the steel works in the past two months have been producing pig iron at the rate of approximately 22,750,000 tons of pig iron per year, steel ingots and castings at the rate of between 31,000,000 and 33,000,000 tons per year, and finished rolled steel at the rate of 24,000,000 or 25,000,000 tons per year. The steel ingot rate is convenient for comparative purposes, but is not of commercial importance, since ingots are not a commercial commodity, and the tonnage is excessive on account of the return of scrap produced in rolling.

The current rate of production may first be compared with the previous record. This was attained early in 1910, just after the close of the six or seven-month period of heavy buying, with advancing prices, which followed the slump in prices early in 1909 attendant upon the abandonment of the co-operative policy among sellers of steel. The high point in the productive rate at that time was represented by a rate of about 21,000,000 tons of pig iron per year by the blast furnaces of steel works, a rate of about 30,750,000 tons of steel ingots and castings, and about 23,500,000 tons of finished rolled steel. There have, therefore, been measurable gains shown by all these factors, from 4 to 9 per cent, the greatest gain being in pig iron production. The excess in this item is due to the fact that in the past two years the steel works have become more self-contained, producing a greater proportion of the iron they consume, and buying less from merchant furnaces. The large steel works now produce practically all the pig iron they consume, and the trend among the smaller steel works is towards the building or purchase of blast furnaces.

At the time of the previous record production rate, the steel produced was not all passing into final consumption. The fact may not have been generally recognized at the time, but it forced itself upon attention later, that there had been much speculative buying, induced by constantly advancing prices, so that consumption did not measure up to the high rate of production then reached. It may perhaps be somewhat unsafe to attach too much importance to the apparent difference, but it is the universal claim to-day that the steel which is being produced is also being consumed, and granting that such is the case, steel consumption is to-day more than 10 per cent,

perhaps 20 per cent. in excess of the highest rate reached prior to this year.

When such a position has been reached without a spectacular revival in general industry, it is made quite plain that steel consumption, in relation to population or the general business activities of the people, is represented by a much larger factor than ever before. Such a growth is evidently a normal one, and not the result of special or temporary conditions. It must be due to the progress of the mechanical arts and to the adoption of steel in place of other materials.

Another important aspect of the current rate of steel production is its relation to the existing capacity. It is readily recalled that for practically three years, from late in 1904 until late in 1907, the constantly increasing steel-making capacity of the country was kept in full operation, production increasing simply as available capacity increased. The increase in capacity, however, did not stop with the slump in demand which occurred near the close of 1907, at the time of the great financial panic, but continued uninterrupted. It was then freely observed that capacity had obtained such a lead over consumption that a period of years, perhaps half a dozen, would be required for the overtaking of capacity by demand which has always occurred eventually in this industry. In the winter of 1909-10 there were hopes that demand had overtaken capacity, but while the steel works reached a position of practically full operation, the condition was, as has just been observed, that a considerable portion of the output was a surplus over actual requirements, purchased by buyers because they expected a higher market level to obtain. A survey of operations at present indicates that substantially the full capacity in the majority of instances is fully engaged, exceptions being a few relatively small detached steel works and plants which finish certain descriptions of steel, like wire and tubular goods. These industries are operating at a high rate, but not at their maximum capacity.

Attention should also be given to a somewhat curious aspect of the situation, which is that while the steel industry, now almost fully self-contained, is operating at substantially full capacity, the merchant blast furnace capacity of the country is but indifferently employed. The time was, many years ago, that the market of the merchant furnaces lay largely with the iron mills, and secondarily with the iron foundries. Later the steel works came to supplant very largely the iron mills as pig iron purchasers, and still more lately the steel works have become self-contained, leaving the merchant furnaces, as a whole, little market outside of that furnished by the foundries. It is true the steel foundries have grown up and buy all the iron they make. The large steel works which roll steel occasionally, and many of the smaller steel works regularly, buy merchant pig iron, but on the whole the merchant furnace operator's market has been narrowed continuously. The situation is that the merchant furnaces are making only two-thirds as much pig iron as they did at their last period of greatest activity, somewhat more than two years ago, and the proportion of production to capacity is presumably still smaller. It is regarded as normal that in a revival in demand the demand for steel first asserts itself, and later the demand for products of the foundry, but the observation is not supported by such an array of facts as would ordinarily be desired. There is reason to conclude that the province of the iron foundry has grown relatively little in a period in which the demand for steel has practically overtaken the capacity.

The Proposed Oldfield Revision and Codification of the Patent Statutes.

The public hearings on the Oldfield bill, which has for object to codify and revise the laws relating to patents, have already taken over twenty-eight days; they have thus far been published in twenty-eight bulletins, printed by the Government. These bulletins make intensely interesting reading, and will constitute valuable documents for any technical library. Those who desire to obtain copies of the published hearings should apply to the Clerk of the Committee on Patents, House of Representatives, Washington, D. C., and should ask for copies of the hearings on H. R. 23417 (Oldfield bill).

Never before was so much direct information collected on the subject of the working of the U. S. patent system. A large number of representative men, among inventors, lawyers, manufacturers, business men, have appeared voluntarily before the House Committee on Patents; they have had ample opportunity to present their views orally and in writing, and the chairman of the committee, Mr. Oldfield, has shown unfailing courtesy and patience to all who appeared before him.

It is a noteworthy fact that although there clearly exists a great diversity of opinion among the witnesses as to details of proposed reforms, there seems to be a practically unanimous opinion among those who ought to know best, that the defects of the patent system of this country as it is now, do not reside in the fundamental patent law, but in the way the law is administered before the courts. Lawyers and inventors alike point out that the methods of patent litigation in this country are so absurd, so slow, so complicated, and so expensive, that only rich individuals or wealthy corporations can afford to defend a valid patent against infringers, or to contest the validity of a worthless patent.

From this standpoint, the patent system of the United States, is, as has been said in these columns (see Abuses of the U. S. Patent System, by L. H. Baekeland, Vol. X, page 273 (May, 1912) "a godsend for wealthy corporations, lawyers, and experts."

During the hearings, it has been pointed out repeatedly how this could be remedied by adopting the methods of England, Germany, and other countries, and by eliminating the present absurd system of taking testimony in patent suits and by the creation of a single final court of patent appeals, instead of the nine circuit courts of appeal which may render conflicting decisions, so that a patent is declared valid in one circuit and invalid in another.

It has also been stated repeatedly during the hearings how the complications, delays, and expenses of the interference system in the Patent Office give an immense advantage to the party with the well-filled purse, and practically eliminate him who cannot pay for lawyers and experts. This might be easily corrected by awarding priority to the diligent inventor, who first files his application, provided he has made the invention independently, and has not obtained same surreptitiously or by fraud from others. After all, the public is only benefited by the inventor who *discloses* his invention, and not by the

one who keeps his invention secret, until he is compelled to disclose it in interference by another inventor who applies for a patent. The interference system as it is puts a premium on delays and on jokeying in the Patent Office. These are two relatively small reforms; they only relate to rules of practice, yet they would bring about immense changes for the better. They do not touch on the otherwise excellent fundamental patent law; they are no untried things; they are successfully in operation in practically all civilized countries except the United States.

Unfortunately, the Oldfield bill has entirely overlooked these most vital points, and indicates no remedy whatever. What is worse, the Oldfield bill introduces some reforms which, in the opinion of competent critics, will kill off the best parts of the fundamental patent law. These reforms, if adopted, will practically assassinate the very spirit of the United States Patent Law, which hitherto has been generally upheld, by foreigners as well as by Americans, as the best patent law in existence. Nor is the latter statement an idle assumption before the fact that such countries like Germany, whenever they made a change in their patent law, always came a step nearer to the American patent law.

Foreign writers have been unsparing in their praise of the organic American patent law, even if they lost no opportunity to denounce or to ridicule the absurd methods of practice in equity before the courts of this country.

The Oldfield bill, instead of remedying the defects of the patent system, simply mutilates the very best part of the patent law. The bill is evidently aimed at the trusts and some large corporations which have been abusing the patent laws. Animated by the desire of curbing the trusts, the framers of the Oldfield bill have unconsciously proposed means which will favor wealthy corporations more than ever before. Indeed, as was pointed out at the hearings, sections 17 and 32 will still further increase abundant opportunities for expensive and long drawn-out litigation.

Someone has defined an American patent as "a license to enter into patent litigation." By Section 17, an American patent will become "a *compulsion* to enter into litigation." Anybody who possesses a valuable American patent will constantly run the risk of being harassed, by suits, to give compulsory licenses under some pretext or another. Valueless patents or those of which the value has not been demonstrated or tried will be left unmolested, but as soon as a pioneer has gone through all the efforts and expenses of introducing his invention, and establishing its merits at his own expense, by creating a successful business, then nothing becomes easier for a wealthy competitor than to take away his "exclusive" patent rights, granted as if in sheer mockery by the constitution. By simply inventing an *improvement* on the original invention, and suing the pioneer inventor for a compulsory license, he can easily make him divide his monopoly and make him compete afterwards with the wealthier and more powerfully organized corporation.

If nowadays there is still some possibility for a patentee to compete with large corporations, this will soon disappear if this section 17 passes. This provision is so hopelessly bad, so indefensible, that even the originators of the Oldfield bill seem to admit the dangers thereof.

The compulsory license clause in case of non-working of the patent is just as dangerous an opportunity for business pirates for jumping at the throat of the patentee while he is in the difficulties of pioneer work and saddling him, against his will with expensive compulsory license suits, and to ask him: "Your invention or your business life." Germany at least only allows compulsory licenses in rare cases; for instance, safety appliances or inventions for national defense where the public welfare is involved.

Section 32 is almost as bad, because it takes away from the patentee the right to stipulate conditions under which to license, vend or lease his inventions to others. This section 32 has been aimed specially against resale price restriction; but the framers of the bill have upset unwittingly the very essence of the patent law, and of the provisions of the constitution which guarantee to the patentee, or his assigns, seventeen years of "*exclusive* right to make, use and vend the invention."

Evidently, those who drew up the Oldfield bill are or were not aware of what an immense amount of mischief and injustice these two sections of the bill would cause, and they remind one of the man who set fire to his barn in order to destroy a hornets' nest. If this Oldfield bill passes as presented, it may be a real calamity for the industrial and intellectual development of this country.

The most eloquent result of the hearings is that among all the many witnesses who have appeared, there was practically unanimous denunciation of Section 17 and Section 32, as framed. One of the very few who were in favor of Section 32, was a lawyer retained by a large Chicago dry goods store, and it was alleged by his critics that this store had frequently violated its business contracts as to selling agreements. On the whole the large majority of those who have given careful thought to the Oldfield bill agree that Sections 17 and 32 would be a great boon to business pirates, habitual infringers, or those who live by appropriating the work or pioneership of others.

The single taxer and the socialist may use their arguments against private ownership of landed property which has always existed before it was owned privately and of which the private owner reaps the benefits of the unearned increment conferred upon it by the efforts of the community. Yet the landowner may let his land lie idle and unproductive to the detriment of his neighbors, and the community at large; furthermore, his title of property or monopoly runs forever.

Why then should an unjust discrimination be made against intellectual property, the most justifiable form of private property, and of which the private ownership exists only for the short period of seventeen years, after which it is confiscated for the benefit of the public?

The status of patent property has been well defined by Albert Walker, in his textbook of patent law: "Patents are property; the owner of a patent is legally and equitably entitled to the same protection that the owner of any other species of property may enjoy. * * * The right of property which an inventor has in his invention is excelled in point of dignity by no other property right whatever. It is equaled in point of dignity only by the rights which authors have in their copyrighted books. The inventor is not the pampered favorite of the Government or of the Nation. The benefits which he confers are greater than those which he receives. He does not

cringe at the feet of power, nor secure from authority an unbought privilege. He confers upon mankind a new means of lessening toil or of increasing comfort, and what he gives cannot be destroyed by use nor lost by misfortune. It is henceforth an indestructible heritage of prosperity. On the other hand, he receives from the Government nothing which cost the Government or the people a dollar or a sacrifice. He receives nothing but a contract which provides that for limited times he may exclusively enjoy his own. Compared with those who acquire property by gift or marriage, compared with those who acquire property by profits or sales or by interest on money, the man who acquires property in inventions, by creating things unknown before, occupies a position of superior dignity. Even the man who creates value by manual labor, though he rises in dignity above the heir, the donee, the merchant, and the money lender, falls in dignity below the author and inventor. * * * *No inventor has any special right in his invention at common law.* This is not a virtue in that law. It is an imperfection, an omission."

Whatever tends to increase and multiply the causes which may involve patent property in litigation, or to render that litigation more complex and ruinous, certainly works to increase the existing insecurity of patent property. The proposed law if made effective would overburden the inventors with litigation uncertainties beyond anything which can at present be estimated.

No one proposes that the principle of compulsory license be applied to landed estates or to any other form of property, however it may have been acquired. Patents are treated as if they were privileges, when, as a matter of fact, a patent to a valid invention of economic and social value is merely a public recognition of an inherent right. If there is reason why the inventors should be compelled to divide their property rights with others, who have in no way contributed to their development, especially along the lines proposed, in sections 17 and 32 of the Oldfield bill, there is even greater reason why the same principle of extraction should be made operative against other forms of private property rights. It does not promote the progress of the useful arts to expose the inventors to dangers which they cannot meet.

It is neither good public policy nor good reason, and certainly not justice, to penalize the inventors because they cannot market their inventions or bring them to the stage of commercial use in the face of legal and economic obstacles created by the long-continued abuse of patent rights and the progressive degradation of the patent system. It is not justice that the inventors should be compelled to surrender their inventive and economic independence, or the prospect of this independence, because society, in its long neglect of their rights, needs, and interests, has permitted a condition to grow up under which the patent system is cunningly and systematically employed to defeat the very aims for which it was created by constitutional provision.

Now that the hearings have disclosed the dangerous mistakes of some of the provisions of the Oldfield bill, it becomes self-evident that this bill ought to be amended considerably before it be submitted again.

If it be redrafted, let provisions be included to simplify and to render less expensive, all actions in equity as well as patent interference proceedings.

The Producer and Smelter of Lead-Zinc Ores.

Prices and penalties usually have been the bone of contention between the producers and smelters of mixed lead-zinc ores. The former are quite certain they are being robbed and the latter are sure they are paying all that the market and the grade of the ore will warrant. Whatever right or merit there may be in the customary attitude of the producer, occasionally it becomes quite evident that he does not understand certain fundamental conditions which must always govern the purchase and treatment of these ores.

From Utah comes the plaint that the smelter catches the producer "coming and going." Formerly, when zinc was an undesirable metal in the ores of that State, contaminating in a high degree the profitable lead ores, it formed the basis of a penalty that was exacted by the lead smelters. During that period much ore was left untouched which contained a comparatively high percentage of zinc and little lead. Now, however, when the demand for zinc has made these once rejected ores desirable for zinc smelting, the producer finds that the zinc smelter exacts a penalty on the lead contained therein. Hence the producer feels he is caught "coming and going."

Here are a few points that the producer of zinky lead ores, or leady zinc ores, should remember. Metallurgical processes give the best results and are most profitably operated when applied to ores that are most amenable to them. Zinc smelting and lead smelting are two widely differing processes and neither metal is profitably recovered in the process adapted to the other. Zinc is undesirable to the lead smelter and vice versa. Zinc in a lead blast furnace charge becomes a total loss, in addition to being a source of trouble to the metallurgist; while lead in a zinc charge not only is partly a loss, but that portion which is recovered is saved against the will of the operator, contaminating the resulting spelter and necessitating further refining. In either case the percentage of undesirable metal in an ore must be reduced by mixing the contaminated ore with others that are free from the undesirable metal.

Hence lead smelters usually exact a penalty on each unit of zinc over 10 per cent. Before such ores can be smelted they must be mixed with other zinc-free ores so that the resulting charge will contain from 5 per cent to 8 per cent zinc. On the other hand, zinc smelters lay a penalty on each unit of lead over 5 per cent, because the lead is detrimental to the process, and a charge must be mixed to contain only from 2 per cent to 3 per cent lead.

It is apparent, then, that metallurgical conditions determine in a large measure the basis of payment for zinc-lead ores, and as long as producers persist in shipping undesirable ores they cannot expect the best treatment. They might do better to introduce the intermediate step of concentration, for if an ore contains enough of either metal to make it objectionable to either smelter it probably is worth separating into two desirable products which would command beter rates at the different smelters. In this way the producer would not only avoid penalties, but actually get higher rates of payment for both metals. If the ore does not carry enough of the undesirable metal to make it worth concentrating, then the producer may not justly object to penalties, because the smelter can scarcely be said to be making a profit out of the penalized metal.

Eighth International Congress of Applied Chemistry.

The attention of all intending to acquire membership in the International Congress of Applied Chemistry (which will be held in Washington, D. C., and New York City from September 4 to 13) is called to the importance of qualifying before July 1, 1912, since, according to the rules, copies of the printed report of the Congress cannot be guaranteed to members who will qualify later. The membership fee is $5.00 and checks should be sent to the treasurer of the Congress, Mr. W. J. Matheson, 182 Front Street, New York City.

All the papers which have been received by July 1 will be printed in advance, and the volumes containing these papers will be ready on September 1.

Some 700 papers have been promised for the Congress. A list of some particularly interesting papers which will be presented before various sections, including the Metallurgical Section, will be given in our next issue.

Electrochemistry at the Congress.

An incomplete yet interesting and suggestive list of papers which will be presented before Section Xa (Electrochemistry) is given in a recent press bulletin issued by the Secretary of the Congress, as follows:

Corrosion Tests of a Series of Iron Alloys. By James Aston, Madison, Wis.

Qualities of Carbon as Influencing Dry Cell Construction. By Carl Hambuechen, Madison, Wis.

Heat Losses in Furnaces. By F. A. J. Fitzgerald, Niagara Falls, N. Y.

Some Analogies in the Electrochemical Industries. By W. McK. Johnson, Hartford, Conn.

Inclusions and Impurities in Electrolytic Silver. By C. D. Buckner, G. A. Hulett and J. Stanley Laird, Princeton, N. J.

Determination of Total Oxygen in Iron and Steel by Means of Carbide Formation. By W. H. Walker and Walter A. Patrick, Massachusetts Institute of Technology.

The Cadmium Coulometer and the Electrochemical Equivalent of Cadmium. By G. A. Hulett and J. Stanley Laird, Princeton, N. J.

Electrolytic Oxidation of Sugar and Oxalic Acid. By Warren K. Lewis, Massachusetts Institute of Technology, Boston, Mass.

Electrolytic Production of Mannite and Sorbite from Invert Sugar. Warren K. Lewis, Massachusetts Institute of Technology, Boston, Mass.

Influence of Cinders on Corrosion of Imbedded Iron. By Walter B. Schulte, Madison, Wis.

Electric Iron Smelting in Scandinavia. By Thomas D. Robertson, Toronto, Canada.

Factors Controlling the Cost of Sodium-Hypochlorite Production. By William H. Walker and Ralph E. Gegenheimer, Massachusetts. By Institute of Technology.

Electric Induction and Resistance Furnaces. By C. H. Vom Baur, New York.

Nouvelle Contribution a la Theorie des Electrolyseurs a Diaphragmes. By Ph. A. Guye, Geneva, Switzerland.

Chemical Reactions on High Temperatures and Pressures. By John M. Pring, Manchester, England.

Power Supply Characteristics of the Electric Furnace. By Charles P. Steinmetz, Schenectady, N. Y.

The Function of Slag in Electric Steel Refining. By Richard Amberg, Crucible Steel Company, of America.

Of considerable interest will be a joint session of the sections on Electrochemistry, Inorganic Chemistry, Physical Chemistry, and Agricultural Chemistry, when an address will be delivered by Mr. Samuel Eyde, of Kristiania, Norway, entitled "Oxidation of atmospheric nitrogen and the development of the resulting industries in Norway." Mr. Eyde is one of the inventors of the commercially successful Birkeland-Eyde process for the fixation of atmospheric nitrogen. This session will be held on the afternoon of Saturday, September 7, at 2 o'clock, in the American Museum of Natural History.

Fall Meeting of American Electrochemical Society.

In this connection the announcement of the Secretary of the American Electrochemical Society is of interest that the fall meeting of the Society will be held in connection with the Congress, Section Xa on Electrochemistry. The joint meetings have been scheduled for September 7, 9, and 10.

On September 7 the American Electrochemical Society will hold a joint meeting in conjunction with the American Institute of Mining Engineers and Congress Section IIIA on Metallurgy, the topic being "Electrometallurgy."

The Annealed Copper Standard.

A report on copper wire tables has been made by the Bureau of Standards. Copper wire tables are based on certain standard or assumed values for the conductivity or resistivity and the temperature coefficient of resistance of copper. But the same standard values are not in use everywhere, and confusion has accordingly resulted. These conditions led the American Institute of Electrical Engineers to request the Bureau of Standards to make an investigation of the subject. This has been done and has resulted in the establishment of standard values based on measurements of a large number of representative samples of commercial copper—values which in certain respects are more satisfactory than any preceding standards.

In the investigation it was discovered that the temperature coefficient is proportional to the conductivity. This new law has been corroborated by the German Reichsanstalt. Bending and winding a wire do not change the temperature coefficient.

A proposal from Germany of a standard conductivity based upon this investigation has been accepted, and will probably soon be adopted all over the world. This new standard is a slightly lower conductivity than the former American value and the average of the experimental values published by the Bureau of Standards, but can be considered as substantially representative of average commercial copper.

This report gives a history of wire gages, showing that the trend of practice is toward expressing diameters directly in decimal fractions of an inch. The report contains fifteen tables, including complete reference and working tables for annealed copper, both in English and metric units. Tables for copper cables and for hard-drawn aluminum wire are also given. The tables have been adopted as the official wire tables of the American Institute of Electrical Engineers.

The Iron and Steel Market.

The steel industry probably reached its maximum rate of production for the time being at the beginning of June, as no important additional capacity has since been made active, or is likely to be started in the next few weeks, while hot weather has begun to have its influence in curtailing outputs, and there will be many brief closures in July for necessary repairs. Labor conditions are also being felt as a restrictive influence since there is an absolute shortage of labor, recognized two or three months ago, but now become decidedly acute. Contractors engaged in outside operations find the supply of Italian labor greatly deficient and have been bidding for mill labor with considerable success. A symptom of the labor scarcity is the breaking out of minor strikes at many plants, based upon grievances which do not usually lead to such action.

The current rate of steel production is between 5 and 10 per cent in excess of the highest rate formerly attained, this having been in the early part of 1910. The present rate is well in excess of 30,000,000 tons of steel ingots annually, and may amount to 32,000,000 tons, indicating a rate of between 24,000,000 and 25,000,000 tons of finished rolled steel. The percentage of

existing capacity in operation is slightly less than in the early part of 1910, there having been a very considerable increase in productive capacity in the interim. While steel demand has been very active, on the whole, it has not resulted in absolutely full operation for the reason that it is, naturally enough, not precisely distributed among the different products as productive capacity is distributed. The wire and tubular goods branches of the industry are those which in particular fall short of full operation. Such was not the case in the previous period of great activity, and quite likely the reason is that at that time part of the buying of steel products was speculative. Pipe, in particular, was bought by jobbers far in excess of their current requirements, and stocks were accumulated which required a long time to liquidate. So far as can be observed, the present flow of steel products is exclusively into actual consumption.

The total actual business received by steel mills during June probably exceeded slightly the shipments. The great bulk of the new business was in the form of specifications against contracts. A considerable proportion of these contracts were to expire June 30, and as the prices were below what could be done on fresh contracts and as the mills purposed cancelling unspecified tonnages at the expiration of contracts, buyers have been careful to specify fully. There has been a very moderate amount of strictly new buying in June for early delivery, wants having already been well covered. Of fresh contracting there has been little, except by a few groups of consumers. Agricultural implement makers, who had already contracted for bars for their new season, beginning in July, placed contracts freely for sheets and other materials. The automobile manufacturers began placing contracts for sheets also, paying premiums over the current market on account of the extended delivery period involved.

Prices of steel products have been showing a slight hardening tendency, occasional purchases for prompt shipment being made at premiums, while the balance of probabilities appears to be that a definite advance of $1 a ton in bars and of $1 or $2 a ton in plates and shapes is likely to be announced by the various mills within a very short time.

Pig Iron.

The trend of prices has been upwards, but only slightly so. In most markets prices are stationary, though firm, while foundry iron at Cleveland and basic iron in the valleys have advanced during the month by 25 cents. Consumers were already fairly well covered for third quarter, and have not shown much interest in fourth quarter deliveries. Quotations are: No. 2 foundry, Birmingham, $11 to $11.50; delivered Philadelphia, $15.25 f. o. b. valley furnaces, $13.25; f. o. b. Chicago furnaces, $14.50; Bessemer, $14.25, valley; basic, $13.25, valley. Prompt ferromanganese has eased off slightly, but still commands a premium over the contract prices of $48.50, Baltimore.

Steel.

Unfinished steel has become extremely scarce. Practically all the large mills in the Central West have been out of the market as sellers for some time, but occasionally have been able to spare small tonnages. Until early in June the eastern Pennsylvania mills have had some surplus steel, and in a few instances the rare spectacle has been witnessed of such steel being sold for shipment to the Pittsburgh district, the normal market position being that the freight is against such shipment. While consumers are well covered by contracts, their operations are heavy and deliveries are frequently short, so that there has been a constant demand for billets and sheet bars, but at a price which sellers have not usually been ready to meet. The market cannot be quoted precisely, but the following figures are fairly representative: Billets, $21.50; sheet bars, $22, f. o. b. maker's mill, Pittsburgh; billets, $21; sheet bars, $22, f. o. b. maker's mill, Youngstown. Wire rods are dull and quotable at $25, Pittsburgh, a price which it has generally been possible to shade about 50 cents.

Finished Steel.

Effective June 1 the National Tube Company reduced its discount on merchant steel pipe and oil country goods, on sizes 6 in. and under, by one point, involving an advance of about $2 per ton. The independent producers promptly followed. The new discount on "jobbers' carloads," card weight, ¾ to 1½-in., is 80 per cent off list. Buyers were well covered by contracts, on which specifications had been fairly liberal, and specifications have since increased, leaving the mills on July 1 with specifications under old contracts for about sixty days' operation.

Current prices, f. o. b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer; 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, tank quality, 1.25 cents

Shapes, 1.25 cents.

Steel bars, 1.20 cents.

Iron bars, 1.25 cents, Pittsburgh; 1.30 cents, Philadelphia; 1.25 cents, Chicago.

Sheets, blue annealed, 10 gage, 1.40 cents; black, 28 gage, 1.90 to 1.95 cents; galvanized, 28 gage, 2.95 to 3 cents; painted corrugated roofing, 28 gage, per pound, 2.15 cents; per square, $1.35; galvanized corrugated roofing, 28 gage, per pound, 3.05 cents; per square, $2.55.

Tin plates, $3.40 to $3.50 per 100-lb. cokes.

CORRESPONDENCE.

Determination of Methane in Producer Gas by Means of Copper Oxide

To the Editor of Metallurgical and Chemical Engineering:

Sir:—With reference to the article by S. H. Worell, published in your issue of November, 1911, page 576, permit me to say that the proposed method of determining methane in producer gas by burning the methane to carbon dioxide and water by means of copper oxide, is not new.

As early as 1898 the chemist of the Berlin gas works, Prof. Jaeger, has used copper oxide for this purpose and has even shown that it can be used for the determination of hydrogen and methane in succession by heating first to 250° C (whereby the hydrogen is burned to water while the methane is not reacted on) and by heating then to red heat in order to oxidize the methane. This method has been published in the *Journal für Gasbeleuchtung*, 1898, page 764. The apparatus devised for use of this method may be had, for instance, from the Vereinigte Fabriken für Laboratoriumsbedarf in Berlin N.

Two years ago the late great analyst, Prof. von Knorre, used the copper oxide for determining nitrogen in illuminating gas by passing the whole gas over red-hot copper oxide, whereby, with exception of the nitrogen, all constituents of the gas are changed to carbon dioxide and water, so that by introduction into potassium-hydroxide, the nitrogen may be separated.

Since even difficultly fusible glass is gradually destroyed in contact with the copper, Prof. von Knorre filled the copper oxide into a quartz-glass (fused silica) tube. His paper has been published in the *Chemiker Zeitung*, 1909, No. 79.

Charlottenburg, Germany.

Steel?

To the Editor of Metallurgical and Chemical Engineering.

Sir:—In your May issue, in an article entitled "Steel?" Dr. J. W. Richards proposes that a new classification of iron and steel should be introduced to supersede all the old well known names such as wrought iron, blister steel, ingot iron, mild steel, pig iron, cast iron, etc.

Dr. Richards wishes to subdivide all these different products into two general classes:

Steel = usefully malleable = carbon under 2.2 per cent, and

Cast Iron = not usefully malleable = carbon over 2.2 per cent.

What would be gained by such a classification? As far as I can see nothing would be gained, but much would be lost.

As long as different varieties of that product which is commonly known by the name "iron" exist—and I feel sure these varieties will not only exist but their number will keep on increasing—it will be necessary to distinguish each variety with a special name instead of throwing them all together into a heap from which they again must be picked out and given new names based on the old ones.

I am very much afraid that such a new classification would make matters worse than they are now. Suppose some manufacturer wanted to buy what we now call "wrought iron" and when ordering this from the salesman what should he ask for if he wanted to use the new classification? He should ask for steel, but in order to get the kind he wanted he would have to explain that the "steel" must be very low in carbon, very low in manganese and silicon, it must not be red-short, etc.; but would he be sure to get what he wanted? No, he would be just as liable to get mill steel as wrought iron. How much simpler is it to ask for "wrought iron."

This is only the practical side of the matter. Another reason why I consider Dr. Richards' new classification out of place is that as yet we know too little about the properties of "iron" to be able to introduce a new classification which would not be thrown over in a near future.

Let us wait and see. Perhaps the new electric processes will surprise us with products with new properties. Well, we do not even have to wait for them. The old processes, Bessemer and Siemens-Martin, sometimes surprise the steel-man by putting forth products with very strange properties.

In my practice it has happened when blowing Bessemer (as the process is carried out in Sweden, where the process is stopped when the desired percentage of carbon is reached) that something went wrong with the converter and the heat had to be poured shortly after the process had started; the product attained was a "steel," as it was usefully malleable, but not with *less than 2.2 per cent* of carbon, but *with 4.4 per cent* of carbon.

Examples like this one go to show that what we know about iron and steel is mostly the chemical composition and its relation to mechanical properties, but about the physical composition or structure we only know that it has certain influences on the mechanical properties of the product, but we have not yet the power to control and make use of the physical composition or structure, or, as it may perhaps be better called, of the power to regulate the arrangement of the molecules.

I, therefore, propose that the old classification should be kept until we have learned more so that when a new classification is introduced we feel more sure that it really is an improvement on the old one.

Axel Hartman.

Hardanger Elektriske Jern-og Staalverk, Tyssedal, Hardanger, Norway.

To the Editor of Metallurgical and Chemical Engineering.

Sir:—Referring again to Prof. Richards' correspondence on "Steel?" it may be said that the malleability of cocker plates for wire drawing is made use of first, in forging the bar or plate from the ingot and second, in closing up the holes through which the wire is drawn when they are worn too large. They are undoubtedly steel from every point of view.

Henry D. Hibbard.

Plainfield, N. J.

To the Editor of Metallurgical and Chemical Engineering:

Sir:—I am pleased that my Norwegian friend, Mr. Hartman has contributed his views on "Steel." His advice to "wait and see" has some force to it, but confusion may become worse confounded while you wait, and reform more hopeless than ever.

I did not propose "to supersede all the old, well-known names"; I distinctly stated that wrought iron would retain its name as a commercial material, and so would all the other varieties named. The sole innovation proposed by me was that all the usefully malleable forms of iron should collectively constitute the great class "steel," each, however, retaining its individual commercial name, as at present. The materials in this class might have less or more than 2.2 per cent of carbon; that definite percentage was named only as a *supplementary* criterion in case doubt existed as to whether the material would be designated usefully malleable, or not.

It follows that the "Cocker plates" cited by Mr. Hibbard would be classed by me as steel since they are forged down from an ingot. As to Mr. Hartman's statement that he made metal in a Bessemer with 4.4 per cent of carbon which was "usefully malleable," he must really permit us to doubt that it was usefully malleable in any ordinary meaning of that term.. The burden of proof is distinctly upon Mr. Hartman to prove such a fact—hitherto unknown to iron metallurgists. When the fact is proved I promise not to exclaim, as the countryman did on first seeing a hippopotamus: "There ain't no such beast"; but, on the contrary, I will admit the fact and yet "stick to my guns" to the extent of maintaining that such a material admittedly usefully malleable is not cast-iron, but should be classed as "steel."

I submit that Mr. Hartman's and Mr. Hibbard's illustrations instead of exposing any contradictions in the classification I proposed, simply emphasize its necessity and illustrate its easy, logical and general applicability as the solution of a very difficult question.

Lehigh University Joseph W. Richards.

Why Do Many Solids Float on Their Liquids?

To the Editor of Metallurgical and Chemical Engineering:

Sir: According to generally accepted theories heat increases and cold decreases the amplitude of molecular oscillations, giving rise to a change of specific gravity, as the mass remains constant, and the volume of a substance changes with the temperature. In the literature on the subject I cannot find that curves representing the changes in volume and specific gravity of any substances with varying temperature, have been definitely determined. It does not, however, seem probable to me that such a curve would be a regular one, but I think it would show well defined "jogs" and that these would appear most marked, where a change from the solid to the liquid and from the liquid to the gaseous state takes place.

At this point we are confronted with an apparent inconsistency and that is: why do the solids of a substance float on their own liquids, since most of them contract upon cooling, which is evidenced, for instance, in the shrinkage of castings upon solidifying? Two notable exceptions to this rule are water and bismuth, both of which expand on changing from the liquid to the solid state. Still with the majority of substances the rule holds good that the same weight occupies less space in a solid than in liquid condition, and that at the same time its true specific gravity is lower in the former state. We would be very much surprised to see a liquid floating over its own gas, yet I have been unable to find any comment on the fact that most solids float on the liquids of their own kind.

The correct understanding of these phenomena should open up a wide field of investigation particularly to the metallurgist. Take for instance, a metallic alloy; does it not seem possible, in the light of above facts, that a metal of higher specific gravity and higher freezing point should separate by "liquidation" from one of lower specific gravity and lower freezing point, and may not these phenomena account in some measure for the lamellar structure of the eutectic, and shists and gneiss?

I hope that some of your readers will find this subject of sufficient interest to give their views on the matter.

New York City. W. A. C. Pape.

The Idol of Quick Returns.*

The Real Objects of University Education—Culture, Friendship, Inspiration.

By DAVID H. BROWNE.

There are here at Queen's University some 1200 students who have come here to spend from four to six years of their life in the pursuit of some definite object. These students will each spend, perhaps, five hundred dollars a year in railway fares, college fees and living expenses, which means that about $600,000 a year is expended by these young men and women. In addition to this they have during their time surrendered their earning power and become non-producers. We will assume that during eight months of the year these young people are idle, and that their earning capacity is $50.00 a month. This amounts to a monetary loss of at least $400,000 a year. So that I am quite within the bounds of reason when I say that it costs these students at least one million dollars a year to maintain their attendance at this university.

Now, why do they do this? No one pays out money, no one devotes his time, his labor, his ambition in this way without hope of recompense. Ask these boys and girls and they will answer that they do this to be successful in life. Successful in life—this means two things, greater earning ability and greater enjoyment capability. The end of life is happiness. Happiness is not mere Hedonism, not the simple pursuit of pleasure for the sake of pleasure. Happiness means the attainment of man's best, highest, noblest desires. We seek for riches, not for the sake of money alone, but for what we can do therewith to further our physical, mental and spiritual welfare. I take it that these students are here at Queen's in order to gain two things, first, the ability to attain a higher position in life, and second, the capability to enjoy that position when they have attained it.

The first proposition is, then, that these students came here with the idea that when they leave college they will be able to earn more and fill higher positions than if they had never attended college. Is this correct?† . . . . .

Now Mr. Crane's attack is directed against American technical schools, but it is reasonable to suppose that his arguments are equally applicable to those on this side of the border. There are, however, some important points in which our Canadian schools differ from the American. It is customary in the States to carry on a course of nine months, even in some cases of eleven months' work. On this side our custom is to limit the class work to a period of six or seven months, and to allow the boys to spend three or four months of each year at practical work, in the mine, smelter or shop, according to whatever branches of scientific work they intend to make a specialty of. It has been my privilege at the smelter at Copper Cliff to hire a large number of Canadian students during the summer months. The majority of these are hard-working, diligent, intelligent men, keen to grasp a new situation, and manly enough to accept the discomforts incident to the work in a cheerful way. We are glad to have them there. Those who make good are always welcome again. Of course, as in any other body of men, there are a few goats. I have had a student come to me after a week's work around the furnace and ask for his time, giving as his reason that he wanted to get away, as he had learned all there was about the work, except the details. He got his time.

But the vast majority of Canadian boys are manly and self-reliant My only regret is that more of them do not stay with us. Like all other commercial enterprises I know of we are always hard pushed to find among our men some men of intelligence and experience to make foremen. I can assure you that such men are hard to find. Many times we have had to put in responsible positions men who were none too well qualified for these positions, simply because no others were available. What we and many other firms need is bright young men who will remain in our employment, even if their present positions are not to their liking, until we have had time to move them from one department to another in order that they may get a broad experience in their work. But frequently the very man we have talked over and planned to move into some responsible position gets another opportunity offered him elsewhere, and when we want him, he is gone. This fact, which I wish to emphasize, shows very clearly that the demand for such intelligent work as these boys give is greater than the supply.

This fact disposes in very large measure of Mr. Crane's argument that the technical schools turn out a lot of young men who are worthless to their employers, and who can not obtain responsible positions. But Mr. Crane goes on, "these technical school men are not fully trained craftsmen, they are not competent along any line. They come out of college and have to compete with the uneducated laborer, who by sheer dint of sticking to one line of work has mastered that line and is receiving good wages." This is very true. Take a college boy who, after studying, say Electrical Engineering, goes into the shops at Peterboro. He finds men who can do the work he is put at far better than he can, men who know nothing but this particular work. These are his competitors. He has to accept their wage rate, and pit his brains against their experience. He is at a disadvantage for a time. If he considers his present condition only, he may regret that he had not followed Crane's advice, which was to omit the technical school course, go directly into shop, and spend four years of practical training at one line of work.

Now, all I say to this is that if a boy desires to become a highly efficient machine, this is certainly the best way to go about it. The modern shop is always in advance of the technical school; the surrounding influences are all in one direction, and a young man thus spending six years of his life is undoubtedly a better craftsman, and can immediately earn higher wages than one who has spent four or six years in a university.

We will admit once for all that there are some subjects which a university or technical school can not teach, does not attempt to teach, and should not be expected to teach. A university does not aim to make machines, but to make men. It does not take a boy and perfect him along one narrow line. It aims to lay broad foundations, to inculcate principles, to train in culture, to foster taste for all that makes life livable and men and women lovable.

Take this technical school at Kingston for example. If a boy wishes to become a mine foreman, or a smelter man, or an expert winder of commutators, he will never get that training here. Any of his professors would advise him to go into the mines at Granby, or the smelter at Copper Cliff, or into the General Electric works at Peterboro. In four or five years he would be a skilled craftsman, he would earn three or four dollars a day, he might even be in charge of some commercial enterprise—but that is all. He would be successful as he measures success. Like Selkirk on Juan Fernandez, he is monarch of all he surveys, but how far can he survey, how limited his horizon!

Many, many generations have gone by since the preacher said, "Where there is no vision the people perish"—where there is no vision, no broad outlook on life, no scope for larger ambitions. What phrase could better describe the condition of one who spends his best years in mere striving to learn a craft whereby to earn his daily bread. Is this then

*Extracts from an address delivered at the annual dinner of the Engineering Society of Queen's University, Kingston, Ont., Canada.

†There follows at this place in Mr. Browne's address a long analysis and refutation of Mr. Crane's well-known attacks on university education. As Mr. Crane is now dead and his views are hardly liable to survive him long, this part of Mr. Browne's address is here omitted.—Editor.

all we are to strive for? Is the training we get here simply a meal ticket? I claim that life is more than this. Man cannot live by bread alone. Remember that happiness arises not merely from greater earning power, but from greater capacity for enjoyment.

There are schools, exactly such as Mr. Crane describes, where a man can learn to be a telegraph operator, or a stenographer, a watchmaker, or a barber, and at the end of his training course he comes out a brisk useful craftsman, needing only practice to make him perfect. But what profiteth it a man if he gain the whole world and lose capacity for enjoyment? Wherein is he a gainer if he can earn a living, and his life is not worth living? He can wind a commutator, but he has never heard of Franklin or Faraday. He can cut stone or mix paints, but is blind to the smile of the Venus of Milo or the grace of the Sistine Madonna. He can tune a piano, but is deaf to the pathos of Beethoven and the pious exaltation of Händel. He can survey a wilderness into town lots, but has never lifted his thoughts to Pleiades and the flashing belt of Orion. He has mastered the books of the Scranton Correspondence School, and has never heard of the madness of Hamlet, or the troubles of Tristam Shandy. He can work for a party victory in his own riding and knows not that his liberty to vote was won by Pym and Hampden and William the Silent and Stephen Langton. He is living by bread alone. He has no vision, he cannot see the world as a whole, he has bartered his birthright for a mess of pottage and sold his manhood for a meal ticket.

You are taught many things which may appear to you dry, tedious, irrelevant, uninteresting. Never mind that. You will forget more than you will remember. But always remember this, it isn't the water that stays in the fleece that scours it, it's the water that goes through the fleece. It isn't always what you remember that does you most good, it is the act of grasping new ideas, of fixing the attention, of facing novel problems, of training your brain to act quickly in emergencies. These studies you grind out here are useful, not solely for what you remember of them, but for what they suggest to you.

Mathematics is not, as the beloved Vagabond says, a lot of damned facts about triangles; it is the plan on which the Creator fashioned the universe. Chemistry and biology are not the mere study of reactions and adaptations; they are the keys to all life, past and present. Mining and metallurgy are not hand-crafts; they are factors that open new continents and change the map of the world. French and English are not simply languages in which to call for another wheelbarrow of concrete; they are the open doors to the literature and history, the wisdom and pathos, the wit and humor of a thousand years.

All this broad outlook on life is summed up in one word—culture. No one can give you this, but every college gives you an excellent opportunity to attain it. Culture, friendship, inspiration—these are three things that make life worth living, three things which are here for you to grasp and take with you. Culture, as I have said, comes from study of broad principles and can never be attained by undivided attention to one narrow subject. Here in these halls, among these libraries and museums, you have the chance to attain it.

Friendship, the good-will and affection of your fellows, is here also for you. You cannot dig this out of dead books. Here around you are young men who may be leaders of the future. Learn to know them, find out the best that is in them, be loyal to them, for as the Norse proverb says, "Back is bare without brother behind it." The loyalty you give to the captain on the campus is the same loyalty that has made Canada a great country, and some day will make it, in name as well as in fact, a great self-governed, self-centred nation.

Culture, friendship, and inspiration, these three, and the greatest of these is inspiration. This is the one thing which all the others lead to, for this is the true vision. Inspiration means the inbreathing of a great spirit, the breath of life in man's nostrils. We cannot define it, we cannot analyze it, we can only feel it as we feel a chord of music. It comes from the consciousness of the presence of the mighty dead who have molded the nation, it comes from the companionship of noble men and women living around us, from the memories with which the college halls are hallowed. You know the feeling that comes over you in a close-packed crowd when the leader arises and you see the tense upturned faces around you and hear the quick intake of breath, as the truth he speaks sinks home. You picture the gaunt figure of Lincoln at the National Cemetery and the hushed audience that hangs on his words as he gives them the greatest speech ever made in the English language, the matchless Gettysburg address. They turn away too deeply moved to applaud, too much uplifted to cheer, because they have received the inspiration, they have seen the vision.

There has been in every college some man around whom the highest and noblest ideas have crystallized, men that have molded the nation; such men are our greatest inspirations. Such men as Arnold of Rugby, Elliot of Harvard, Wilson of Princeton, Angell of Michigan, and fit companion of the greatest, Grant of Queen's—these are the men who have made us men. Can any narrow course of training such as Mr. Crane desires give us anything for which we would exchange these memories? Never. Man cannot live by bread alone.

You will go from here in a few days, less skilled perhaps in the profession you enter than many trained apprentice, you may earn less for a few years than if you had never come here, you will have your struggles as we have all had; but when you do attain your ideals you will have brought with you a greater capacity for enjoyment, a broader outlook on life, a nobler patriotism, and a higher ideal than if you had never spent these years at Queen's, for you will take with you somewhat of these three, culture, friendship, inspiration, to broaden and brighten your life, and you will have glimpsed the vision without which the people perish.

Copper Cliff, Ontario, Canada.

Electrolytic Production of Oxygen and Hydrogen Gases.

In our issue of September, 1911 (Vol. IX, page 471), a full description was given of the process of the International Oxygen Company, of New York City, for the production of oxygen and hydrogen by electrolysis of water.

The following table gives the results of a test recently made by the Electrical Testing Laboratories of New York for the International Oxygen Company.

The object of the tests was to determine the output of four of the cells in actual operation in the plant of the International Oxygen Company at Waverly Park, N. J., in the battery and the corresponding electrical energy required. The four cells tested were selected as being representative of the entire battery after taking a set of preliminary electrical measurements on each of the cells.

All of the data given herewith are from readings as actually observed and corrected for instrument errors. Gas volumes are corrected for moisture and calculated to 20° C. and 760 mm.

Cell No.	Average Amperes	Average Volts.	Average Watts.	Max. Temp	Purity of Oxygen	Cu. ft. per hour		Cu. ft. per Kilowatt hour	
						Oxygen.	Hydrogen.	Oxygen.	Hydrogen.
8	405.1	2.388	967	31.8° C	97.73%	3.247	6.184	3.358	6.395
14	405.0	2.562	1038	30.0° C	98.67%	3.239	....	3.120	....
66	368.8	2.826	1042	32.0° C	98.46%	2.886	5.788	2.770	5.555
70	392.0	2.660	1043	26.5° C	98.50%	3.082	6.254	2.955	5.900
Average	392.7	2.609	1022	30.1° C	98.34%	3.114	6.075	3.051	5.950

For **platinum melting** the oxy-hydrogen flame is particularly useful. The International Oxygen Company has introduced for this purpose a torch with a special alloy tip.

Ammonium Sulphate from Ammonia and Sulphur Dioxide.

The Extraction of Ammonia and Hydrogen Sulphide from Coal Gases and the Direct Production of Ammonium Sulphate Therefrom Without Using Sulphuric Acid.

By Walther Feld

For the production of ammonium sulphate the by-product coke oven industry depends at present on the sulphuric acid industry, since the usual method of producing ammonium sulphate is based on the reaction between ammonia and sulphuric acid. This commercial inter-relation is at times very troublesome.

Evidently a great advance would be made if ammonium sulphate could be produced commercially and economically from ammonia and sulphurous acid. The advance would be great if the sulphurous acid were to be obtained from the roasting of sulphides. But the proposition would look even more promising and important if the sulphur contained in gasified coal and a large part of which passes into the gas as hydrogen sulphide, could be used directly for combining with the ammonia in the coal gas for the formation of ammonium sulphate.

For these reasons it is hardly surprising that for a long time attempts have been made to combine directly ammonia and sulphurous acid. Laming tried it as early as 1852 (British patent 14260). But he and others who worked along similar lines, overlooked that the reaction by which ammonia and sulphur dioxide combine will not proceed until it is complete. Neutral ammonium sulphite $(NH_4)_2SO_3$. H_2O gives off ammonia and the quantity of the ammonia given off increases with the temperature. The residue is a wet acid salt $(NH_4)_2SO_3$. SO_2 which, on air, gives off sulphur dioxide, while only a small part is changed into sulphate. This whole behavior of the sulphites is due to the high vapor tension of both ammonia and sulphur dioxide and for this reason it is an impossibility to absorb *completely* ammonia contained in gases by means of an aqueous sulphurous acid solution or to absorb *completely* sulphur dioxide in gases by means of an ammonia solution.

But even if these difficulties could be overcome in practice (which seems impossible), the resulting salt would be of a very unstable nature. To use ammonium sulphite directly as a fertilizer (Lachomette's British patent 17050 of 1887), is impractical for more than one reason, especially on account of its tendency to give off sulphur dioxide and ammonia to the atmosphere. All attempts to change ammonium sulphite into ammonium sulphate by contact with air have been unsuccessful and must be so for good inherent reasons.

Absorption by Tar Oils

For many years I have been interested in the reaction between sulphur dioxide and hydrogen sulphide, which is rather complicated, although the equation usually and probably erroneously assumed for it

$$2H_2S + SO_2 = 2H_2O + 3S$$

is simple enough.

In the course of our extended researches in this field, my collaborator, Mr. A. Jahl, established the fact that certain tar oils are excellent solvents for sulphur dioxide and sulphur.

Pure sulphur dioxide, introduced into heavy tar oils, is eagerly absorbed with a strong evolution of heat. If this is carried out in a closed bottle with shaking, the reaction is so energetic that the atmospheric pressure above the liquid is considerably reduced, while the temperature rises.

Now, if a tar oil has been saturated with sulphur dioxide and pure hydrogen sulphide is then passed into it, this is also completely absorbed, while simultaneously the temperature increases and the pressure decreases. In this reaction the sulphur dioxide and hydrogen sulphide react, forming sulphur and water, the sulphur dissolving in the hot tar oil.

If now the tar oil is treated alternately with sulphur dioxide and hydrogen sulphide, part of the dissolved sulphur will in time crystallize out of the saturated oil in crystalline grain form.

While this process appears to be very simple, yet it involves great difficulties when applied to gases which contain sulphur dioxide and hydrogen sulphide in great dilution.

Absorption by Zinc Thiosulphate.

Further experiments showed that hydrogen sulphide decomposes zinc thiosulphate in such a way that zinc sulphide and elementary sulphide are formed:—

$$ZnS_2O_3 + 3H_2S = ZnS + 3H_2O + 4S$$

If concentrated or dilute hydrogen sulphide is introduced into a solution of ZnS_2O_3, the hydrogen sulphide is completely absorbed. In experiments carried out on a large scale with illuminating gas which was practically free from ammonia, one single washing apparatus was sufficient to absorb 80 to 90 per cent. of the hydrogen sulphide in the gas by means of zinc thiosulphate solution.

The intention was to regenerate the ZnS_2O_3 from the zinc sulphide by means of sulphur dioxide, according to the equation

$$2\,ZnS + 3\,SO_2 = 2\,ZnS_2O_3 + S$$

But this regeneration process does not work. First, the zinc sulphide is dissolved very slowly only in sulphur dioxide. Second, the regenerated zinc solution has lost most of its ability of absorbing hydrogen sulphids. The reason is that the regeneration process does not take place as had been supposed, since when zinc sulphide and sulphur dioxide react together, polythionate ZnS_4O_6, instead of the thiosulphate ZnS_2O_3, is mainly formed, and it is a fact for which good physico-chemical reasons may be given, that hydrogen sulphide acts strongly on zinc thiosulphate, but slightly only on polythionate.

In spite of these short-comings, the process indicated a direction in which the work was to be done. It is especially noteworthy that a possibility of absorbing simultaneously hydrogen sulphide and ammonia from the gas was indicated according to the equation:

$$ZnS_2O_3 + 2\,NH_3 + H_2S = ZnS + (NH_4)_2S_2O_3$$

As a matter of fact, experiments showed that not only hydrogen sulphide, but ammonia could be absorbed in this way.

Absorption by $Fe S_2 O_3$

The regeneration difficulty in the use of ZnS_2O_3 is overcome by using the iron salt FeS_2O_3 instead of the zinc salt for absorption.

The gases which contain ammonia and hydrogen sulphids are washed with FeS_2O_3, whereby iron sulphides are precipitated.

$$FeS_2O_3 + 2NH_3 + H_2S = FeS + (NH_4)_2S_2O_3$$

The iron sulphide is dissolved in sulphurous acid forming FeS_2O_3 which is again used for treatment of gases:

$$2FeS + 3SO_2 = 2FeS_2O_3 + S.$$

When the alternate treatment with gas and sulphur dioxide has been repeated several times, the content of the ammonium salt has increased to such an extent that the recovery of ammonium sulphate from the solution becomes profitable.

The thiosulphate is now changed into polythionate by treatment with sulphurous acid

$$FeS_2O_3 + (NH_4)_2S_2O_3 + 3SO_2 = FeS_3O_6 + (NH_4)_2S_4O_6$$

and then into sulphate by increasing the temperature

$$FeS_2O_6 + (NH_4)_2S_4O_6 = FeSO_4 + (NH_4)_2SO_4 + 2SO_2 + 3S.$$

The heating may be carried out simultaneously with the treatment with sulphurous acid so that the last reaction takes place practically simultaneously with the preceding one.

The formation of ferrous sulphate is accompanied by the formation of sulphur dioxide and free sulphur. The free sulphur is burned to sulphur dioxide, while the sulphate solution is again treated with crude gas:

$$FeSO_4 + 2(NH_4)_2SO_4 + 2NH_3 + H_2S = FeS + 3(NH_4)_2SO_4.$$

The ammonium sulphate solution is separated from the iron sulphide and concentrated by evaporation.

This process has proven practicable on a large commercial scale and is being used at present in an illuminating gas plant and in a coke-oven gas plant, 60,000 to 70,000 cubic meters of gas being treated daily in each plant.

If there is an excess of hydrogen sulphide over ammonia, no special difficulty is experienced. Hydrogen sulphide alone, without ammonia, reduces ferrous thiosulphate to iron sulphide, according to the equation:

$$FeS_2O_3 + 3H_2S = FeS + 4S + 3H_2O$$

although the low speed of this reaction necessitates comparatively large apparatus when dilute hydrogen sulphide is treated.

On the other hand, the application of this process in such cases in which there is an excess of ammonia over hydrogen sulphide, is impossible without further serious complications.

Polythionate Process

In my researches on the physicial and chemical properties of metallic thionates, I also paid considerable attention to the behavior of the sodium and ammonium salts. It was found that especially ammonium thiosulphate has the characteristic property of being very easily changed into polythionate by treatment with sulphur dioxide,

$$2(NH_4)_2S_2O_3 + 3SO_2 = (NH_4)_2S_4O_6 + (NH_4)_2S_3O_6.$$

This reaction is rapid and complete so that sulphur dioxide may be completely and successfully washed out of dilute gases by treating these gases with ammonium thiosulphate.

Now, ammonium polythionate is a very effective means for washing out hydrogen sulphide and ammonia, either together or separately. The reactions are probably quite complicated. I, therefore, give only the final results.

$$(NH_4)_2S_2O_3 + (NH_4)_2S = 2(NH_4)_2S_2O_3 + S.$$

further

$$(NH_4)_2S_2O_3 + 3H_2S = (NH_4)_2SO_3 + 5S + 3H_2O,$$

and

$$(NH_4)_2S_2O_3 + 2NH_3 + H_2O = (NH_4)_2SO_3 + (NH_4)_2S_2O_3 + S.$$

In each of these three cases thiosulphate is formed, which is changed again by means of sulphur dioxide into polythionate according to our former reaction

$$2(NH_4)_2S_2O_3 + 3SO_2 = (NH_4)_2S_4O_6 + (NH_4)_2S_3O_6.$$

By an alternate treatment of the solutions with gas and sulphurous acid, the content of ammonium salts gradually increases. Finally by treatment with sulphurous acid and application of heat, the solution is changed into polythionate and finally sulphate.

$$3(NH_4)_2S_4O_6 = 3(NH_4)_2SO_4 + 3SO_2 + 6S$$

and

$$2(NH_4)_2S_2O_3 + 3SO_2 = S = 2(NH_4)_2S_3O_6,$$

and by addition of the two equations

$$(NH_4)_2S_4O_6 + 2(NH_4)_2S_2O_3 = 3(NH_4)_2SO_4 + 5S$$

That is, when the content of polythionate has reached a certain maximum, then the sulphurous acid which is set free during the sulphate formation, is sufficient to change the present thiosulphate into polythionate and then into sulphate. The precipitated sulphur grains are separated from the sulphate solution for the recovery of crystalline ammonium sulphate.

This polythionate process (British patent 5838 of 1911) represents the simple and reliable solution of the old problem of completely combining ammonia and sulphur dioxide in coke-oven gas or illuminating gas for the production of ammonium sulphate.

In going over the reactions given above, it will be seen that no other oxidizing agent is used besides the atmospheric oxygen consumed for burning the sulphur to sulphur dioxide. The simple furnace in which sulphur is burned to sulphur dioxide replaces completely the sulphuric acid factory which was hitherto a necessity.

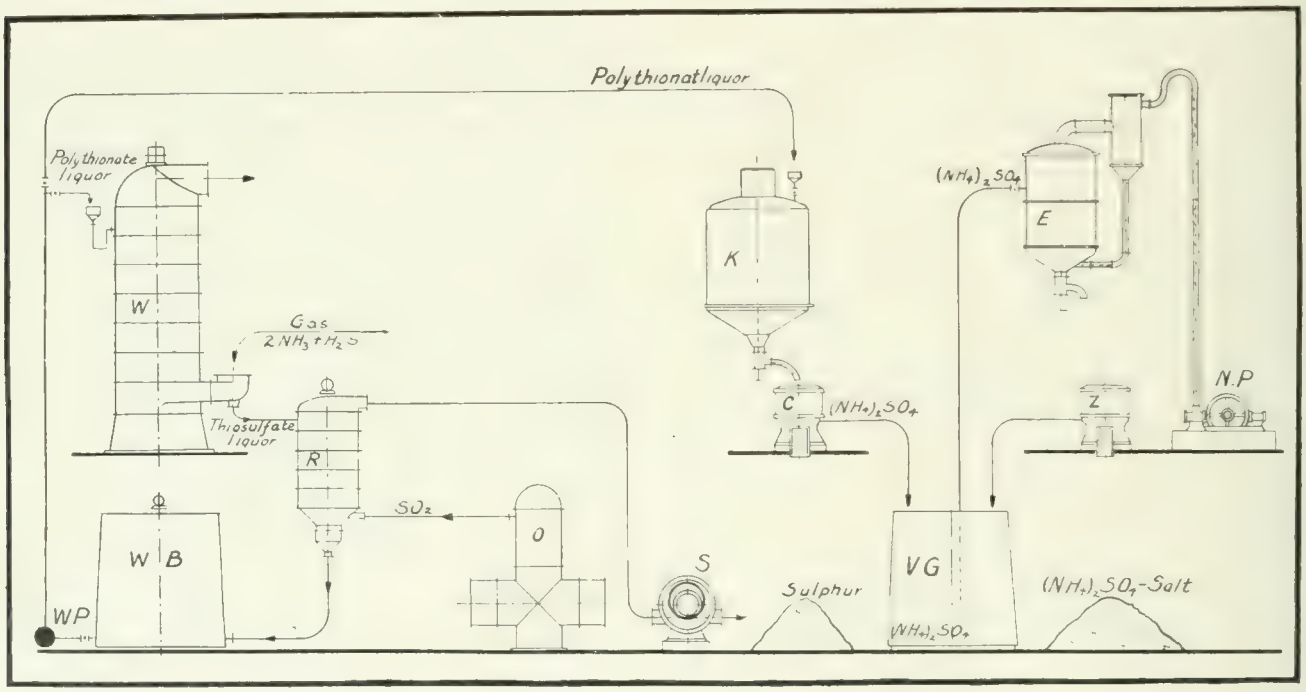

FIG. I.—DIAGRAM OF APPARATUS AND REACTIONS IN POLYTHIONATE PROCESS.

Practical Operation of the Polythionate Process

Fig. 1 is a diagram of the Feld polythionate process.

W is the washer,
W B the washer liquor tank,
R the regenerator,
O the sulphur oven,
S the air blower for the sulphur oven,
K the boiler,
C the centrifugal machine for separation of sulphur,
V G the tank for the final ammonium sulphate liquor,
E the vacuum boiler,
Z the centrifugal for separation of ammonium salt, and
N P is a vacuum pump.

The polythionate liquor enters the washer *W* at the top and by the action of ammonia and hydrogen sulphide in the gas, is reduced into hyposulphate solution.

The hyposulphate solution coming from the washer* enters the regenerator *R* where it is treated with sulphur dioxide. By this treatment the hyposulphate solution is regenerated into polythionate. The polythionate liquor leaves the regenerator *R* and is run into the washing liquor tank *W B*. By the washing pump *W P*, the liquor is circulated constantly as above mentioned, through washer *W* and regenerator *R*, until the liquor has obtained such a strength as is equivalent to a 35 or 40 per cent ammonium sulphate solution. Part of the concentrated polythionate liquor is now pumped into boiler *K* and is here heated by steam. By this treatment, the polythionate in the solution is decomposed into sulphate and free sulphur. The free sulphur separates in form of hard grains which are separated from the ammonium sulphate solution in the centrifugal *C*. The clear ammonium sulphate liquor is run into store tank *V G* and from there into vacuum boiler *E*. By evaporation in the vacuum apparatus, crystals of ammonium sulphate are obtained which are dried by the centrifugal *Z*.

This process is in successful operation in the municipal gasworks in Koenigsberg in Prussia, since June, 1911, dealing with a maximum production of 100,000 cubicmeters (3,530,00 cubic feet) of coal gas per day.

Linz am Rhein, Germany.

*For a description of this washer see the article published on page 436 of this issue.

The Non-Ferrous Metal Market.

Since our last report there has been considerable activity in the non-ferrous metal market, and generally higher prices have prevailed. Copper especially has shown a steady advance and lead was advanced considerably by the principal producer. Spelter has held its own at a high figure, while tin has fluctuated on account of the unsettled conditions abroad and the small quantity of metal afloat to this country.

Copper.—In spite of the steady advance in price a large volume of business has been transacted both for foreign and domestic consumption. Electrolytic has been in demand, while Lake has not been sold so heavily. The last quotations are 17¾ to 17⅝ cents for Lake and 17.20 to 17.30 for electrolytic.

Lead—On June 12 the A. S. & R. Co. raised the price of lead to 4.50 cents. Consumption is reported excellent and a further advance is not unexpected. Missouri lead has been selling above its parity with New York. The last quotations show New York 4.50 cents and St. Louis 4.40 to 4.42½ cents.

Tin.—The London market has been fluctuating, and the domestic market has been uncertain. At the last reports the London market had risen on account of dock strikes and New York spot tin was quoted at 47½ cents.

Spelter.—Considerable business has been transacted for future delivery, but the spot market has been dull. A few deliveries of spot tin have brought premiums. The latest quotations are, St. Louis, 6.60 to 6.75 cents, with a firm market.

Other Metals.—Aluminium is quoted at 22½ to 23 cents, New York, with little business transacted. The antimony market also is rather quiet with metal quoted at from 7.10 to 8.10 cents for various brands. Business in quicksilver has been fair and 75-lb. flasks are quoted at $41, New York, and the same at San Francisco.

Annual Convention Colorado School of Mines.

The thirty-eighth annual commencement of the Colorado School of Mines was held in Simon Guggenheim Hall, Golden, Colo., May 24, 1912. Fifty-one students were graduated, forty-eight receiving the degree of Engineer of Mines, one Metallurgical Engineer, and two receiving both degrees. The address was delivered by Mr. William Lawrence Saunders, president of the Ingersoll-Rand Co., New York, who spoke on Culture in the Education of Engineers. This is printed in full on page 427 of this issue.

"Pig Steel" Made Directly from Ore in the Electric Furnace.

At a recent meeting in Pittsburgh of the Engineers' Society of Western Pennsylvania Dr. Jos. W. RICHARDS, of Lehigh University, presented a paper on "electric furnace production of pig iron and pig steel." We herewith give an abstract of this paper, which may be found in full in the March issue of the *Proceedings* of the Society.

After some introductory remarks on the pioneer experiments carried out at Sault Ste. Marie under the auspices of the Canadian government on the production of pig iron in the electric furnace (our Vol. IV, pages 124 and 265, 1906), the author referred to the extended work which has been done on this subject in Sweden. Groenwall, Lindblad and Stalhane originated this work. Their leading idea was that within the last few years the price of charcoal in Sweden has doubled, so that their manufacturers are facing the necessity of giving up the manufacture of charcoal iron; they could not import coke, for such fuel would bring their pig iron in direct competition, as regards quality, with the rest of Europe. If therefore the only salvation of their pig iron industry was to continue making pig iron by means of charcoal, the electric furnace was the only chance to save the industry, because in the electric furnace only one-third as much fuel is required, per ton of iron, as in the blast furnace, so that with a limited supply of charcoal it is possible to get three times as much pig iron from electric furnaces as from blast furnaces, and the cost of charcoal figures only one-third as much per ton of pig iron made in the electric furnace as for the pig iron made in the blast furnace.

Dr. Richards reviewed the work carried out by the Jernkontoret (the Association of Swedish Iron Masters), as described in our Vol. IX, pp. 368, 459, 505 (1911); also p. 413 of this issue.

In a critical comparison of the reduction of iron ore in the electric furnace and in the blast furnace Dr. Richards pointed out that the most important point is that the former requires only one-third as much carbon per ton of iron as the blast furnace. When iron oxide is reduced by carbon ($Fe_2O_3 + 3\,C = 2\,Fe + 3\,CO$), the maximum amount of carbon which can be used to reduce the iron oxide to iron is 36 carbon to 112 of iron. Not only is it useless to put more carbon into an electric furnace than is thus theoretically required for reduction, but it is absolutely prejudicial to the running of the electric furnace. On the other hand, in running a blast furnace one can make a ton of iron with a ton of coke, and if foolish enough one can put in a ton and a quarter of coke or a ton and a half and it does not hurt the furnace. The latter works hotter, but it does not stop the operation.

This difference in the behavior between blast furnace and electric furnace is due to the fact that in the electric furnace the excess of carbon accumulates because there is no oxygen to burn it, as the only source of oxygen to consume the carbon is that in the iron ore itself.

This was not understood by the early experimenters, but now the fact is appreciated that a ton of pig iron can be made with about a third of a ton of charcoal and that the more charcoal is used above that, the more difficulties arise in running the electric furnace. When carbon accumulates in the lower part, it lowers the electric resistance of the furnace, makes it difficult to keep it hot, and the best remedy is a dose of iron oxide without any carbon.

In the electric furnace the gas produced is not entirely CO, but CO mixed with CO_2. If one produced all CO_2 only half as much carbon would be required. While this is impossible, it is possible to produce somewhere about half of CO and half of CO_2, so that only about three-fourths of the stated amount of carbon is needed in actual practice, when getting down to the real working conditions.

There is a thermochemical anomaly connected with this point to which Dr. Richards drew particular attention. Having a

fixed weight of oxygen to be taken away from a given quantity of iron ore if it is taken away by carbon forming CO, the formation of this CO gives a certain amount of heat, contributed to the furnace. If some of it is changed to CO_2 more heat is contributed to the furnace, because when carbon unites with oxygen to form CO_2 it gives out more heat per unit of oxygen combined than when it forms CO. Therefore, the *less* carbon is used in the furnace the *more* heat of oxidation is obtained from it for the same quantity of oxygen or of iron ore. In other words, a fixed weight of oxygen gives out more heat and combines with less carbon when forming CO_2 than when forming CO.

Of course, the more heat assistance is obtained from the carbon the less electric power has to be used. So that the less carbon one can get along with in the furnace for reduction, the more assistance will be obtained from it in a thermal sense, and the less electric energy will have to be used per ton of pig iron. All the experiments that have been made, and all the work of the Swedish furnaces confirm this principle. As they reach economy in carbon and use less fuel, they also use less electric energy, and they thus save at both ends.

As to the power consumption, Dr. Richards thinks that the lowest limit would be one-fifth of an electric horse-power-year per ton of pig iron. In Sweden they have reached one-quarter of a horse-power-year per ton at times for a period of a week or more. The first week in last September the furnace was working well, and then they reached 4 tons of pig iron per horse-power-year (see our Vol. IX, page 482, 1911). Dr. Richards thinks that when a large furnace of perhaps a hundred tons daily capacity is built, and is run with the knowledge which will exist within perhaps five years, the output will probably be raised to 5 tons of pig iron per horse-power-year. The consumption of electrodes is at present 5 per cent of the weight of the pig iron produced, which is much less than before, representing a great reduction of expense. As to the circulation of the gases Dr. Richards thinks that the use of this method in the Swedish furnace involves more disadvantages than advantages. (See his recent American Electrochemical Society paper in our present volume, May issue, 1912, page 289.)

As stated before, when in these experiments the amount of carbon used for reduction was cut down, the furnace worked better, consumed less power and less carbon, and worked more rapidly, and a pig iron was produced that was white instead of gray. It is well known that as a blast furnace is run faster the tendency is to make white iron. By reducing the amount of fuel and running at a low temperature a product was obtained with 0.1 per cent silicon, 0.1 per cent manganese, and as low as 1.5 per cent of carbon.

To call this product pig iron would be a misnomer. It is called **pig steel,** because in composition it is simply steel. Pig steel is a metal with 2.2 per cent or less of carbon, a very small amount of silicon and manganese, low in sulphur and phosphorus, made directly from iron ore in the electric pig iron furnace. It is not pig iron, it is really crude steel, so it is called pig steel, a name which has generally been accepted. Its German equivalent is "Rohstahl" and in French "Acier brut."

As to the advantages of this material for steel making, the fact that it contains 97 to 98 per cent iron instead of the 92 to 94 in pig iron means that there are only 2 or 3 per cent or less of impurities (instead of six or eight) to be removed in the steel furnace. The steel workers found out at once the advantages of pig steel. Put into the open-hearth furnaces it is converted into steel with half or less of the ordinary refining. The output of open-hearth furnaces using pig steel is increased nearly 50 per cent.

Thus the result has been beneficial all around. The pig iron furnace makes more of this pig steel in a day than it does of pig iron, and at less cost; the steel furnace makes more steel per day from this material and at less cost. This rather accidental discovery has completely absorbed the attention of the Swedes and Norwegians. They say that not only have they a new process for making pig iron cheaper than in the blast furnace, but they can make a product which they never could make in the blast furnace which is dollars a ton cheaper when converted into steel.

In conclusion Dr. Richards said that in Pittsburgh with its present prices of coal and coke and with power generated by steam or gas it would not be possible to make pig iron as cheaply in the electric furnace as in the blast furnace, but the possibility of producing pig steel in the electric furnace direct from ore may change the situation, although Dr. Richards was noncommittal on this point.

The *Proceedings* of the Society contain a complete abstract of the long discussion which followed the paper.

As to the comparison of cost in the blast furnace and electric furnace in Sweden, Dr. Richards pointed out that the real factor is that they substitute for two-thirds of a ton of charcoal, costing $8, one-quarter of a horse-power-year costing $2, and the cost of electrodes. Of course, the furnace is being run on a smaller scale than a blast furnace. A furnace of 2000 kw produces about 18 tons a day. What sort of economy could be had in a blast furnace producing 18 tons per day? The comparison with the blast furnace will become more interesting when we have an electric furnace making 100 tons a day.

Mr. F. F. Snyder, of Chicago, referred to the possibilities of the electric furnace in foundry practice and gave some of the results which they are getting in a 500-hp electric steel refining furnace which is operating commercially in Chicago on castings. The records of this furnace seem to show that in a properly designed furnace metal can be melted from the cold and refined electrically at a cost very close to the open-hearth cost for the same service and output. He emphasized that rails made from electric steel were becoming a commercial possibility.

Mr. Snyder questioned the advisability of copying the general design of the blast furnace in an electric furnace, especially the necessity of a shaft. Why not do all the reducing in 2 or 3 ft. instead of letting it fall 30 or 40 ft.? Dr. Richards replied that the reason is that when iron is reduced with carbon the first product of that reduction will be CO, and if it has a chance to reduce some further iron oxide some CO_2 may be obtained, and the more CO_2 is obtained the less carbon will be needed in the furnace and the more heat will be obtained from the combustion of the carbon. Therefore, it is desirable to get as much reduction by CO as possible, although it is impossible to cut out the reduction by solid carbon, with which it is necessary to start. The more chance the CO has to pass over red-hot iron oxide the more CO_2 will be produced and the less fuel will be needed. This is the rationale of the shaft, which, however, Dr. Richards believed can be cut down to very small dimensions. If the circulation is cut out and the gases are permitted to slowly filter upwards, 6 or 8 ft. may give them a chance to do all the reducing they can possibly do. Dr. Richards does not believe 40 ft. of shaft is necessary.

Mr. Snyder asked whether the amount of CO_2 which will be formed is not a function of the temperature rather than the height of the shaft. In other words, if the temperature at the top of a 6-ft. shaft is the same as at the top of a 40-ft. shaft the proportion of CO_2 will be approximately the same in both cases. In reply Dr. Richards stated that the temperature is not the only determining factor, but also the time during which the gas is in contact with the ore at that temperature, since the equilibrium which corresponds to that temperature needs time to be established.

The smelter production of primary copper in the United States in 1911 was the largest in the history of the country. It amounted to 1,097,232,749 pounds, as compared with 1,080,159,509 in 1910, an increase of about 1.5 per cent. Arizona, Montana, Michigan and Utah were the leading producers.

The Chemical and Physical Reactions in a Zinc Retort.

By F. L. Clerc.

A charge of roasted ore, mixed with reducing carbon, and moistened with water, is thrown into a red hot retort. When the retort is full, a vent for the escaping steam is made by thrusting a rod along the top of the retort to the end, and quickly withdrawing it. The moisture in contact with the walls is quickly evaporated by the heat conducted through the walls from the flames which encircle the retort.

To escape from the retort, the steam thus formed, must pass through successively cooler portions of the charge.

It is inevitable that some of the water evaporated near the walls will condense in a cooler locality within the retort. At the start some air is entangled with the charge, and the gas issuing from the retort will be a mixture of air and steam. The drying of the charge is a gradual operation, but we can safely say of the current gas passing through any layer of it that it is not only saturated with the vapor of water, but also carries along mechanically any minute globules of water it can entrain on its way to the mouth of the retort; the air being swept out of the retort, the issuing gas is supersaturated steam.

Let it be assumed that the charge is dry, before any particle of the carbon which it contains is hot enough to decompose steam; the issuing gas is then superheated steam, and none being evolved, its current is due to expansion by heat. When a temperature is reached at which the superheated steam can react with hot carbon, other gases are evolved, namely hydrogen and carbon monoxide. So long as any vapor of water is present, this steam continues with diminishing current, until a temperature is reached at which one or other of these new gases reduces zinc oxide. The amount of water vapor present, from which hydrogen is evolved, is very limited, and the action of hydrogen need not be further considered. As soon as the reduction begins, by the reaction $ZnO + CO = Zn + CO_2$, two other gases are given off, zinc gas and carbon dioxide. These gases are continuously evolved so long as zinc oxide and carbon are present at a temperature at which this reaction occurs For the carbon dioxide formed by this first reaction, immediately reacts with the hot carbon, producing twice the original amount of carbon monoxide, as is shown by this (2) equation $CO_2 + C = 2CO$, thus replacing the carbon monoxide originally present, and an equal amount which mingles with the zinc, and passes out of the retort. The second reaction occurs at a lower temperature than the first, and must quickly follow it. The mixture of zinc gas and carbon monoxide on its way to the mouth of the retort passes through successively cooler layers of the charge.

Zinc gas, like steam, can be condensed to a liquid. Is there any reason to suppose it will behave differently from the water evaporated in drying the charge? Carbon monoxide does not condense, but some of the zinc must condense to a liquid on the cooler surfaces it meets with.

Are we not safe in assuming that there will pass through every successive layer of the charge a stream of uncondensed zinc gas, mixed with carbon monoxide, carrying along with it any minute globules of liquid zinc which it can entrain by the force of its current?

When such a stream, so burdened, enters the condenser, it passes out of the narrow channels it occupied in the interstices between the particles of the charge, into an open space, through which the liquid globules can subside, and between cooler walls against which the uncondensed zinc will condense, and to which the globules will adhere.

So considered, the condenser of a zinc retort presents an analogy to the device adopted for freeing supersaturated steam from the water it carries with it; and it is not necessary to believe that in the short length of the condenser, less than 2 ft., and in the very short time required to pass through it, the mixed gases coming out of the retort part with all of the heat needed to keep the zinc in the gaseous state.

In the drying of the charge, water is first evaporated next to the wall of the retort; zinc is also first reduced and volatilized here by heat passing through the adjacent wall, and the evolved gases carry this heat through the rest of the charge. As the zinc is gradually expelled, there remains a porous layer against the wall, through which heat will pass very slowly by conduction. It is, therefore, easy to understand why it is necessary to run the retort hotter according to the time distillation has been going on, and why the rate of distillation varies from time to time, increasing slowly to a maximum, which is maintained for only a small fraction of the length of the shift, and diminishing to a rate which is no longer profitable. Local conditions, such as the value of ore and metal, cost and quality of fuel, quality of fire clay, wages, etc., largely determine the percentage of extraction which should be striven for. The influence of local conditions can be traced in the variations which are found in good practice in all of the following particulars: in the form and size of the chamber in which the retorts are heated; in the method of firing adopted; in the number, shape and dimensions of the retorts, and in the time the charge remains in them.

The object of this minute analysis of the chemical and physical changes occurring within a zinc retort, has been to discover if possible something in practice which can be improved.

Nothing has been shown to indicate that the charge can be heated in any other way than by heat conducted through the wall of an enclosing vessel, which isolates it from the atmosphere and products of combustion. Incidentally it may be noticed that all attempts to smelt zinc by means of heat generated within the charge, by the partial combustion of carbon mixed with it, have met with such practical difficulty in separating and condensing distilled zinc from the accompanying gases that blast processes for zinc smelting may be dismissed from consideration.

No substitute for fire clay, as a material for retorts, has been found. But intelligent effort has been made in very many ways to improve the quality of retorts, as for instance, by the selection of clays: by weathering the raw clays; by varying the proportion of plastic to non-plastic clay in the mixture, or the degree of fineness to which either of them is ground; by increasing the amount of pugging given to the wet mixture; by varying the time allowed for the clay to temper, both in blocks and in the molded retorts before firing, and by varying the heat in firing.

Furthermore, improvement has been sought by substituting for a part of the non-plastic clay, or burnt stock, some other refractory material like crushed quartz, coke, or graphite; by coating the retort within or without, with some infusible and less easily corroded material, such as retort carbon, graphite or carborundum, and particularly by increasing the pressure used in molding the retorts, up to several thousand pounds to the square inch.

I have no desire to minimize the value of what has been accomplished by all of these improvements, but it is evident that no radical advance can be expected on these lines.

Where local conditions permit, great advances have been made in systematizing the manual labor involved in zinc smelting, and supplementing it with machinery.

There remains only to be considered the composition of the charge. No substitute has been found for carbon as the reducing agent; and it may be assumed that every successful smelter is using it, in the form best adapted to his conditions, whether as charcoal, anthracite coal, coke, or non-coking coal. It is well known that some ores are much more easily smelted than others, and therefore more desirable. Without entering into particulars, ores may be classified either according to their richness, that is their zinc contents, or according to their uniformity in composition. The advantage of treating rich ores

is easily seen. The advantage of uniformity is due directly to the fact that when all of the dimensions of a furnace are adjusted for economically smelting ore of a certain zinc content the furnace is not well adapted for doing good work on either much richer or much leaner ores; and is due indirectly to the fact, that the workmen can only get the best work out of the furnace when the charge is sufficiently uniform for them to learn how best to work it off. Uniformity may be secured in a measure by carrying large stocks of ores, and properly mixing them. The concentration of ores, which is usually done near the mines, is really a metallurgical operation; and no judgment of the progress which has been made in the metallurgy of zinc, which overlooked the improvements which have been made on widely divergent lines in the art of preparing the ore for furnace treatment, would be comprehensive or sound. I have recently called attention to fire concentration for some classes of ores as a method of enrichment which appears to offer some attractive possibilities.

Before presenting the numerical results of various calculations of the heat required for the chemical reactions, and changes of physical state which are known to occur within the retort, I think it is well to have in mind some definite idea of the proportions of the different substances which are present at the same time in the retort. From these proportions, whether by weight or by volume, expressions for their relative concentrations may be found.

The capacity of a circular cylindrical retort, whose internal dimensions are 120 C. and 20 C., is 37,700 cu. C = 37.7 liters. The thickness of its walls is 3 C. and the area of its inner cylindrical surface is 7540 sq. C. A corresponding condenser 50 C. long has a capacity of 7407 cu. C. = 7.41 liters; the thickness of its walls is 1.5 C.

For convenience in calculations, and because I believe it corresponds very closely to actual conditions, I assume that the space which is not actually filled by the solids of the charge amounts to 22,200 cu. C. This is .001 of $22.^{22}$ M^3, which is the unit of molecular volume for a gas under standard pressure at 0 deg. This unoccupied space, which includes the pores in the charge, I have called the voids. It is equal to the volume of gas present in the retort.

Subtracting the voids from the total capacity, the space filled with solids is 17,700 cu. C., which, with a charge of 21 kg. of 80 per cent ZnO, mixed with 14 kg. of C., figures an average sp. gr. of 2.26. This is considerably less than the average, as figured from their true specific gravities. The bulk is made up by adding lighter inert material, as is common practice. In this limited discussion I consider only the chemical and physical changes occurring within the retort and the condenser. I have assumed that 80 per cent of the zinc contained in the charge is distilled during 15 hours of active production, and that the remaining 9 hours are occupied in cleaning and charging retorts, drying out the charge, and collecting blue powder. The charge then contains 16.8 kg. metallic zinc of which 13.44 kg. is obtained in 15 hours.

Passing now to the gases contained in the retort: If the voids were filled with CO at 0 deg., standard pressure, the weight of CO would be 0.001 molecular volume x 28 kg. = 28 gr. But gases expand by heat and a less weight of this gas would fill the voids at a higher temperature.

At constant pressure, gas expands to 2.83 times its volume, at zero, in going from 0 deg. to 500 deg.; 3.82 times in going to 770 deg. and 4.81 times to 1040 deg. The weight of CO filling the voids will therefore be 10 gr. at 500 deg., 7.33 gr. at 770 deg. and 5.82 gr. at 1040 deg. The weight of zinc liberated by the chemical reaction is directly proportional to the weight of CO produced. The constant ratio is 65/28, that is, if these products do not separate, there will always be 2.32 times as great a weight of zinc mixed with the CO gas. At 1040 deg., zinc is a gas, and its volume is equal to the volume of CO which is present with it. Each gas then fills only half of the voids. Under these circumstances, the weight of CO in the retort is only half of 5.82 gr., that is 2.91 gr., associated with 6.75 gr. of zinc. At 770 deg. the zinc as a liquid has such a small volume that it may be neglected, and the whole of the voids be considered filled with CO. Thus with the 7.33 gr. CO in the retort at 770 deg., is mixed 17.03 gr. Zn, in liquid globules. With 10 gr. of CO at 500 deg., will be 23.21 gr. of zinc in liquid globules, and with 28 gr. of CO at 0 deg. will be 65 gr. of zinc, solid.

Considering now the conditions at 770 deg., if the 17.03 gr. of zinc is distributed uniformly throughout the CO gas, each of the 22,200 cu. cm of gas contains 0.00077 gr. If this zinc were united in a single liquid globule, it would have a volume of 0.00013 cu. cm whose diameter would be 0.063 cm (0.0252 in.).

There are probably very many liquid globules in one cu. cm of gas, and they must be correspondingly minute. It can be readily seen that they will be carried along by the current of accompanying gas.

If 80 per cent of the zinc in the charge is distilled in 15 hours, 13.44 gr. are distilled in 54,000 sec. = 0.25 gr. per second.

To find the volume of gas which issues from the condenser per second at 500 deg.: since 65 kg of zinc is accompanied by 2.83 times 22.22 M^3 of CO = 62.886 M^3, we have, 0.25 : 65,000 = X : 62.886 M^3, from which X = 0.000242 M^3 = 242 cu. cm. If this volume issues through an orifice with a diameter of 6 cm having an area of 28.27 sq. cm it has a velocity of 8.55 cm per second.

This is so slow that it is worth while to test numerical results by another calculation. A discharge of 0.000242 M^3 per second for 15 hours = 13.068 M^3. The volume of 28 kg of CO at 500 deg. is 2.83 × 22.22 M^3 = 62.8826. In 15 hours 13.068/62.88 = 0.208 times this weight is discharged. The corresponding weight of zinc is 65 kg × .208 = 13.52 kg, as against 13.44 kg, with which we started. In practice a large part of the mouth of the condenser is covered, except while metal is being drawn. With a velocity corresponding to 8.55 cm per second, there is a good chance for the liquid globules of zinc to settle out of the gas current in the condenser. Calculation of the average temperature in the condenser, from the conductivity of its walls, determined by measurements of the conductivity of similar material, is apt to give erroneous results; for if it is assumed that the inner surface of the condenser has the average temperature of the gas, this involves an instantaneous and perfect transfer of heat from a gas to a solid, which cannot occur. The alternative is to guess at a probable rate of heat transfer. Moreover, the higher the temperature of the inner surface, for a given tempeature of the outer surface, the more rapid is the outflow of heat. It is found that the conductivity required to cool from an assumed initial temperature with a high heat potential differs from the conductivity required to cool from a much lower initial temperature, with a less heat potential, by an amount which does not exceed the probable error of observations of temperature.

Some difference of opinion exists as to what proportion of the heat which is conducted through the walls of the retort is utilized to effect chemical and physical work. When this question is approached from the theoretical side, this difference rises not so much from difference in the physical data employed as from different methods of using them.

For while it is not claimed that all the data used are absolutely correct, it is generally believed that they approximate closely to the truth, and that they are the best available.

To state my case clearly at the outset, so that my argument can be easily followed, I will say here, that I believe the reduction of zinc oxide is effected by carbon monoxide, and that a subsequent reaction takes place, by which the carbon dioxide first formed is reduced to carbon monoxide. It is true that the total heat expended to effect these two endothermic reactions is the same as would be required to reduce zinc oxide directly by carbon, in one operation, if this were possible under the conditions present.

But the method I have chosen brings out clearly how it is

possible that the sensible heat contained in products of the first reaction may help to bring about the second reaction. The external heat required to produce the end products will be less, by exactly the amount of heat in the first products which is thus utilized. Taking then the temperature of reduction to be 1040 deg., we have for the first reaction begun and ended at 1040 deg.

Heat furnished by 81 kg ZnO @ 1040°..	12,973 kal.	
Heat furnished by 28 kg CO @ 1040°..	7649 kal.	
Heat absorbed by reaction ZnO + Co = Zn + CO_2 (referred to zero) 84,800 — 68,040		16,760 kal.
Heat contained in Zn gas at 1040°.....		36,894 kal.
Heat contained in CO_2 gas at 1040°.....		13,838 kal.
External heat required	46,870 kal.	
	67,492 kal.	67,492 kal.

Similarly for the second reaction begun and ended at 1040° we have:

Heat furnished by 44 kg CO_2 at 1040°....	13,838 kal.	
Heat furnished by 12 kg C at 1040°....	4800 kal.	
Heat absorbed by the reaction (referred to zero) 97,200 — 2 × 29,160.....		38,880 kal.
Heat contained in 56 kg CO at 1040°....		15,298 kal.
External heat required	35,540 kal.	
	54,178 kal.	54,178 kal.

But one-half of the CO formed simply replaces the CO originally present, and the heat which it contains supplies the 7649 kal. furnished by this reagent in the first reaction.

If the two reactions are simultaneous and begin and end at 1040 deg., the heat absorbed by both of them, which amounts to 82,410, must come from outside. If to this sum be added the 12,973 kal. required to heat 81 kg of ZnO to 1040 deg., and the 4800 kal. to heat the 12 kg of C., a total of 100,183 kal. is reached. Of this total, 16,760 + 38,880 = 55,640 kal. has been expended in doing chemical work, and 44,543 kal. is held as sensible heat in the products. If the products leave the retort at this temperature, most of the heat is wasted. But what warrant do we have for thinking that they leave it at anything like this temperature, since it is well known that the second reaction occurs much below this temperature. The zinc in cooling to 500 deg. parts with 31,784 kal., and the 28 kg of CO loses 4133 kal., the total of which is 35,917 kal., which is more than the external heat required for the second reaction. In other words, the total heat required from outside will be reduced by the amount of heat in the products which is expended in effecting the second reaction.

Moreover, if it be granted that the heating of the reagents was accomplished during the several hours of heating up the charge, 17,773 kal. must be deducted from the 100,183 kal. to get the total heat which must be transmitted through the retort during the hours of distillation. This leaves 82,410 as all the heat which must be supplied during distillation; but before reduction begins there is an atmosphere of heated CO in the retort which furnishes 7649 kals. This atmosphere is constantly renewed by one-half the carbon monoxide of this second reaction which replaces it. Only one-half of the sensible heat in the second reaction is carried out of the retort. The remaining 7649 kal. remains and is utilized to repeat the first reaction. Consequently if the second reaction can be effected by the sensible heat contained in the products of the first reaction above 500 deg., it will be necessary to conduct only enough heat through the walls of the retort to bring about the first reaction, and the final products of both reactions will leave the retort at a temperature of about 500 deg.

It should be noticed that most of the heat in the zinc gas is liberated by condensation at 930 deg. This physical change is strongly exothermic, and the heat so disengaged at 930 deg. must be active in the second reaction.

There are theoretical objections against the other hypothesis, that the gases enter the condenser above the temperature of the volatilization point of zinc, quite apart from the improbability of so intricate a process as condensation being effected in the condenser during the very short time the gas requires to pass through it. I will not discuss them, but after calling attention to the impossibility of any loss of heat from the retort by radiation, which would have to pass out through the hotter walls into the hottest combustion chamber, and the correlary from this, that all the heat present which does not pass out in the products must be expended in doing either chemical or physical work, I will briefly consider the rate of conduction of heat during the hours of active distillation, required to bring about the first reaction. In the case considered, only 0.208 of a molecular weight of zinc is distilled in 15 hours, consequently only 0.208 × 46,840 kal. is required; 9743 kal. in 15 hours = 65 kal. per hour = 1.0833 kal. per minute = .018 kal. per second. The inner surface of the retort has an area of 7540 sq. cm.

In a retort whose radius is 10 cm, one-half the charge lies in a core whose radius is 7.11 cm. The difference between the two radii may be taken as the average distance the heat must be conducted beyond the walls to reach all of the particles which are reduced. Adding this difference 2.89 cents, to the thickness of the wall 3 cm we have the average distance the heat is conducted 5.89 cm. The amount of heat which is conducted through any resistance, in one second for one degree fall in temperature, is directly proportional to the specific conductivity of the material offering the resistance, and to its area, but inversely proportional to the distance it is conducted. Calling x this conductivity of retort and charge, we have: .018 kal. per second = x × 7540/5.89 = 0.000014 thermal ohms. This is very much less than the conductivity found by experiments on burnt fire clay, but it should not be rejected unless it can be shown that sufficient account has been taken of the resistance offered by the break between the retort and the charge, and by the resistance of the porous charge to the flow of heat.

I have used throughout the physical data given in "Metallurgical Calculations," by Dr. Jos. W. Richards, and subjoin the more important:

Heat in 28 kg CO from 0° to t° = 22.22 [0.303t + 0.000027t^2].

Heat in 44 kg CO_2 from 0° to t° = 22.22 [0.37t + 0.00022t^2].

Heat in 65 kg Zn from 0 to melting point = 65 [0.09058 (420) + 0.000044 $(420)^2$] kal.

Latent heat of fusion of 65 kg Zn = 65 × 22.61 kal.

Heat in melted zinc to boiling point (930°) = 65 [0.1275 × (930 — 420)].

Latent heat of vaporization = 23 × (930 + 273).

Molecular volume of gases at 0° and 76° mm = 22.22 M^3 using kg.

Molecular heat of combustion Zn + o	84,800 kals.
Molecular heat of combustion C + o	29,160 kals.
Molecular heat of combustion C + o_2	97,200 kals.

Estes Park, Colo.

Alcohol from Paper-Mill Wastes.—In his annual report as chemist to the American Paper and Pulp Association, Mr. Arthur D. Little, of Boston, Mass., summarizes the new devices of the past year looking toward the use of the waste liquors of pulp mills. Perhaps the most important development in this direction, says Mr. Little, is the process introduced in Sweden for the production of an impure grade of ethyl alcohol by fermentation of the waste liquor after neutralization with lime. Although alcohol in considerable quantities can unquestionably be produced in this way, and the process is one involving no serious technical difficulties, it nevertheless unfortunately, holds out no hope of avoiding the nuisance created by the waste liquors since the slop from the distillery is far more objectionable than the original waste liquor, because of the presence of great quantities of dead yeast.

The Magnetic Properties of Alloys.

The sixty third ordinary meeting of the Faraday Society, held in London on April 23, 1912, was devoted to a general discussion on the magnetic properties of alloys, and was presided over by Sir Robert Hadfield, who in his introductory remarks gave a brief account of the early work in this field, referring more particularly to the non-magnetic ferro-alloys with which he had been associated. He pointed out how magnetic properties depended on heat treatment as well as on composition, and showed a bar of manganese steel which was magnetic at one end and non-magnetic at the other. To illustrate the necessity of working carefully through whole series of alloys before any conclusions could be arrived at, he remarked that whereas a 5 per cent. manganese steel was very brittle and magnetic, the addition of 14 per cent. nickel rendered the steel both very tough and non-magnetic.

Magnetic Properties of Iron-Carbon and Iron-Silicon Alloys.

The first paper was read by Geheimrat Dr. E. Gumlich (Berlin), and dealt with "the magnetic properties of iron-carbon and iron-silicon alloys." The photomicrographs shown were the work of Professor P. Goerens.

The experiments conducted by the Physikalisch-Technische Reichsanstalt, on which the author reported, were commenced a few years ago on the instigation of German technologists and with the joint assistance of the Verband Deutscher Elektrotechniker, some German ironmasters, and the Metallurgical Laboratory of the Technical High School at Aachen (Professors Wüst and Goerens).

The experiments aimed at investigating the relations between the magnetism of iron alloys and their chemical composition and thermal treatment. Although the researches are by no means completed, the Reichsanstalt would like to communicate some of the results obtained to the Faraday Society as a contribution to this discussion. The results concern magnetization up to saturation, coercive force, remanence, and the electric resistance of the alloys iron-carbon and iron-silicon.

Carbon, it is well known, behaves in these alloys in very different ways according to the thermal treatment (slow or rapid cooling) it has undergone, and the differences can be traced in the physical properties, as well as in the structure (cementite, pearlite, martensite, temper-carbon) which is characterised by the presence of the carbon. The carbon which is *dissolved* in the iron has the strongest influence upon the magnetic properties, and it has resulted that the coercive force of these alloys increases proportionally as the dissolved carbon, while the remanence decreases. These conclusions are important for the manufacture of permanent magnets. The carbon present as impurity plays, however, also an exceedingly important and very disturbing part in the manufacture of dynamo steel, transformer iron, &c., which are to be particularly soft magnetically, because the carbon decreases the permeability and increases the hysteresis loss. Since carbon cannot altogether be eliminated in practice, the manufacturer has to attempt to render it innocuous so far as possible, and the author's experiments demonstrate that a considerable addition of silicon has this effect.

In 1890 Barrett, Brown, and Hadfield published experiments which proved that the addition of silicon to iron diminishes the electric conductivity without impairing the magnetic properties. On the strength of these observations, the Reichsanstalt induced German iron-works to make transformer sheets out of silicon-iron in order to reduce the Foucault-current losses in the transformers. The realized improvement was much greater than was expected; for it resulted that the magnetic properties were generally improved, and the hysteresis losses in particular much reduced. The part which the silicon plays in this improvement is not clear yet. The experiments of the Reichsanstalt show that the influence is not a direct one, for in that case the magnetization should increase with increasing silicon percentage, particularly in fields of high intensity. The *saturation* value should hence *increase* whereas it *decreases*, just as if the silicon were a non-magnetic addition to the iron merely acting by reducing the effective cross-section of the iron. The influence of silicon is hence indirect, and it seems in some way to counteract and to eliminate the detrimental effect of the carbon. For it would appear that on continued heating the carbon cannot remain *dissolved* in the iron, being transformed partly into the less detrimental cementite, and partly into the altogether harmless temper-carbon.

The microphotographs which Professor Goerens (Aachen) has taken of the magnetically examined specimens are in very satisfactory agreement with the results of the studies of the alloys of iron-carbon and iron-silicon.

Magnetism and Stoichiometry.

Professor E. Wedekind (Strasburg) then read his paper on "relations between the magnetism and the stoichiometrical constitution of chemical compounds."

The present state of our knowledge concerning the dependence of the magnetic properties of compounds upon the nature and the number of the elements entering into combination may be summed up in the following statements: (1) The magnetism of simple chemical compounds, derived from a ferromagnetic metal or a metal of latent magnetism, is a well-defined molecular property of the compound which is connected with the stoichiometrical composition or with the constitution of the compound. (2) The magnetism of simple compounds of ferromagnetic metals is throughout essentially feebler than that of the metal, so far as independent representations of valencies are concerned. (3) Simple compounds of metals of latent magnetism (Mn, Cr, V, presumably also Ti) are as a rule more strongly magnetic than the metals; the maximum intensity depends upon the stoichiometrical composition, however, particularly in cases where several compounds exist of the same components. Manganese has a maximum in its trivalent state with regard to the elements which can themselves be trivalent, *i. e.*, in the atomic ratio 1 : 1. Some of these compounds behave like permanent magnets. (4) With the independent oxides of manganese, chromium, and vanadium, the susceptibility appears to be a function of the metal percentage, in the case of the vanadium sulphides a linear function of the sulphur percentage; the magnetic susceptibility is thus dependent upon the valency of the metal in the respective compound. (5) So-called mixed oxides or sulphides which do not represent uniform valencies are with *all the metals* more intensely magnetic than the independent classes of compounds. There is a correlation with the acid nature of the one component, which always represents the higher oxide. Such a compound is always graphically revealed by a sharp bend in the curve. (6) The magnetic susceptibility decreases on the whole with decreasing atomic weight of the chief metal. Several manganese compounds are still ferromagnetic. Of chromium compounds only the two mixed oxides already referred to are still ferromagnetic; none of the vanadium compounds are any more decidedly ferromagnetic. The minimum is probably reached in titanium, which stands to the left of vanadium, and in the titanium compounds which are now being investigated. The next element in succession, scandium, is already diamagnetic as oxide.

Magnetism at Low Temperatures.

Dr. James G. Gray and Dr. Alexander D. Ross (Glasgow) presented a paper on "the magnetic properties of a variety of special steels at low temperatures," which was read by Dr. Ross.

Specimens of iron, carbon steels, silicon steels, chrome steels, &c., were tested at room temperature and when immersed in boiling liquid air, in the conditions brought about by normalizing, annealing and quenching the metal at various temperatures. It was found that the effect of cooling the specimens

was in general to diminish the permeability for low field strengths, and to increase it for high fields. A magnetization curve corresponding to —190° C. lies initially below and finally above one corresponding to 15° C. This is shown to be in harmony with the theory of elementary magnets whose intensity of magnetization and polar length varies with the temperature. It was found that in general the crossing point of the I-H curves corresponding to 15° and — 190° C. respectively, is higher the greater the amount of the added element present. This rule holds in any of the conditions mentioned above. The value of the magnetizing force necessary to bring about crossing of the magnetization curves for the material at 15° and — 190° C. is very low in the case of chrome steel. For a specimen of this variety of steel containing 1 per cent. of chromium the curves crossed for a field strength of 8 c.g.s. units.

Cooling to the temperature of liquid air results in the coercive force being increased, and this effect is very pronounced in the case of materials which have been quenched. For high carbon steel in the quenched condition the coercive force at room temperature is 32; at — 190° C., it is 50.

Heusler Alloys.

Dr. ALEXANDER D. ROSS also read a paper "on the magnetic properties and microstructure of the Heusler alloys."

The paper describes a series of tests on ternary alloys of copper, manganese, and one of the elements aluminium, tin, antimony, and bismuth, and also on several magnetic binary alloys. Details are given of the method of casting and annealing the metal, and a description is given of a special form of magnetometer which was designed in order to increase the accuracy of the tests. The primary object of the magnetic tests was (1) to determine the magnetic quality of the alloys in the condition as cast, (2) to find the best thermal treatment for rendering the metal of good magnetic quality, (3) to test the variation of permeability with temperature, and (4) to investigate the effects of annealing and quenching the alloys at various temperatures. The Heusler alloys are improved by annealing at 180° C. The best duration of the annealing process varies from a few minutes to several hours, according to the composition of the specimen. It is found that the effect on the magnetic quality brought about by cooling these alloys to the temperature of liquid air is decidedly different from what is found in iron alloys. The magnetic experiments combined with thermal and microscopic tests have proved that the Heusler alloys are solid solutions probably consisting of Cu_3Al and Mn_3Al in the case of magnetic ternary alloys of copper, manganese and aluminium. There is no indication of the occurrence of ternary compounds, and the experiments do not support the theory that the magnetic quality is due to a change brought about in the transformation temperature of manganese through its solution in copper or copper-aluminum.

Magnetism of Nickel and Manganese Steels.

A paper by Dr. S. HILPERT (Berlin) and Dr. E. COLVER-GLAUERT (Sheffield) on "the magnetic properties of nickel and manganese steels with reference to their metallographical composition," was read by Dr. Colver-Glauert.

A series of nickel and manganese steels (5 to 33 per cent. nickel and 5 to 10 per cent. manganese) were investigated, by quenching from various temperatures and other thermal treatment, and then quantitatively measured magnetically at room temperatures.

From the products so produced cooling experiments were carried out to — 180° C., and the specimens were then reheated in stages to the highest initial temperature employed, and similar magnetic investigations pursued. The following results were obtained:

At high temperatures (1,200° C.) compounds are produced which at room temperatures are strongly magnetic, the only exception being the 33 per cent. nickel steel. This proves that the allotropic theory, which holds that magnetism rests entirely with alpha iron, is no longer tenable as regards these steels, since the slowly cooled steels are less magnetic than those quenched from high temperatures.

The 25 per cent. nickel steel, which most commonly occurs in practice when a non-magnetic alloy is required, was subjected to very close investigation, and a diagram produced showing the magnetic "life" of this steel for all temperatures, and showing the conditions under which its magnetism may vary between zero and maximum. This maximum is practically such as would be expected from a mixture of iron and nickel of the proportions found in the steel. In this steel two irreversible temperature hysteresis loops are found and shown in diagrammatic form. The 33 per cent. nickel steel was found to be quite different to the other iron alloys, and it seems highly probable that steel of this composition must be regarded as a special compound.

Metallographic investigations prove that for these steels it is impossible to correlate any given structure with given magnetic properties. In this investigation sulphurous acid was used as the etching medium, and the structures obtained are different to those usually shown for nickel steels, being much more similar to those of meteoric iron.

The manganese steels were investigated in collaboration with W. Mathesius.

Magnetism of Manganese Compounds.

Dr. S. HILPERT and Dr. T. DIECKMANN presented a paper entitled "the magnetic properties of the compounds of manganese with phosphorus, arsenic, antimony and bismuth." This was also communicated by Dr. Colver-Glauert.

The magnetic change points of these compounds were proved to be closely connected with the atomic weights of the substance compounded with the manganese.

The highest is that of MnBi (380° C.) and the lowest that of MnP (18° to 25° C.). If this latter is warmed in the hand, it no longer reacts with a magnet, but immediately does so if it is placed in cool water. This was experimentally demonstrated.

Heusler Alloys.

The following is a summary of a paper communicated by Dr. E. TAKE (Marburg) and Dr. F. HEUSLER (Dillenburg):

1. In order to account for the pronounced ferromagnetism of the Heusler alloys, aluminium or tin-manganese bronzes, Guillaume assumes with Faraday that pure manganese exists in a strongly magnetic modification, which undergoes transformation at a very low temperature; this temperature is said to be raised by the addition of Al or Sn, so that the magnetism of these alloys becomes apparent. This hypothesis is not based upon facts, and the arguments are not sufficiently supported; it would, moreover, not explain the strong ferromagnetism of the Heusler manganese alloys with As, Sb, Bi and B.

2. Heusler, on the other hand, has advanced a hypothesis which perfectly explains all the phenomena; for he has not only discovered the ferromagnetic manganese alloys, but he has also first proved, in 1903, that the appearance of the strong ferromagnetism is due to the formation of chemical compounds, and that the ferromagnetism is thus a molecular phenomenon.

3. It is stated and demonstrated in detail which these strongly ferromagnetic chemical compounds are. (Heusler, Haupt, Preusser, Williams, Ross, Hilpert.)

The research above referred to proves the Heusler Al-Mn bronze to be, in physical respects, exceedingly interesting material, of valuable properties, especially as regards hysteresis.

4*a*. By the process described by Heusler the malleable Al-bronzes in particular can be converted into an unmagnetic modification which, suitably aged, yields a strongly magnetic material of very small hysteresis. (Heusler, Asteroth, Take.)

4*b*. By the method of Take the malleable Al-bronzes in particular may, by another ageing process, be transformed into a permanently magnetic modification of high intensity.

5. Hypotheses for explaining the strong ferromagnetism of the chemical compounds on the electron theory have been suggested by Richarz, Weiss and Take.

6. The physical properties mentioned under 4*a* are due, according to Richarz, to a very slight formation of complexes of the elementary magnets in the one case and to a very pronounced formation of such complexes in the other case.

7. According to his experiments the phenomena of ageing are due, according to Take, to *two* transformations; the first transformation is the gradual formation of the strong ferromagnetic compound of Heusler; the second is the gradual complex formation, as also suggested by Richarz with regard to the experiments by Heusler and Asteroth. This complex formation also gives rise to the enormous coercive forces which are observed in the case 4*b*.

Professor A. A. Knowlton and Dr. O. C. Clifford (Utah, U. S. A.) also presented a paper on the Heusler alloys.

The paper is a contribution to the study of the following questions:

1. What conditions of preparation and thermal treatment must be observed in order that any alloy of any given composition may be in condition to exhibit the maximum possible intensity of magnetization at saturation?

2. What are the exact relations between composition and the two factors of magnetic quality—hardness, and intensity of magnetization at saturation?

3. Upon what factors does the transformation point of a given alloy depend, and what is the exact form of the relation?

The specimens tested were in the form of rings, prepared by prolonged heating in a graphite crucible and cast in a hot carbon mould. A large series of alloys was made, but either on account of poor mechanical or poor magnetic qualities, tests were confined to the following seven:

No.	Cu	Mn.	Al.	History.
1	67.8	27.8	4.4	Cast from scrap from many previous specimens. Materials have been often cast and remelted. Chilled from 250°.
3	63.8	27.5	8.7	New mixture. Annealed to room temperature.
4	63.3	26.4	10.3	Cast from scrap. Chilled from dull red heat.
5	63.3	26.4	10.3	From same melt as No. 4, but annealed to room temperature.
6	68.0	28.0	4.0	New mixture. Annealed to room temperature.
7	63.3	29.5	7.2	Al added to No. 6, remelted and chilled from 200°.
8	60.3	25.4	14.3	Al added to No. 7, remelted and chilled from 250°.
9	60.2	26.7	13.1	Remelted from scrap. Chilled from 200°.

The results of the tests show that percentage composition is relatively unimportant in determining magnetic quality as compared with heat treatment. Thoroughness of mixing is also an important factor, difficult to separate from heat treatment. It would appear that under the best conditions of mixing and chilling the maximum possible induction, for a given manganese content, increases with increasing percentage of aluminium. Heusler and Starck's assumption that the best results are given by atomic proportions is not regarded as conclusive. For the details of the experiments made the original paper must be consulted, but the authors conclude that it will be impossible to decide what composition will give the alloy of maximum possible magnetization until the conditions of the best thermal treatment have been worked out over a wide range of composition. Sensitiveness to heat treatment and magnetic hardness are closely dependent upon the proportion of aluminium present, while the transformation temperatures depend largely upon the percentage of copper.

The paper ends with a brief consideration of the following possible hypotheses as to the nature of the magnetic units in the Heusler alloys. These may consist of:

1. The molecules of a chemical compound of manganese and aluminium, or groups of such molecules.

2. Manganese molecules or groups of such molecules.

3. Complex groups, which form the structural elements of a certain type of mixed crystal and contain at least two different kinds of chemical molecules.

Magnetism of Iron-Nickel, Iron-Cobalt and Nickel-Cobalt Alloys.

Professor Pierre Weiss (Zurich) communicated a paper entitled the magnetic properties of the iron-nickel, iron-cobalt and nickel-cobalt alloys.

When the results of quantitative investigations of magnetic properties are considered from the standpoint of the author's kinetic theory of ferromagnetism, all the metals appear to be homogeneous solid solutions. The saturation intensity of magnetism is the resultant—not the sum—of the molecular moments and at absolute zero, when heat movements have ceased to exist, the saturation intensity gives the true moment of the molecule. By molecule the author understands the atoms which are rigidly connected with one another; the atoms may also be articulated, *i. e.*, magnetically free to assume any orientation. In the case of substances like oxygen and the salts of metals (in the solid or dissolved states) the coefficient of magnetization is inversely proportional to the absolute temperature. By multiplying this coefficient by the absolute temperature we obtain the Curie constant, and the molecular moment (which cannot experimentally be determined in these substances) can be deduced from the Curie constant. When the magnetic moment of the nickel atom is followed through varied temperature conditions in the nickel compounds, the moment is found to be represented by multiples of a common factor, 1123.5, which the author calls the "magnéton." At absolute zero the magnetic moment of the Ni-atom is 3 x 1123.5, or 3 magnetons; at temperatures above the Curie point (at which the strong magnetism disappears) it is 8 magnetons, in salts 16 magnetons. The same common factor is found in the magnetic moments of the atoms of Co, Mn, Cr, V, Cu, U, and seem therefore to constitute the common elementary magnet.

The assumption of the existence of these magnetons has proved useful in the study of the alloys of iron-nickel, nickel-cobalt, iron-cobalt, which the author has been investigating in conjunction with G. Foëx, F. Hegg, O. Bloch and A. Preuss. The researches, details of which are given, indicate the existence of the compound Fe_2Ni (30 magnetons, or 10 per atom) already to be traced on the melting-point curves of Guertler and Tammann, though not recognized by them. In solid solutions the molecular magnetic moment is additive, but not in compounds. Conclusions are also drawn as to β iron (probably Fe_3), γ iron (Fe_2), δ iron (Fe). The interpretation of the results appears clear in the case of the reversible Fe-Ni alloys and of the Ni-Co alloys; the irreversible Fe-Ni alloys and the Fe-Co display complex phenomena. There is, however, also a definite compound, Fe_2Co, which is more magnetic than pure iron; its technical application is being studied. One of the curious features is that nickel, in its reversible ferro alloys, is in a state which the pure metal only assumes at higher temperature; the surrounding iron molecules thus exert a "repercussion" effect upon the interior magnetic condition of the nickel atom. Cobalt does not affect nickel in the same way, but cobalt has this effect in the alloys of cobalt and iron.

Discussion.

The chairman communicated a note in which he criticized the evidence usually brought forward for the existence of a non-magnetic adamantine β form of iron. There might be modifications in the molecular constitution of iron at high temperatures, but that there was allotropy in the accepted sense of the term remained to be proved. There were iron

alloys which were more magnetic than iron, and under the allotropic theory this would mean still another allotropic form of iron. He supported Professor Knowlton's view that ferromagnetism is neither atomic nor molecular, but crystalline, but more light would have to be thrown on the molecular constitution of iron itself before one could generalize on the question.

Professor H. Du Bois opened the general discussion on the papers. He recalled the fact that in addition to the three classical magnetic metals, Weiss has prepared manganese electrolytically, which is ferromagnetic. He next referred to the magneto-optical researches that were being carried out in his laboratory, and he stated that a piece of manganese steel which was non-magnetic as a lump distinctly showed the Kerr effect, the effect being variable for different patches on the mirror which reflected the light. This magneto-optical method affords a means of studying the surface patch by patch. A great many other alloys and compounds which are non-magnetic in the lump also show the same effect.

Professor B. Hopkinson thought that the most promising direction in which to pursue a systematic study of magnetic materials with a view of throwing light on the nature of magnetism was investigation in fields of very high density. Another promising line of investigation was the relation between the saturation value of magnetization determined in that way and the temperature effect. As far as was known at present, the general character of that relation was much the same as that obtaining between the pressure and temperature of a gas or liquid near its critical point, and this was a very illuminating analogy. Experiments in high fields was of value in that accidental effects of structure were eliminated. He had shown, for example, that iron could be stretched far beyond the elastic limit in a very powerful field without changing the intensity of magnetization by so much as 1 per cent.

Dr. W. Rosenhain criticised Professor Hopkinson's statement regarding the "accidental" character of minute internal structure. He considered that while the use of fields of high intensity was of value it would obliterate the effect of many things of interest and importance in themselves. It seemed to him that there were circumstances of a purely molecular character and also of a structural character, and one would have to try to disentangle the two.

As regards the existence of a hard form of β iron, he objected to the use of the word "adamantine," although he believed in the existence of a distinctly harder form of iron which was stable at high temperatures and which could be retained by quenching.

As regards the Heusler alloys, his own work, confined to a range of 11 per cent. aluminium and 10 per cent. manganese, confirmed Dr. Ross's view as to the non-existence of a ternary compound to the cupra-manganese system which explained the magnetic effects of these alloys. The alloys of aluminium alone are strongly magnetic, and consequently the view he took was that the magnetic qualities of the Heusler alloys were due to the presence in them in solid solution of Mn_3Al. An ingot of this substance would spontaneously disintegrate to a heap of powder, and it was magnetic both in the bar and in the powdery form.

Dr. Cecil H. Desch, in a written communication, suggested that the "ageing" of the Heusler alloys may be a complete effect caused by the formation of inter-metallic compounds, the equalization of composition by diffusion and the union of ultramicroscopic particles of various phases to form physically more stable aggregates. All of these processes may be concerned in modifying the magnetic properties. Further careful investigation of the alloys, made from pure materials, was necessary in a thoroughly well-equipped laboratory and working at high magnifications.

The late Joseph Dixon, founder of the Joseph Dixon Crucible Company, is the subject of a biographical sketch by Elbert Hubbard, entitled "Joseph Dixon, One of the World Makers"

Manufacture of Sulphuric Acid at Ducktown, Tenn.

A bulletin just issued by the U. S. Geological Survey, on "Sulphur, pyrite, and sulphuric acid in 1911," by Mr. W. C. PHALEN, contains as an appendix some notes, by Mr. F. B. LANEY, on "the manufacture of sulphuric acid from smelter fumes at Ducktown, Tenn." The following notes are therefrom extracted:

The manufacture of sulphuric acid has solved the problem of taking care of the smelter fumes of the Tennessee Copper Company and the Ducktown Sulphur, Copper & Iron Company, manufacturer of sulphuric acid as a solution of utilizing the sulphur dioxide fumes is, of course, practicable only in localities where there is a market for sulphuric acid, and this is the case in Ducktown, Tenn., in connection with the important fertilizer industry of the South

The situation became critical a few years ago for the two Ducktown copper companies when the State of Georgia obtained an injunction against them. It was then decided to build acid plants, but the problem involved great difficulties. Both companies were smelting large quantities of ore—the Tennessee Copper Company handling about 400,000 short tons and the Ducktown Sulphur, Copper & Iron Company, about 150,000 short tons annually. In addition to the necessity for handling larger quantities of gas than had ever before been attempted in acid plants, there were the problems to solve of irregularity of supply of gas, variable temperatures, large quantities of flue dust, and, finally, considerable and variable quantities of carbon dioxide gas, in part derived from the ores themselves and in part from the limestone and coke used in the furnace charges.

Work on the plant of the **Tennessee Copper Company** was begun in 1906, and it was completed in 1907 but not put in full operation until 1908. At this time its rated capacity was 120,000 short tons of 60 deg. Baume acid annually. In 1910 an addition was made which brought the rated capacity up to 180,000 tons yearly, with a probable capacity of over 200,000 tons.

The following account of this plant is taken largely from two articles, one by N. H. Emmons (Copper Handbook, Vol. 10), and one by Wilbur A. Nelson (Resources of Tennessee, Tenn. Geol. Surv., vol. 2, 1912).

The plant as it now stands is the largest sulphuric acid plant ever built. It comprises two octagonal Glover towers, 50 feet high and 30 feet in diameter, with suitable niter pots at the base of each; a flue 10 x 20 x 120 ft. from the Glover towers to cooling chambers; sixty-four cooling chambers 10 ft. 10 in. x 10 ft. 10 in. and 70 ft. high and eight cooling chambers 10 ft. 10 in. x 20 ft. and 70 ft. high; four hard-lead fans, each with capacity of 67,000 cu. ft. of gas per minute; twelve chambers 50 ft. x 50 ft. and 70 ft. high; six chambers 50 ft. x 50 ft. and 75 ft. high; eight chambers 23 ft. x 50 ft. and 80 ft. high having a total volume of 4,600,000 cu. ft.; four Gay-Lussac towers 23 ft. x 23 ft. and 50 ft. high; 4 octagonal Gay-Lussac towers 19 ft. in diameter and 70 ft. high and two octagonal Gay-Lussac towers 36 ft. in diameter and 65 ft. high; acid coolers, pumps, and hoists; and fifteen storage tanks with a capacity of 15,000 tons of acid.

In the construction of this plant 50,000 square feet of asphaltum were put in for flooring under the chambers; nearly 1,500,000 chemical brick, about 300,000 fire brick, and nearly 2,500,000 red brick were used in flues and connections; nearly 8000 tons of quartz for packing the towers, over 500,000 lb. of asbestos in insulating flues; and nearly 8,000,000 lb. of lead in chambers, towers, etc.

In a general way the chambers are of conventional design, but the enormous volume of fumes received and of acid produced have brought about developments new to the acid industry. Among the most notable of these is the size of gas connections, acid lines, acid coolers and fans, all of which are on a scale never before known. Other developments of importance are means for screening the "fines" from the ores; the

erection and operation of a Messiter ore-bedding plant; an increase in size and number of the Gay-Lussac towers; changes in blast-furnace top so as to deliver a uniform supply of gas; the construction of a dust chamber 26 ft. x 36 ft. and 163 ft. long, in which are arranged sets of baffles so as to secure a large dust precipitation; and the construction of an electric acid hoist.

It was discovered that a material decrease in fuel needed in the furnace charge could be made by screening out the fine material from the ores. This also permits a higher oxidation in the furnaces and consequently a higher percentage of sulphur dioxide in the gases.

By means of the bedding plant the furnaces are served with a uniform charge, and at the same time it has been possible to reduce the carbonaceous fuel by about 20 per cent, thereby lowering the troublesomely high temperature of the gases and also reducing the percentage of carbon dioxide in the gases from 5 to about 4 per cent.

One of the expensive items in the operation of an acid plant is the loss of nitrogen. The object of the Gay-Lussac tower is to prevent such loss. The exceptionally large towers which were erected in 1910 have proved to be efficient far beyond original estimates in the recovery of the oxides of nitrogen.

The furnace top (Emmons, *Trans.* Am. Inst. Min. Eng., vol. 41, 1910, p. 723) in use before this acid plant was built, the standard brick top supported by structural steel, was found to be unsatisfactory when the gases had to be dampered back to force them into Glover towers. After much experimental work a simple type of furnace which works very satisfactorily was devised. It has cast-iron corner posts and dividers with walls and ends of fire brick. The half circle top is supported on 20-inch I-beams resting on columns and all metal parts as far as possible are exposed to the cooling influence of outside air. The important features are the large elbow and the flue, 9 feet in diameter, leading to the dust chamber. Flues, elbows, and half circle tops are made of boiler plate with magnesia blocks between the metal and the lining of fire brick.

The dust chamber serves two purposes, it allows a large part of the flue dust to settle, and it conserves and regulates the heat of gases, delivering them at the base of the Glover towers at steady temperature and uniform pressure.

The electric acid hoist has proved itself a very valuable adjunct in raising the acid to the top of the high towers. It is simply a large lead-lined bucket arranged somewhat as a Kimberley skip, electrically controlled throughout. It is believed that this method will effect a saving over the usual blow-case or "acid egg" method. However, it is not intended to supplant the blow cases with the hoist, but to use it with them.

With the enlarged and improved equipment now in operation the Tennessee Copper Company finds that all the ore from its mines is needed to furnish sufficient gas to keep the acid plant up to full capacity. This means that all the gas produced by the green ore furnaces must go to the acid plant, thus completely abating the smoke nuisance.

That the ultimate utilization of the sulphur of their ores was the intention of the **Ducktown Sulphur, Copper & Iron Company** at its organization in 1891 is indicated from its name. The problem was a difficult one and much time was spent in experimental work. The difficulties were finally overcome, and the company is today operating on a satisfactory basis a plant with an estimated capacity of 160 short tons of 60-deg. Baume acid daily. The following notes on the plant are condensed from an article by W. H. Freeland and C. W. Renwick (*Eng. & Min. Jour.*, vol. 89, 1910, p. 1116), and another by Wilbur A. Nelson (Resources of Tenn., Tenn. Geol. Survey, vol. 2, 1912, p. 83).

The plant consists of two Glover towers, 12 ft. square and 45 ft. high; a series of dust chambers; four leaden fans; sixteen chambers 96 ft. long, 22 ft. 8 in. wide, and 30 ft. high, having a total volume of 1,050,000 cu. ft.; six Gay-Lussac towers; and the necessary equipment for operating the plant.

From the furnaces the gases pass through flues into a dust chamber. From this chamber they pass into and rise through a cylindrical tower, thence through a kite-shaped flue to a special dust catcher on a higher level. This dust catcher with its system of flues is of special importance in that it controls and regulates the temperature of the gases delivered to the Glover towers and also serves to eliminate the zinc and other light dusts.

From the dust catcher a brick flue runs the full length of the tower building with offtakes to each Glover tower. In these offtakes are placed the niter pots. There is also an auxiliary set of niter pots at the end of the dust catcher for emergency use. In addition to these there are also special methods of handling the nitrogen compounds.

The gases, having been cleaned and reduced to the proper temperature, enter the bottom of the Glover towers. Upon reaching the top of these towers, the gases are led downward through a system of pipes to the base of a special tower through which they ascend and from which they pass through two large lead flues into the chambers. In these towers fully 40 per cent of the SO_2 is converted into SO_3. The concentration of the chamber acid is also accomplished here, and no concentrating pans are needed.

Between the Glover towers and the chambers are located the four large leaden fans which force the gases through the system. The fans are placed in two units of two fans each. One unit forces the gases into the front chambers and the other withdraws them from the rear chambers.

From the chambers the gases pass, as in all acid plants of this type, into the Gay-Lussac towers in which the nitrogen compounds are recovered in the usual way.

This company complies with requirements of the State of Georgia by holding its smelting on a basis to meet the capacity of the acid plant. The ore treated contains from 14 to 19 per per cent of sulphur, averaging about 16 per cent.

Although this plant is rated at a normal capacity of 160 tons of 60 deg. Baume acid a day, this does not represent the maximum, as, when actually necessary, it has attained a capacity of over 200 tons a day.

"Assisted Research" Fund of the American Electrochemical Society.

In order to further the objects of the American Electrochemical Society as stated by its constitution, it was decided at the meeting of the Board of Directors, held at the time of the Boston convention, to try the experiment of assisting purely scientific research work in electrochemistry where this is done under conditions which would make the application of a few hundred dollars annually of effective and efficient assistance.

For this purpose, $250 is made available for this year, to be given in whole or in part to help members of the society who need such assistance to carry on some predetermined work.

The committee, which consists of Dr. W. R. Whitney, chairman, Dr. W. H. Walker, and Mr. F. A. J. FitzGerald, does not wish to burden the scheme with unnecessary rules or requirements, and proposes to carefully consider requests for this assistance on the merits of the case as it may be presented. If the further developments of the scheme warrant the issuing of limitations on the distribution of the fund, such will be published.

The committee's aim will be to give assistance to those who are apparently equipped to do effective work along those purely scientific lines which are not usually explored by commercial or industrial organizations. In other words, the endeavor will be to advance the science of electrochemistry.

The research work thus assisted must be published in the Transactions of the Society.

Applications may be sent to the chairman of the committee, Dr. W. R. Whitney, General Electric Company, Schenectady, N. Y., and should be received before August 1.

Condensers and Condensation for Vacuum Plants.

Automatic Water-Feed Regulation.

By B. Viola, M.E., Member Am. Soc. of M. E.

The construction and operation of the automatic controlling device by which the results described in my article in the June issue were obtained is shown in Fig. 78. The stem B expands and contracts in response to temperature changes of the condense water. The pipe E supplies compressed air of about 15

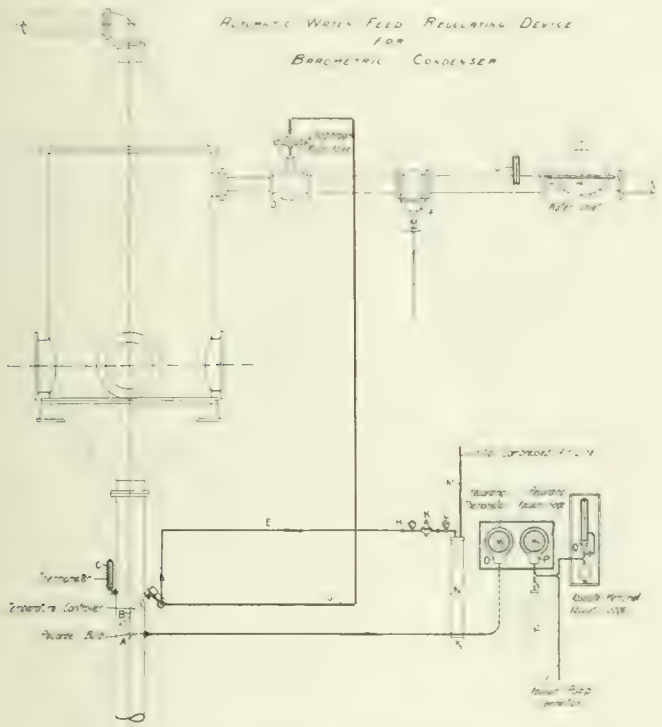

FIG. 78.—AUTOMATIC WATER FEED REGULATING DEVICE FOR BAROMETRIC CONDENSER.

pounds pressure to the valve mechanism of the controller, from which it passes through pipe G to the water-inlet valves, where it actuates a regular globe valve, D, by means of a diaphragm motor which replaces the ordinary hand wheel.

The temperature of the condense water affecting the stem of the controller permits all, a part, or none of the compressed air to pass to the diaphragm-motor valve and consequently the latter is very nearly closed, partly open, or wide open, according to the conditions prevailing, allowing the proper flow of water to the condenser.

Let us assume that the vapor pipe has been delivering an amount of vapor to the condenser which requires such an amount of water as will flow through the inlet valve when the latter is exactly half open. Should now more vapor enter the condenser the temperature of the water passing through the tail pipe will, of course, start to rise, and as soon as the controller stem is affected by this higher temperature it will expand and cause the valve mechanism of the controller to allow less air to flow to the water-inlet valve. Consequently this water valve will act to allow more water to pass through and thus maintain the proper proportion between the volumes of vapor and cooling water.

The auxiliaries are J, a thermometer to indicate the temperature of the cooling water; F, a hand valve for emergency use; C, a thermometer to indicate the temperature of the water passing through the tail pipe and serving as a check on the recording thermometer, which has its bulb at A and its dial at O; and P, a recording vacuum gage, checked by a mercurial absolute-pressure gage, Q.

The initial supply line of compressed air M, which ultimately operates the diaphragm-motor valve on the water inlet, enters the trap N, where any moisture or sediment is separated and which also acts as a storage reservoir. Gage L shows the initial pressure of the compressed air supply, which is reduced by passing through the reducing valve K to the pressure required for the controller, as shown by gage H.

Fig. 79 shows the very simple construction of the controller by means of a section through A-B. The stem S is in two parts, the outer brass tube and the inner rod. The latter is composed of a material which has an extremely low ratio of expansion and therefore remains of almost constant length, regardless of temperature, while the outer brass tube elongates

FIG. 79.—CONSTRUCTION OF CONTROLLER.

or contracts in response to temperature changes. The tube and rod are so arranged that they are always in intimate though frictionless contact at the extreme end. R shows the extension of the inner non-expanding member, which recedes when the outer tube elongates and advances when the outer tube contracts.

The movement thus obtained at R is transmitted by the lever T to the valve mechanism shown in cross section. This is simply a three-port valve, shown more clearly in the section A-B, and all ports are controlled by the one ball W. The first port V is the inlet for the compressed-air supply; another port, the second, connects with the line leading to the diaphragm-motor valve; the third port is the outlet for the air which has served its purpose by actuating the diaphragm motor. The position of the ball W depends upon the stem X which is in contact with the lever T at Y. When extension R moves outward, due to the drop in temperature at S, the lever T is raised and the stem allows the ball W to leave port V where the compressed air enters.

The air can then flow through the second port to the diaphragm-motor valve, which starts to close. If a higher temperature acts upon S, expanding the outer tube and turning extension R inward, lever T forces stem X against ball W. The latter then closes port V, shuts off the air supply, and also opens the third port so that the air can escape from the diaphragm-motor. The diaphragm-motor valve consequently begins to open.

In actual practice, the diaphragm-motor valve is only completely closed or wide open if the conditions are such that the tendency is toward a sudden change in temperature. The controller is so sensitive that the diaphragm-motor valve is constantly throttling, that is, letting in just a little more or a little less water as may be required properly to effect the condensation.

If it is desired to change the setting of the controller, to maintain a higher or lower temperature, it is necessary simply to apply a key to the port Z and by turning it one way or the other require extension R to travel more or less before the controller operates.

Fig. 80 shows the diaphragm-motor valve in section. This valve has a regular globe body, with a seal and disc arranged in the usual manner, but with a sliding stem that is operated by the diaphragm-motor. The compressed air enters chamber

C at opening A. This chamber is composed of a cast-iron top B and a rubber bottom D, called the diaphragm. The air pressure forces the diaphragm downward and the saucer E thus forces the stem F downward while compressing the spring G. When the air pressure is relieved the spring opens the valve again.

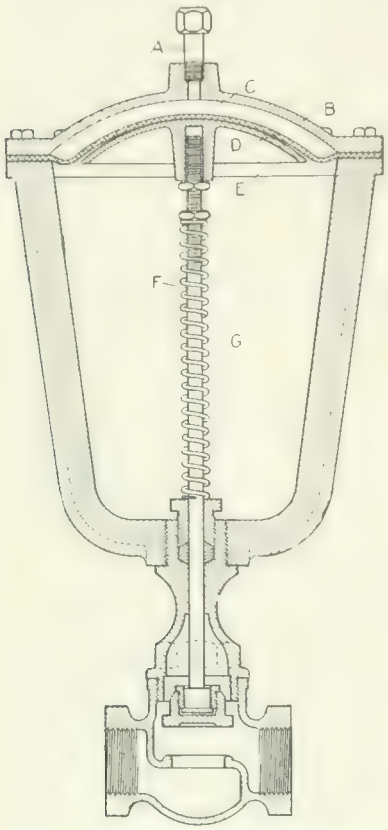

FIG. 80.—SECTION OF DIAPHRAGM MOTOR VALVE.

This installation has been the means of saving about $400 monthly for over a year in the charges for city water which was formerly wasted.

In Fig. 81 is shown an autographic chart obtained with a temperature controller and applied to a single surface condenser connected to the single vacuum dryer shown in Fig. 52 (this journal, vol. IX, p. 300, August, 1911). With this installation very good results have been obtained and the quantity of cooling water has been decreased from 35 to 50 per cent below that required with hand regulation.

Another construction of an automatic temperature controller for the regulation of the cooling water to a counter-current condenser and applied by the author may be seen in Fig. 82. Part 21 is a bulb which contains a volatile liquid and is inserted in the tail pipe through a screwed flange 23 similarly as shown in Fig. 78. The flexible metallic transmission tube 20 connects the bulb 21 with the syphon metallic bellows 16 which operates the cooling water-inlet valve 1. The bulb 21, the metallic tube 20 and bellows 16 are hermetically sealed and confine a liquid which vaporizes at low temperature.

When the water in the tail pipe becomes warm, the vapor generated in bulb 21 forces some of the liquid into the bellows, which expands this by overcoming the counterweight 23 and opens the valve 1. When the water reaches a certain lower temperature, the vapor in the bulb condenses and allows the liquid to flow from the bellows back into the stem so that the bellows now collapses and closes the water-inlet valve.

This regulator can be set for different temperatures by adjusting the counterweight on the lever arm at 27. The variations of temperature of the condens water can be seen on charts Figs. 64 and 70 in my article in the May issue, 1912, p. 268

To determine the quantity of cooling water the following formula can be used:

$$W = \frac{H - h}{t_1 - t_2}, \text{ where}$$

W = weight of cooling water in pounds necessary to condense one lb. of steam,

H = total heat of steam at condenser pressure and vacuum (which may be taken from a steam table),

h = heat of liquid of the condensed steam (B.t.u.),

t_1 = temperature of condens water (cooling water and condensed steam),

t_2 = temperature of cooling water.

According to the charts Fig. 73 and 75, in my article in the 1 June issue, we may take in average

t_1 = 115° F.,

t_2 = 55° F.,

H = 1120 (according to steam table),

h = 115 − 32 = 83 B.t.u.,

then it follows

$$W = \frac{1120 - 83}{115 - 55} = \frac{1037}{60} = 17.3$$

or 17.3 lbs. of water was necessary to condense one lb. of steam.

During the 24 hours chart. Fig. 73 = 20.400 c.ft.

During the 24 hours chart. Fig. 75 = 19.450 c.ft.

water was measured by a Thomson water meter and the results have shown that the quantity of the condensed water and vapors of the six connected vacuum pans were nearly correct.

By comparison with chart Fig. 72 in my article in the June issue, where the evaporation in the vacuum pans was considerably smaller, the resulting saving of the cooling water can be easily seen.

In sugar refineries, combined surface and spray condensers are usually employed which are similar to that shown in Fig. 83. The vapor from the vacuum pans first passes through the surface condenser, so that in case the vapor carries along some sugar particles, they will be condensed at that point and can be used to dissolve the raw sugar. In this way nothing is lost. The remainder of the vapor passes to the spray condenser, is condensed, and flows down the tail pipe.

Condensers of this type require a considerable quantity of water and there may be a great waste of water if no controlling device is employed.

Even where salt water is used this waste should not be permitted, because it increases materially the quantity of steam necessary for the operation of the pumps. In many cases where salt water is now used on account of the great quantity required, the use of a well-constructed counter-current condenser operated economically with a precise temperature con-

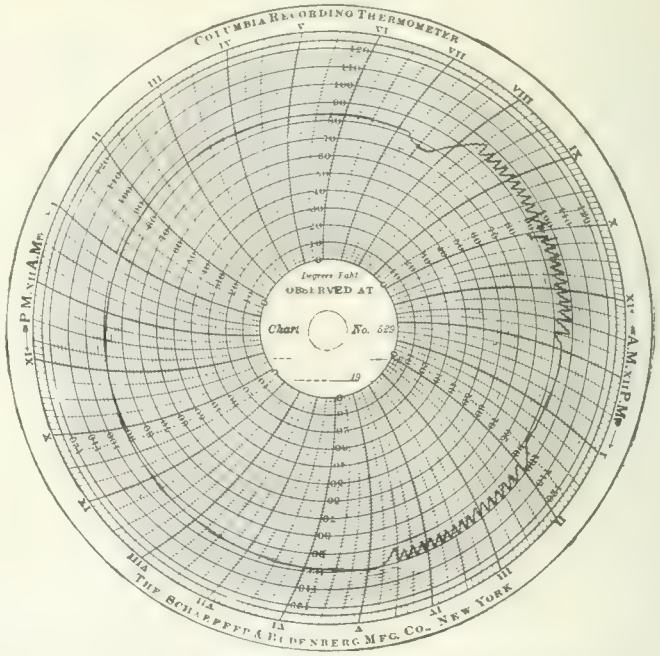

FIG. 81.—TEMPERATURE CHART OF SURFACE CONDENSER WITH AUTOMATIC REGULATOR.

troller may render possible the use of sweet water. This is a decided advantage in all cases in which the condens water can be used for boiler-feed purposes.

I would not recommend its use in the same condition in

which it comes from the tail pipe, in spite of the assertion that condens water does not contain any impurities carried over from the source of the vapor. That the opposite is true

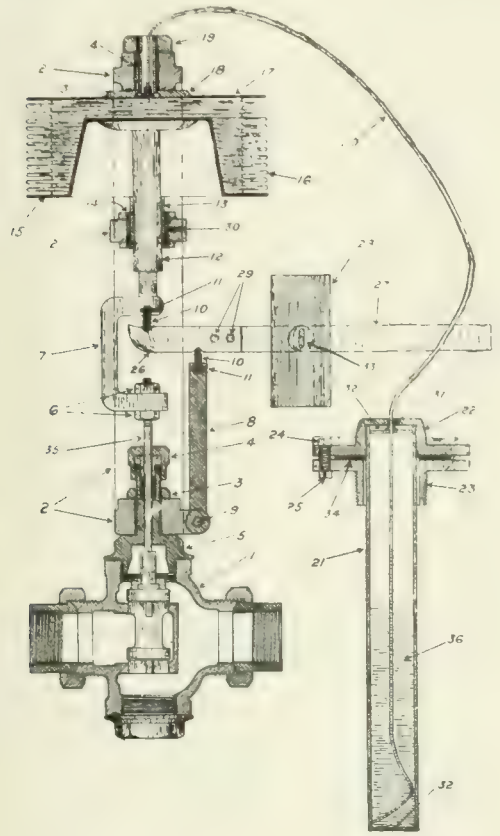

FIG. 82.—SYPHON AUTOMATIC CONDENSER REGULATOR.

can be established in many cases. In steam-engine plants, for instance, it is well known that condensed steam contains oil, etc., and it is never pumped direct to the boilers. Frequent analyses have shown that condens water from vacuum plants does not contain sugar or acid from the evaporation of acid liquor, but the so-called untraceable losses in vacuum plants

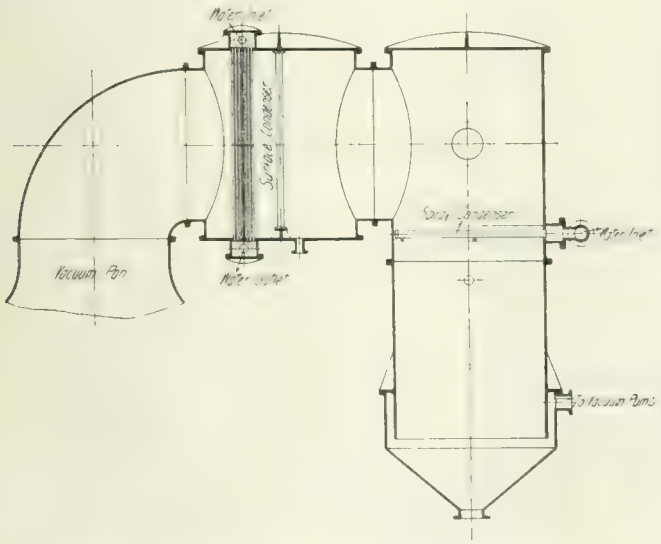

FIG. 83.—COMBINED SURFACE AND SPRAY CONDENSER.

must necessarily be looked for in the condens water. The quantity of water used is so great that the presence of these impurities is not always noticeable, but practical experience has proved them to be present.

This can even be understood by reference to the following simple mathematical formula: $a : \infty = a$, where a means a small quantity of material which is evaporated in the vacuum pan, and which is carried over in every case by the vapor into the condenser. Here it comes naturally in contact with very great quantities of water, so great, in proportion, that it is not possible to prove its presence in the condens water. Or in other words, it is divided in so many countless parts, that it is infinitely small. However, as the same formula shows $0 \times \infty = a$, or in other words, it is present in the condens water in spite of the contrary assertions.

This is very plainly proven by practical experience.

However, when this condens water at a high temperature (110° to 120° F.) is passed through an efficient water-purifying plant, there is no doubt that it may safely be used for boiler feed. The author has accomplished this and in some later articles will refer to this subject more extensively.

Surface Combustion

In an article in our issue of December, 1911 (Vol. IX, p. 628) the application of flameless or surface combustion to industrial purposes was described, in connection with several lectures then delivered in this country by Prof. William A. Bone, of England.

The widespread attention which these lectures attracted to the subject of surface combustion, have had the effect of bringing into the foreground some almost forgotten important work done by Dr. CHAS. E. LUCKE, now professor of Columbia University, along similar, if not identical lines, as early as 1900. Dr. Lucke's experiments were described in his paper on The Heat Engine Problem, presented before the Society of Mechanical Engineers in 1901, and two fundamental patents were granted to Dr. Lucke for his process (U. S. patents 755,376 and 755,377, both of March 22, 1904).

These two patents of Dr. Lucke have been bought by Dr. Hugo Lieber, of New York City, who has organized the Gas and Oil Combustion Company, with office and laboratories at 50 East Forty-first Street, New York City, where extensive experiments are being conducted to commercialize Dr. Lucke's inventions under the inventor's supervision. Various tests on larger scale concerning the practical application of these inventions are also being conducted now in several factories under supervision of the Gas and Oil Combustion Co.

In the meantime Prof. WILLIAM A. BONE has delivered another lecture on the subject, this time before the Cavendish Society of Leeds University. The lecture is printed in full in (London) *Engineering*, May 10, 1912.

The feature of the method of surface combustion is that an explosive mixture of gas and air is burnt without flame in contact with a granular incandescent solid. We mention here only the more recent developments of the system.

With a small muffle furnace heating a muffle measuring 9½ in. x 5¼ in., the results recorded in table I were obtained. The most noteworthy point, Professor Bone said, was the relatively low temperature of the escaping products of combustion. This was in every case considerably lower than that of the muffle.

TABLE I. RESULTS OF TEST ON A MUFFLE FURNACE.

Dimensions of Muffle 9½ x 5¼ x 3¼.

Temperature in Middle of Muffle		Gas Consumption to Maintain Temperature Constant.	Temperature of Products of Combustion.	
Deg. C.	Deg. F.	Cub. ft.-hr. at 15 deg. C.	Deg. C.	Deg. F.
815	1449	21.0	540	1004
1004	1840	35.3	645	1195
1205	2201	58.0	870	1598
1424	2596	70.0	1085	1085

Mean net cal. value of gas = 540 B. Th. U. per cubic foot at 15 deg. C.

Thus with a temperature of 1424 deg. C. at the middle of the muffle, the temperature of the products of combustion was some 300 deg. C. less. There was no appearance of flame at the vent even with the highest temperatures. In some comparative experiments with a good specimen of the ordinary type of muffle furnace, the maintenance of a temperature of 1057 deg. C. required the consumption of 105 cu. ft. per hour

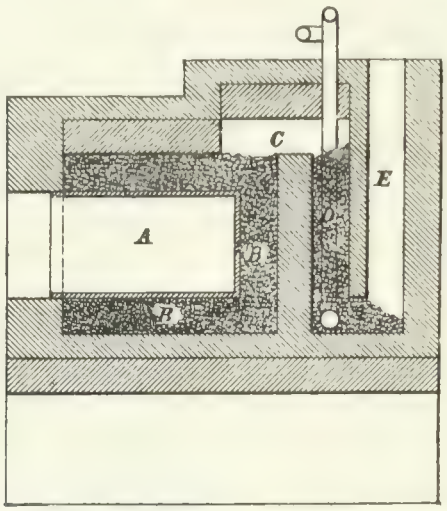

FIG. 1.—MUFFLE FURNACE WITH REGENERATORS

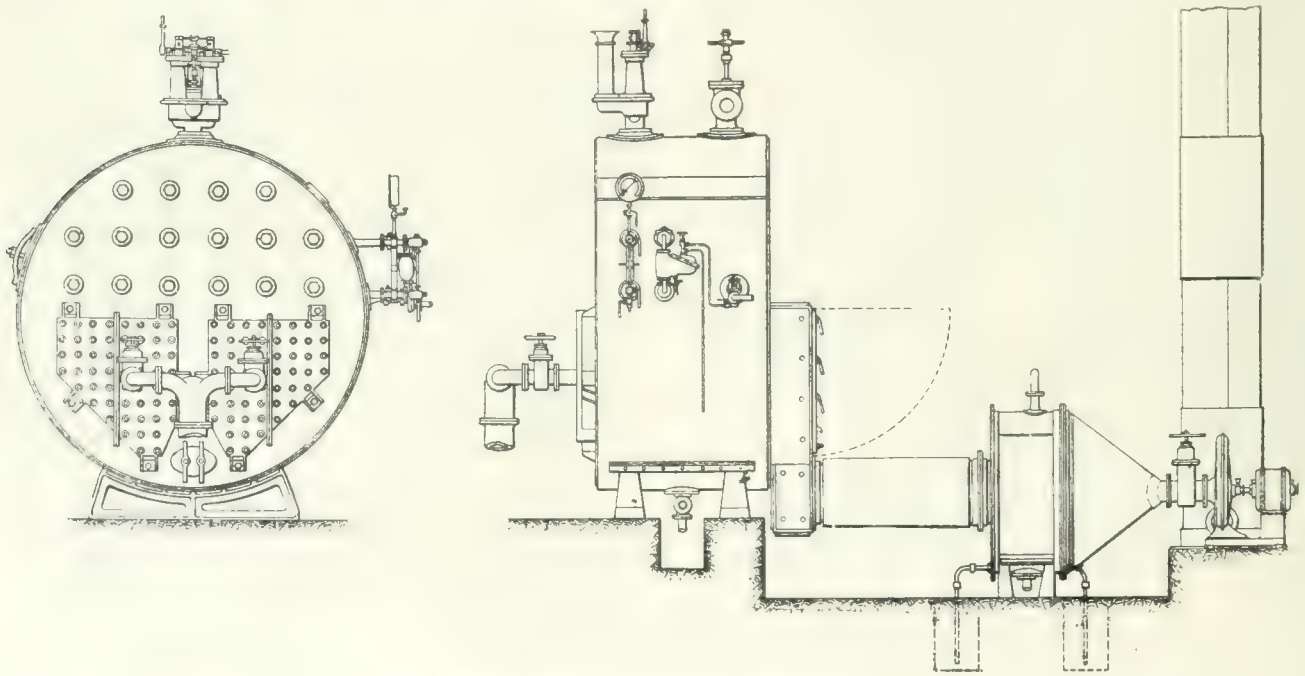
of the same gas. With surface combustion a consumption of 43 cu. ft. per hour would have sufficed. In a series of competitive trials made in the United States with American gas-fired furnaces, the flameless combustion system required only half the gas to maintain a given temperature.

An important application of the principle to a large muffle furnace was, Prof. Bone said, illustrated in Fig. 1. The muffle in question measured 8 ft. x 3 ft. x 3 ft. internal dimensions. The gas and air were fed in at the front to a bed of granular material. On escaping from the top of the furnace the products of combustion were led down through a second bed of refractory fragments, embedded in which was the pipe furnishing the supply of air, which was thus preheated to a temperature of 300 deg. to 500 deg. C. This resulted in a saving of 20 to 25 per cent. of the already low gas consumption. Thus if a surface-combustion furnace without this regenerator required 50 cu. ft. of gas per hour, with the regenerator in use 37 cu. ft. to 40 cu. ft. of gas would suffice. Further, this regenerator made it possible to reach temperatures with "poor" gas which were otherwise only attainable with gas of high calorific value.

An important adaptation of the system, he continued, was to boiler firing. Gas-fired boilers had hitherto been far more satisfactory. The efficiency of a good water-tube boiler thus fired did not, he was informed, exceed 55 per cent or so, and in some experiments made with Lancashire boilers, similarly operated, the thermal efficiency did not exceed 60 per cent, although economizers were fitted. A small experimental boiler, arranged to work with surface combustion (as illustrated in Fig. 4 of our December issue, 1911, vol. IX, p. 629) was a cylindrical boiler, 3 ft. in diameter by 3 ft. long, traversed by ten horizontal tubes, 3 in. in diameter. These tubes were fitted at the inlet ends with a plug of fireclay, this plug having a 3-in. hole through the center, through which the explosive mixture was forced at a speed which prohibited the possibility of back-firing. The remainder of the tubes was packed with refractory material, on which the surface combustion was effected. The air supply was very little in excess of the theoretical requirements, but the combustion was absolutely completed within a distance of about 6 in. from the point of entry. The remainder of the packing then served to baffle the flow.

Though the temperature of the material in the zone of combustion was very high, the boiler tubes there never attained a red heat. The supply of gas to the tubes was at the rate of 100 cu. ft. of coal-gas per hour, or an equivalent amount of a power gas. A ten-tube boiler therefore took 1000 cu. ft. of gas per hour and 5000 to 6000 cu. ft. of air. The temperature of the escaping gases was never more than some 70 deg. C. above the temperature of the water in the boiler, and this was further reduced by passing them through a feed-heater consisting of water-tubes immersed in a bed of refractory material. From this the products of combustion escaped at a temperature of less than 100 deg. C.

On a test of this boiler the air and gas pressure was, he stated, 17.3 in. water-gauge, the drop of pressure being about 15 in. in the boiler and 2 in. in the feed-heater. The steam pressure was 100 lb. per square inch, corresponding to a temperature of 168 deg. C. The products of combustion left the boiler at a temperature of 230 deg. C., and the feed-heater at a



FIGS. 2 AND 3.—BOILER FOR SURFACE COMBUSTION

temperature of 95 deg. C. The total gas supply was 900 cu. ft. per hour, the calorific value being 562 B.t.u. per cu. ft., so that the 559,800 b.t.u. were supplied per hour. The actual evaporation was 450.3 lb. per hour, equivalent to 50 lb. evaporated from and at 212 deg. F. The heat transferred to the water was thus 527,800 b.t.u., so that the efficiency was 0.943. The carbon-dioxide in the escaping gases was 10.6, as against a theoretical value of 11, and the free oxygen was only 1.6 per cent. The rate of evaporation was 21.6 lb. per square foot, or double that of a locomotive.

Since last November a 110-tube boiler had, the lecturer said, been at work with coke-oven gas at the Skinningrove Iron Works, Cleveland. The boiler was built to the designs of Mr. Michael Longridge, by Messrs. Richardson, Westgarth and Company, Limited. This boiler is illustrated in Figs. 2 and 3. The drum is 10 ft. in diameter and 4 ft. long from back to front. It is traversed by 110 tubes 3 in. in diameter, packed, as already explained, with fragments of firebrick. The draught required is supplied by a suction fan, behind the feed-heater, giving a 20-in. water gauge. On test the mean evaporation was 20 lb. per square foot, but of this 70 per cent was effected in the first part of the length of the tubes, and 22 per cent over the next third. This steep temperature gradient along the tubes prevented circulation. Experience, Professor Bone stated, had further shown that scale would not adhere to the tubes. Once

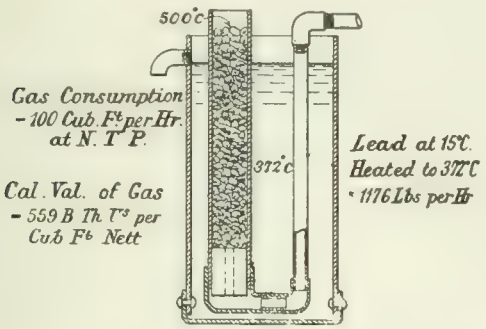


FIG. 4.—SURFACE-COMBUSTION APPARATUS FOR MELTING LEAD.

the thickness became about 1-32 in., it scaled off, falling down to the bottom.

Another application of the system was to the melting of readily fusible metals. One of the London newspapers required to keep 20 tons of type metal molten for 16 hours out of the 24. Coal-firing was inconvenient for this purpose, and gas-firing had hitherto been costly. The apparatus they proposed to use is illustrated in Fig. 3. It consists of an iron tank lagged outside with asbestos, while inside is a 3-in. tube stopped at the bottom with a fireclay plug on which rests the column of refractory material. A ¾-in. hole in the plug admits the supply of gas and air, which is fed in through the down tube on the right. In a test of the apparatus lead was melted at the rate of 1176 lb. per hour, the gas consumption being 100 cu. ft. "The efficiency worked out at 0.686 per cent. The gas left at only 130 deg. above the temperature of the lead, and if it were assumed that the temperature of the latter was a limit to that of the escaping gases, the efficiency was really greater than was represented by 0.686 per cent, being actually about 80 per cent of what was theoretically possible."

The **General Bakelite Company** has brought suits for infringements of its bakelite patents against the Condensite Company, of America and several users of "Condensite"; among them the Dickinson Manufacturing Company, of Springfield, Mass., the Duranoid Manufacturing Company, of Newark, N. J. and Hardman & Wright, of Belleville, N. J. In relation to this, it is of interest to note that the fundamental bakelite patents have been allowed in Germany and have been sustained by the German Patent Office, notwithstanding the fact of several public contestations.

A New Method of Dressing Cornish Tin Ores.

By Marcus Ruthenburg.

The complex tin ores of Cornwall have for many years been dressed for tin, the methods employed giving rise to the so-called Cornish system of tin dressing. Although the methods

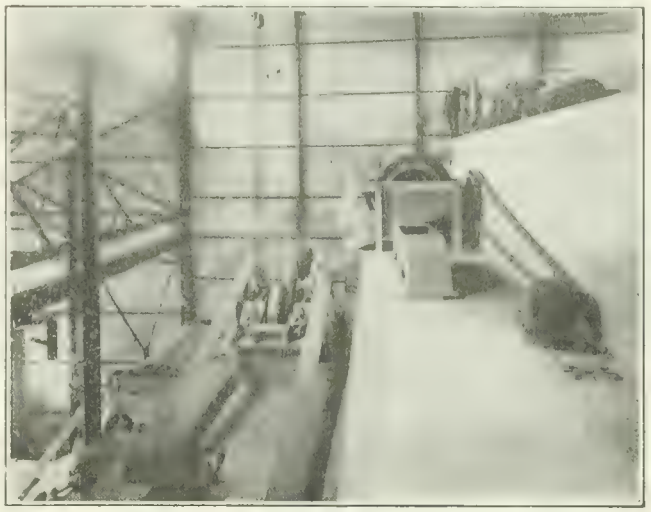

FIG. 1.—VIEW FROM UPPER END OF MILL, SHOWING CRUSHER, FIRST SCREEN, COARSE ROLLS AND SECOND SCREEN.

are crude they are adhered to tenaciously, and the average Cornishman is so wedded to these primitive processes as to be fully convinced that there is nothing in the world equal to them. They are like his Cornish pump, about which he is ready for an argument on the least provocation.

Cornish Practice.

The accompanying photographs show the construction of a mill which is a radical departure from the Cornish methods of dressing tin ores. Before proceeding to a description of it, however, it may be of advantage to outline briefly the Cornish method, so that a comparison between the old and the new can be better understood. In the old process, the ore is crushed in a stamp battery. The more up-to-date of these machines are

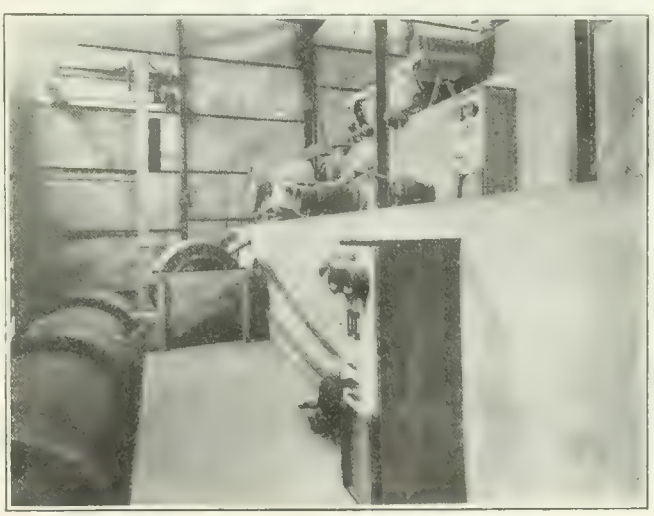

FIG. 2.—VIEW BELOW FIG. 1 SHOWING SECOND SCREEN, FINE ROLLS AND REVOLVING ROASTER.

of the California type or the pneumatic type. The crushed pulp is run to concentrating tables of different types, the Wilfley being largely used. The rough concentrates from these tables, containing all of the complex mineral in the ore—tin, copper, wolfram and mundic—are known locally as whitts. The

whitts are roasted to eliminate arsenic and sulphur, the former being condensed in suitable chambers. Incident to the roasting operation, the iron particles become changed to oxide, and each grain swells and puffs out like a miniature cauliflower head,

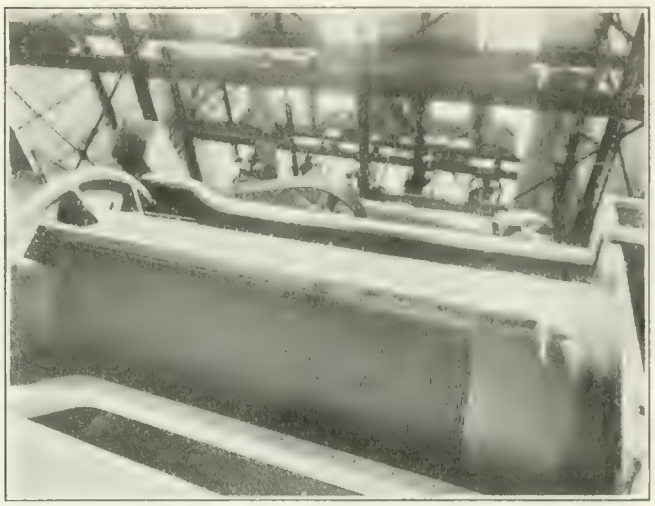

FIG. 3.—A CLOSE VIEW OF FIRST SCREEN—A REVOLVING GRIZZLY.

with consequent reduction in specific gravity. In the second concentration to which the roasted product is subjected, the iron is more easily separated from the cassiterite. Any copper in the whitts has been rendered soluble in the roasting operation, and is washed out. Frequently this wash water is run over scrap iron, and a part of the copper recovered as cement. In the fine crushing required to liberate the crystals of the various minerals, much of the tin is slimed, and good Cornish practice does not recover over 65 per cent of this metal.

Latest Improved Practice.

The above condition of affairs has led to a large amount of research, and the plant shown in the accompanying illustrations is the result of extensive investigation in the dressing of these ores. In this plant the ore is crushed to about 1-in. size in an ordinary rock breaker (see Fig. 1), which is followed by a 30-mesh screen. About 15 per cent of the crushed ore is

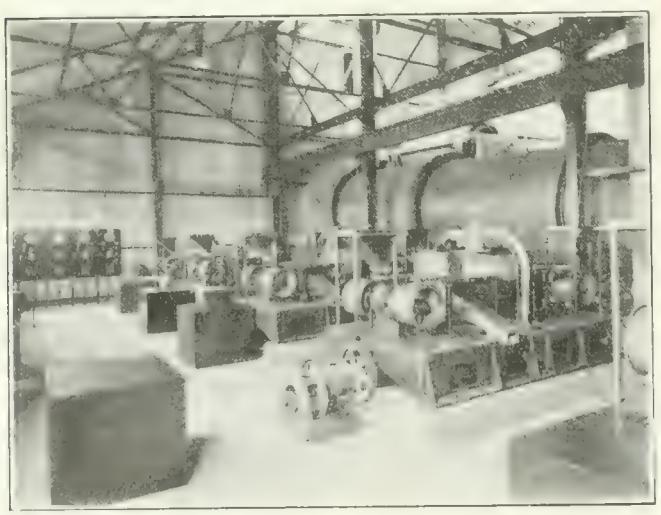

FIG. 4.—VIEW OF ROASTER AND MAGNETIC SEPARATORS.

fine enough to pass this screen, and is immediately removed from the crushing system, thereby avoiding excessive sliming and the rehandling of this quantity of ore. The oversize from the screen is fed to a pair of high-speed heavy steel rolls, 44 in. in diameter with a 6-in. face, set ¼-in. apart, and running at 200 r.p.m. This machine handles 10 tons per hour. Its product passes to a second 30-mesh screen where about 45 per cent of the feed is removed as undersize. The oversize is reground in a second set of rolls of the same type as described. These rolls are set close, and reduce the entire feed to 30 mesh. This part of the plant is shown in Fig. 2.

The various screen products are combined and fed to a gas-fired roaster, where the iron contents of the ore are rendered magnetic in a "flash" roast. The cooled, roasted ore is then treated in magnetic separators, or more properly speaking, magnetic concentrators, inasmuch as it is the raw ore that is fed to them, and not an intermediate product from some previous operation of dressing. Everything that has the least trace of iron or wolfram in it is removed in these machines. The arrangement of the roaster and magnetic machines is shown in Figs. 4 and 5.

The tailing from the magnetic concentration is quartz and free cassiterite, the latter representing about half the tin in the original ore. This product is dressed on buddles which produce a clean tin concentrate.

The concentrate from the magnetic machines contains everything of value except about half the tin, as noted, and consists of iron, tin, copper and wolfram. This product is further treated in magnetic separators, using different magnet strengths, whereby the most strongly magnetic material is removed first and the most weakly magnetic material last. This removes

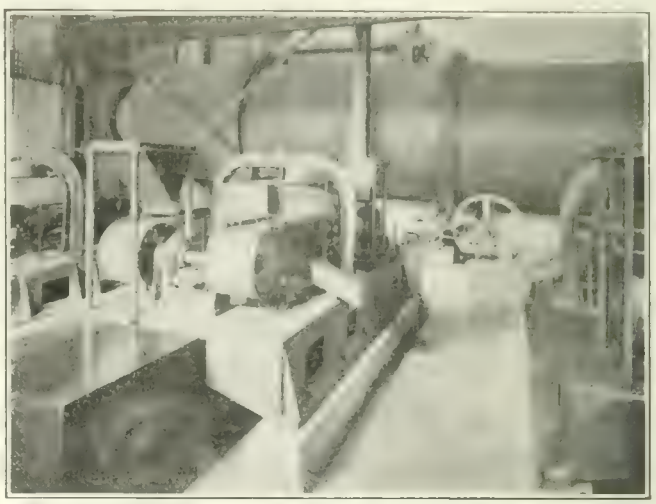

FIG. 5.—CLOSER VIEW OF MAGNETIC SEPARATORS.

the iron and wolfram as separate products, and leaves a mixture of tin and copper. This is roasted to remove arsenic, and then smelted to produce an alloy of tin and copper, which properly may be called a virgin bronze.

In this treatment of the mixed tin and copper, all of the cost of separation and the attendant loss of each metal are avoided. A large proportion of the tin and copper of the world's markets are combined into alloys of these metals by the founders. It seems, therefore, to be the height of folly to throw away a large proportion of the economic metals occurring in these ores merely for the purpose of effecting their separation, especially when they are again recombined by the founder in making his alloys. It has been the object of this work, therefore, to make large savings of the metals by never separating them, and carrying the smelting out in such a manner as to produce a finished alloy acceptable to commerce. By this method of working, the recovery rises from 65 per cent to 95 per cent

Details of Individual Machines.

It may be well to describe the individual units of the plant in the order of their use. The screens must handle a large tonnage of coarse, heavy material, and yet remove only the part which is fine enough to pass a 30-mesh screen. To meet these conditions they were designed in the form of what may be called a ring grizzly, as shown in Fig. 3. The component parts are hard steel rings of V cross section, with the apex

of the V on the outside. The rings are assembled in a frame with distance pieces between them, and thus form a revolving grizzly giving a 30-mesh undersize. These screens handle a large tonnage of coarse material, removing the fine, with practically no wear.

The rolls also are worthy of attention. They are of the high-speed, narrow-tread type, with heavy steel shafts running in self-oiling, reversible bearings. The main feature of the rolls, however, is the device for keeping the faces true. Such rolls, if not kept absolutely true, are a source of great annoyance and do very poor work. At each end of the machine is a table, planed true with each roll shaft. On this table is a motor-driven emery wheel, which, vibrating with the roll (if at all), keeps it ground true. The bearings are self-oiling, with large oil cellars and dust covers. All of the machines have individual motor drive, two motors usually being run in opposite directions on each roll to avoid crossed belts.

The crushing and grinding plant here described handles 10 tons per hour, with a power consumption of 60 kw. A plant working on the same rock, and using forty California stamps of 1050 lb. each, grinding 5 tons per hour, consumed 86 kw. This gives a fair comparison between the two methods of crushing.

Details of the Ruthenburg magnetic separators are shown in Fig. 6. The double mushroom magnet *A* is mounted on a vertical spindle *B* which runs in suitable bearings. The central core is shown surrounded by the exciting coil *C*. The magnetic field is concentrated at the peripheral gap between the upper pole-piece A^2 and the lower pole-piece A^3. A channel *D* of non-magnetic material is secured by flanges to the inside of the pole-pieces, and annular brackets *E* of the same substance are bolted to the outside. Pulleys *G* carry belts *H* which convey the crushed material between the pole-pieces where the magnetic particles are attracted and held to the upper pole-piece from which they are later removed by the rope *M* which runs in the non-magnetic channel *D*. The magnetic particles thus removed from the mass of ore are discharged into a receptacle *N*, while the balance of the non-magnetic material is carried on the belts *H* to receptacles *K*.

This plant was built by the Brush Electrical Engineering Company, London, and is an example of their work in metallurgical engineering. Their works at Loughborough and their agents in different parts of the world are prepared to undertake complete metallurgical investigations and the supply of proper equipment.

London, England

The **Nelson Valve Company** of Chestnut Hill, Philadelphia, Pa., have recently published their illustrated catalogue on Nelson steel valves and fittings. Their prominent feature is that they are all made of acid open-hearth steel.

Electric Furnace Pig Iron at Trollhättan

The Trollhättan furnace of the Jernkontoret of Sweden has now been operating over eighteen months. At the end of six months' work, Mr. Leffler gave to the Jernkontoret his monumental report on the working of the furnace—a report which has been widely reproduced in technical literature. (See this journal, vol. IX, 1911, pages 368, 459, 505.)

After nearly a year of further experience, J. A. LEFFLER and Engineer E. NYSTRÖM contributed to the meeting of the Jernkontoret in Stockholm, on May 31, 1912, a supplementary report of ninety-eight pages which is quite as complete and even more interesting than the original report, for it gives the full details of rapid progress in industrial efficiency. It covers the working of the furnace from August 4, 1911, to March 6, 1912.

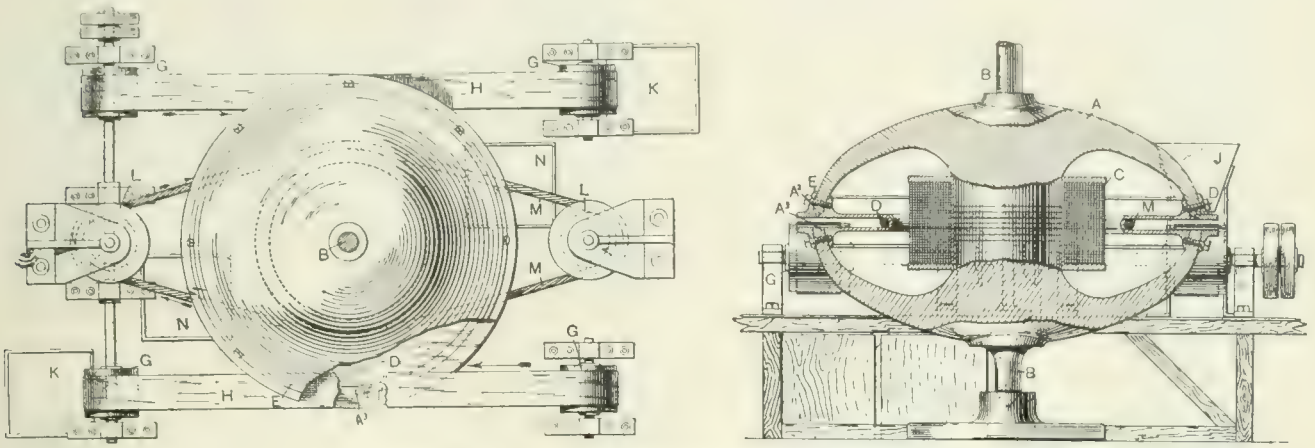

FIG. 6.—DETAILS OF RUTHENBURG MAGNETIC SEPARATOR

During the summer of 1911 the furnace was closed down for alterations and repairs costing $15,000. The four square electrodes were exchanged for six round ones, and a new gas-circulation system was installed for the better drying of the gas returned to the furnace. Figure 1 shows the gas-circulating system now used, consisting of a dust-catcher, cooler and powerful blower. The cooler acts on the condenser system, and requires 100 litres of water per minute to reduce the temperature of the gas so that its moisture content is reduced from 4 grams per cubic meter to 0.5 gram. All the electric pig-iron furnaces now being built and operated in Sweden and Norway are provided with this condenser, in order to avoid returning moisture to the smelting zone of the furnace.

Fuel.—Samples were taken every day of the 215 days run, of the fuel—charcoal from Norrland, Smoland, West Gothland and Vansbro, and 206 analyses are given, for water, gases, carbon and ash, the analyses being also calculated to dry fuel. The average analysis was:

Water	13.21	per cent
Volatile matter	11.72	"
Carbon	72.89	"
Ash	2.18	"
	100.00	"

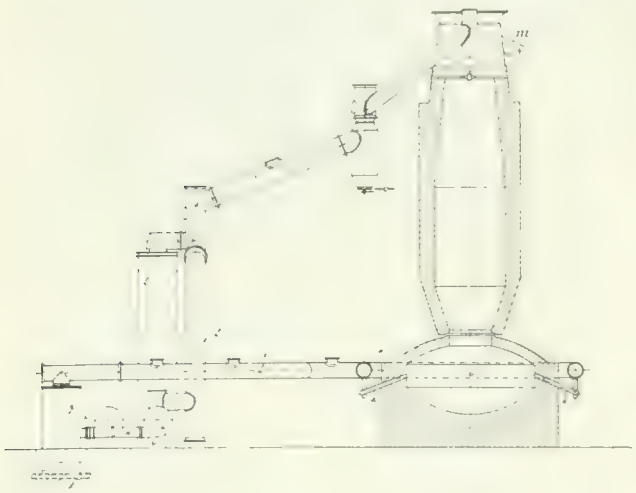
Limestone.—The flux used was from Gasgrufvan, was charged unburnt, and contained:

Lime	54.32	per cent
Magnesia	0.31	"
Silica	1.68	"
Ferric oxide	0.24	"
Manganese oxide	0.35	"
Sulphur	0.001	"
Loss on ignition	42.04	"
	99.841	"

Ores.—Various hematites and magnetites were used, also slimed ore, briquettes and roasted ores. Analyses of thirty-eight different shipments are given, showing the following limits of composition:

Iron	42.02	to	68.95	per cent
Silica	3.42	"	28.46	"
Sulphur	0.001	"	0.138	"
Phosphorus	0.002	"	0.055	"

Electrodes.—The round forms were used, screwed into each other so as to avoid butt-ends. The dimensions were at first 550 mm diameter by 1500 mm long (22 x 60 in.), and later 600 mm diameter by 1800 long (24 x 72 in.). Figures 2 and 3 show two which run well; fig. 4 two which were irregularly consumed by currents of gas in the furnace. For the 215 days running, the average net consumption was 5.18 kg per ton of pig iron produced = 0.518 per cent of the weight of the iron. Mr. Leffler thinks it probable that pig iron can be made with less than 4 kg consumption. The smaller electrodes were from the Planiawerke at Ratibor, the larger from Siemens Bros. &



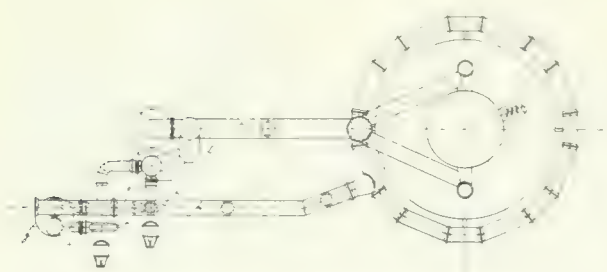


FIG. 1.—ELECTRIC GAS GENERATION APPARATUS.

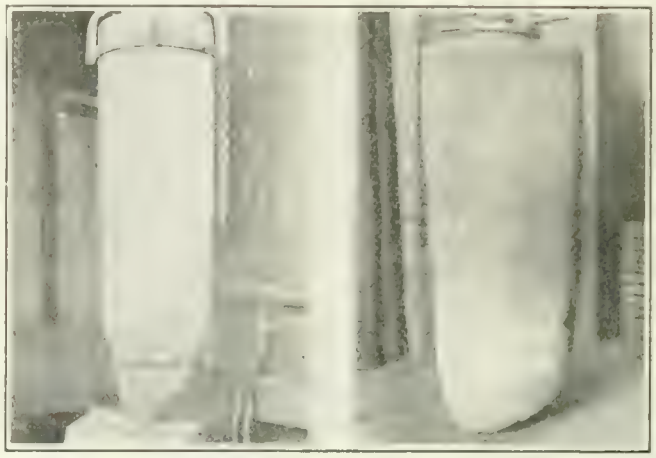
Co., Lichtenberg, near Berlin. The average composition was:

	Electrode per cent.	Electrode Connector per cent.
Ash	4.15	3.72
Phosphorus	0.022	0.011
Sulphur	0.85	0.80
The ash contained:		
SO$_3$	1.37	1.17
P_2O_5	1.23	0.64
SiO$_2$	44.70	38.88
$K_2O + Na_2O$	1.62	1.66
CaO	6.04	5.52
MgO	1.62	2.05
FeO	14.79	30.14
Mn_2O_4	0.52	0.44
Al_2O_3	27.73	18.12
	99.92	98.62

Starting Furnace.—Half a ton of scrap iron and half a ton of limestone was put on the hearth; on this was placed one ton of dry coke; over this a mixture of 3 tons of castings, 1.2 tons of coke and 0.18 tons of limestone. This filled the crucible up to the electrodes. Four-tenths ton of broken electrodes were then scattered on top, to give electrical connection between the electrodes. On top of this were placed regular charges of ore, fuel and limestone.

Running.—The furnace was run 28 days on Tuolluvaara ore, mixed with a little from Striberg (Arvesjöhitan) and Stall



FIGS. 2 AND 3.—ELECTRODES NOT CONSUMED.

berg (Kejsarschaktet); 35 days on a mixture of Tuolluvaara and Klacka-herberg fines; 14 days on a mixture of Norberg (Orling) ore and Mossgrafvet briquettes; 6 days on a mixture of Nyberg ore and Strassa briquettes; 5 days on Tuolluvaara, Persberg and Finnmosse ore and fines; 22 days on roasted

FIG. 4.—ELECTRODES IRREGULARLY CONSUMED.

Tuolluvaara, Persberg and Finnmosse ores and unroasted Persberg fines; 10 days on the same, except the Persberg fines were also roasted; 13 days on a mixture of N. Stallberg (Kronprinzgrufvan), Norberg (Orling and Kolingberg), Grangärde (Björnberg, Länggrufvan), and Vestra Ormberg (Pickgrufvan) ores, with Flogberg briquettes; 17 days on N. Stallberg, Norberg and Bispberg ores with Flogberg briquettes; and 10 days on Dannemora ores alone, mostly middle bed (85

parts) with some south bed (10 parts) and less north bed (5 parts).

Charges.—In the 215 days there was put into the furnace in regular running:

Iron Ore	5274 tons (metric, of 2204 lb.)
Limestone	381 "
Coal	1301 "

Output:

Pig iron	3215 "
Slag	1030 "

Details of Running.—The following are average figures summarizing the contents of two large tables giving the detailed running for the whole period:

Iron in ore	66.95	per cent
" burden	56.84	per cent
Weight of slag per ton of iron	323	kilos
" fuel " "	404	kilos
Volts on furnace	73.6	volts
Amperes on furnace	11,423	amp
Power on furnace	1482	kw
Power per ton of iron	2225	kw-hours
Output of iron per kw-year	3.94	tons
Per cent CO^2 in throat gas	23.49	per cent
Volume circulating gas, per sec.	0.24	cu. meter
Pressure of gas in furnace	225	mm H^2O
Temperature at bottom of shaft	441°	C.
" " middle "	270°	C.
" " top "	17°	C.

Electrode consumption, per ton of iron:

Gross	5.72 kg
Net	5.18 kg

We cannot refrain, however, from considering the several stages of the run, as far as concerns the richness of the charge, amount of slag, output and power consumption. These figures are very instructive, because they show so clearly the dependence of cheap running on richness of the ore:

Per cent Fe in ore	67.66	66.71	57.15	54.83
Slag (kg) per ton iron	160	200	400	521
Coal (kg) per ton iron	347	380	439	490
Kw-hours per ton iron	1819	2253	2369	2525

The composition of the pig iron produced varied between the following limits:

Carbon	2.688	to 3.850	Average	3.406
Silicon	0.183	to 2.473	"	0.725
Manganese	0.190	to 1.366	"	0.477
Sulphur	0.0037	to 0.0341	"	0.0120
Phosphorus	0.0134	to 0.0454	"	0.0200

The composition of the gases produced varied as follows:

CO^2	14.63	to 31.80	Average	23.40
CO	31.80	to 71.10	"	63.15
H^2	7.87	to 14.50	"	10.35
CH^4	0.82	to 2.37	"	1.52
N^2 (difference)	0.50	to 3.41	"	1.40

The ratio CO/CO^2 by volume was 4.8 at the worst and 1.8 at the best. The calorific power of the gas per cubic meter varied from 2035 to 2569, average 2297 Calories

Slags.—The slags produced varied from 2.09 to 1.23 silicates (silica ratio). Analysis showed:

SiO^2	36.54	to	45.15	per cent
Al^2O^3	1.96	to	9.20	"
TiO^2	trace	to	7.42	"
FeO	0.58	to	6.22	"
MnO	0.19	to	6.06	"
CaO	21.08	to	45.58	"
MgO	6.22	to	26.65	"
CaS	0.04	to	0.44	"
P^2O^5	trace	to	0.034	"

Temperatures.—The temperatures of iron and slag issuing from the furnace varied as follows:

Iron	1230° to 1420° C.
Slag	1290° to 1460° C.

A large table gives the temperatures taken at 8 points in the shaft, just inside the wall and in the middle; also the percentages of CO^2 in the gases at these different points.

There are various not very important irregularities in the figures, but the general average shows temperatures up to 985 deg. in the middle at the lower part of the shaft and 585 deg. half way up; while near the wall it is 420 deg. to 565 deg. at the lowest hole and down to 15 deg. at the highest.

The measured percentage of CO^2 shows that reduction takes place ordinarily only one-quarter way up the shaft at the sides and a little over one-half way up in the center.

The extent of the zone of reduction by CO is clearly shown in Fig. 5, in which also some temperatures are indicated.

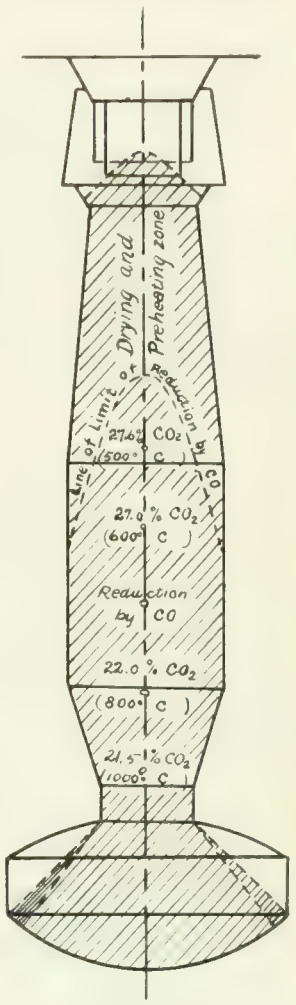


FIG. 5.—TEMPERATURE AND REACTION IN FURNACE SHAFT

Cooling Water.—The contacts and jackets through which the electrodes worked were water cooled. The heat carried away thus varied from 172 to 288 kw, or 10.47 to 19.30 (average 14.50) per cent of the power used.

Thermal Balance.—The heat balance per 1000 kg of pig iron is worked out for the four weeks Sept. 3 to Oct. 1, 1911, in which the average power used (high tension side) was 1407 kw, and the power consumption 1749 kw hours per ton of pig iron; the ores worked were the rich Tuolluvaara ores. The heat balance is, per kg of iron:

Combustion C to CO^2	567	Calories
Combustion C to CO	381	"
Electric energy	1504	"
	2452	Calories
Consumed in reductions	1620	Calories
Decomposition of limestone	35	"
Evaporation of water	24	"
Sensible heat in throat gases	26	"
Sensible heat in slag	75	"
Sensible heat in pig iron	300	"
Cooling water	195	"
Lost in transformers	43	"
Lost in conductors	44	"
Radiation and conduction	90	"
	2452	Calories

The authors then make some interesting calculations, the results of which are, in brief, as follows: The gas kept in circulation was 2.28 times the gas normally produced and escaping. Assuming this gas to enter the furnace at 22° and to enter the shaft at 1000°, it carried into the shaft as sensible heat 343,118 calories per ton of iron, or 22.9 per cent of all the heat electrically generated in the crucible. Since it carried with it 22.5 kg. of water vapor and 174 kg. of CO^2, both of which are decomposed by the glowing carbon, the net heat absorbed in these decompositions is 160,283 calories, or 10.7 per cent of the electric energy used. The gas circulation therefore transferred physically and chemically 33.6 per cent = 1/3 of the electrical

energy used from the crucible into the shaft of the furnace.

[We cannot refrain from asking what would result from simply generating in the shaft 1/3 of the total electrical energy and 2/3 in the crucible. Would not that simple partition of the current effect quantitatively exactly the same distribution of heat as is now obtained by circulating the gases? Would not that, if practicable, obviate the necessity of circulating the gases in order to carry heat up into the shaft?—Translator.]

As a whole, the working of the furnace these seven months may be designated as satisfactory but not satisfying; the system of gas circulation with its limitation on the economy of fuel gives a temporary advantage but sets a sharp limit on future reduction of fuel consumption; the possibilities of very low carbon product—pig steel—have not been tried out; the lower limits of power consumption have not been determined; in short, the whole question still remains in an interesting condition, with the possibilities of the future large and attractive.

Calibration of Radiation Pyrometers.

By G. A. Shook.

Black Body Standards.

In order to calibrate or standardize a pyrometer it is necessary to have a luminous source whose black body temperature is accurately known. The primary standard must be some form of a heated inclosure whose walls can be maintained at a uniform constant temperature. Some means must also be used for determining the true temperature of the inside of the inclosure.

This is generally accomplished by some form of an electric resistance furnace, as shown in Fig. 1. It consists of a central porcelain tube overwound with thin platinum foil through which passes an electric current which can be adjusted to maintain any desired temperature up to about 1600 deg. C. Concentric with this tube are two shorter ones which, with the intervening air spaces, minimize the radiation. Some form of thermo-couple is placed in one end so that the hot junction is near the center of the tube. If there is a cold junction it should be placed in crushed ice.

The thermo-couple may be either connected to a potentiometer or a sensitive potential galvanometer which reads

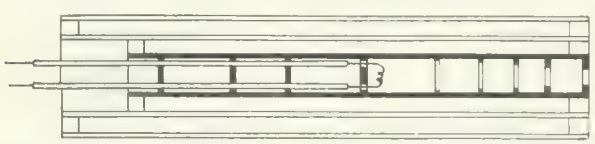

FIG. 1.—ELECTRIC RESISTANCE FURNACE FOR PYROMETER CALIBRATION.

millivolts, and by means of previously determined calibration any temperature may be determined. Except in refined work the ice point is not necessary. The furnace is connected in series with a rheostat and a 110-volt direct-current circuit.

For the calibration of the Wanner or Le Chatelier pyrometer it is necessary, as will be shown later on, to know but one black-body temperature so that as a working standard any convenient luminous object, such as a frosted-globe incandescent lamp, which would give a uniformly illuminated area of about 1 sq. cm, might be used, if its black-body temperature at some particular current strength were accurately known.

For pyrometers like the Holburn-Kurlbaum (H.-K.), however, which can only be calibrated empirically, it is necessary to have a black-body whose temperature can be varied. This is generally done by means of an electric furnace, but when a Wanner, Le Chatelier or a calibrated H.-K. is at hand it is most easily accomplished by direct comparison.

The comparison source may be a thin platinum strip, heated electrically or a wide-filament incandescent lamp. The H.-K. pyrometer may be sighted on one side of the strip and the calibrated pyrometer on the opposite side. The black-body temperature of the strip can be determined by means of the calibrated instrument and at the same time the reading of the H.-K. comparison lamp can be taken.

In the case of a wide-filament carbon incandescent lamp it has been shown that if it is properly aged for about twenty hours at 1700 deg. C., it will remain sufficiently permanent for a secondary standard for fifteen to twenty hours.

If such a lamp is calibrated in terms of black-body temperature and current strength, by means of a pyrometer, it may be used as a standard of comparison for calibrating pyrometers, just as a black-body would be used.

For industrial work, the "Pyrometer Comparison Lamp" *i. e.*, the wide-filament incandescent lamp, is undoubtedly the best standard. It costs considerably less than any sort of a furnace and, being as stable as any incandescent lamp, it can be easily sent to the United States Bureau of Standards for calibration.

The following is a typical table furnished by the Bureau of Standards for a lamp used in the author's laboratory:

Current, Amperes.	Temperature, Centigrade.
3	710 deg.
4	865 deg.
5	985 deg.
6	1090 deg.
7	1190 deg.
8	1280 deg.
9	1365 deg.
10	1450 deg.

If one is constantly calibrating a large number of pyrometers, as is the case with the instrument maker, it is best to have on

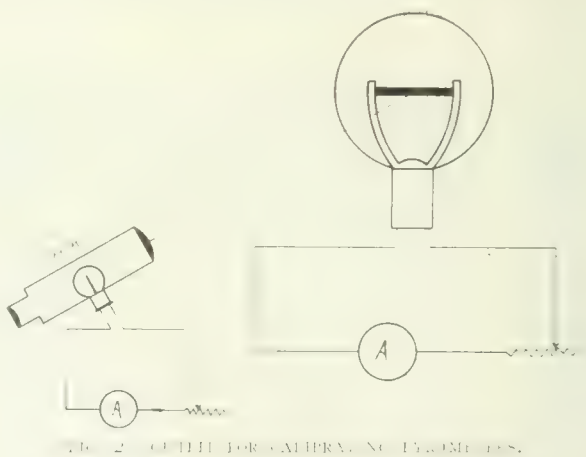

FIG. 2.—OUTFIT FOR CALIBRATING PYROMETERS.

hand five or six of such lamps and to keep in reserve the certified lamp as a primary standard. The others can be used directly as working standards, as they can all be readily calibrated by means of any calibrated pyrometer.

A complete calibrating outfit would consist of a 0-10 amp. ammeter, a suitable rheostat, and a calibrated lamp, Fig. 2.

Such a lamp would entirely do away with such a troublesome standard as the amyl acetate lamp. It should be borne in mind that no matter how carefully an instrument may be constructed or how carefully it may be calibrated, the accuracy of all subsequent measurements is subordinate to the accuracy to which the comparison lamp can be standardized. For all accurate work a standard as unreliable as the amyl acetate flame should not be depended upon.

Calibration of Total Radiation Pyrometers.

Since we are concerned here with the total radiation given out by an incandescent body, we must always use some sort of a furnace. The best method is to calibrate such a pyrometer empirically, point by point, and to mark the temperature upon

the scale of the galvanometer which is used in connection with the thermo-couple. Since glass does not transmit all of the spectrum of a black-body, any incandescent object enclosed by glass could not, of course, be used for calibrating total radiation pyrometers. For the same reason, in using a total radiation pyrometer, which has been calibrated against a black-body, the beam of light reaching the instrument should never be obstructed by a piece of glass.

In the case of pyrometers of the Féry and Thwing type as long as the thermo-couple remains intact and as long as the galvanometer is not injured in any way, such an instrument will require no recalibration.

With optical pyrometers, however, which use comparison lamps, the case is quite different and their calibration must be taken up more in detail.

Calibration of Optical Pyrometers.

It was shown in the first paper of this series that the black-body temperature (deg. C.) of any incandescent object, in terms of the photometric intensity, is given by the expression:

$$t = \frac{K_2}{K_1 - \log J} - 273 \qquad (1)$$

$$K_2 = C_2 \frac{\log e}{\lambda}$$

and

$$K_1 = \log J + \frac{K_2}{T}$$

C_2 = constant = 14,500.

$\log e$ = 0.4343.

λ = wave length in μ.

t = temperature Centigrade.

T = absolute temperature $(t + 273)$.

J = luminous intensity.

The logarithm that is generally used is the *common* or Briggs, but the logarithm that appears in the equation is the *natural*. To distinguish the common log from the natural log the former is sometimes written $\log_{10}$ and from the theory of logarithms $\log J = \log e \cdot \log_{10} J$ or $\log J = 0.4343 \cdot \log_{10} J$

The expression log J is ordinarily taken, however to mean *the common logarithm of* J. In all the following equations the *log* that appears is the common logarithm and is identical with that obtained by means of the so-called *logarithmic tables* which may be found in any engineering handbook. The method of determining the logarithm of a number is generally given briefly in connection with most tables.

Equation (1) is sufficiently accurate for all temperatures up to about 3000 deg. C., but for temperatures of the magnitude of 6000 deg. C. it is better to use Planck's equation. This point, however, will be taken up again in a subsequent paper.

When λ, the wave-length of light used, is known K_2 is determined and if J is known for a particular value of t, K_1 may be determined. Within certain limits, which are determined by the intensity of the comparison lamp, t can be arbitrarily chosen for a particular value of J or vice versa.

When K_1 and K_2 are known, a series of values of t can then be substituted in the "pyrometer equation" (equation (1)) and the corresponding values of J can be determined readily. Hence a complete calibration table can be accurately made without reference to any temperature observation whatever. This fact seems to have been entirely overlooked by most instrument makers.

Such a table containing the values of J and t will, of course, last indefinitely. While this method of calibration may require more time at the outset, it is believed by the author that it is well worth the time to make out a complete table by means of equation (1), rather than to use any of the graphical methods that are sometimes given.

Some time ago the writer worked out a direct-reading scale applicable to pyrometers of the Wanner type and since then direct-reading scales have been applied to the Wanner and to the Scimato pyrometers. The theory of the Scimato is the same as that of the Wanner instrument, but the former has a number of improvements over the Wanner type.

The method of calibrating the different pyrometers may perhaps best be shown by means of examples. The general remarks made on the particular instruments will, of course, apply to any optical pyrometer in which the intensity can be varied in a continuous and determinate manner.

Calibration of Warner Pyrometer.

In the Wanner pyrometer the relation between the luminous intensity and the angle through which the Nicol analyzer must be turned in order to produce a photometric balance is

$$J = \tan^2 \phi.$$

For a particular Wanner pyrometer the value of λ is 0.656 μ.

$$\text{Therefore } K_2 = \frac{C_2 \log e}{\lambda},$$

$$K_2 = \frac{14{,}500 \cdot 0.4343}{0.656}$$

$$K_2 = 9600.$$

Now suppose we have

T = 1273. deg. and ϕ = 45. deg.

Then,

$$K_1 = \log \tan^2 \phi + K_2 \frac{1}{T}$$

$$= 0 + \frac{9600}{1273} = 7.55.$$

Therefore

$$t = \frac{9600}{7.55 - \log \tan^2 \phi} - 273 \qquad (2)$$

or

$$= \frac{9600}{7.55 - 2 \log \tan \phi} - 273$$

A table may then be made out with the values of ϕ and t for subsequent use.

If now the pyrometer be sighted upon any object whose black-body temperature is known, the nicol may be set to correspond to this temperature and the current through the incandescent comparison lamp adjusted until a photometric balance is effected. The table made out will then hold for any unknown temperature given therein.

The angle for the calibration temperature must be chosen to suit the conditions under which the instrument is to be used, which are in turn limited by the intensity of the comparison lamp.

For instance, the nicol analyzer turns through 90 deg., that is, from 0 to 90, but it is most sensitive in the neighborhood of 45 deg. since in this position the values of the tangent change less rapidly with a given change in angle. For high temperatures the analyzer must, of course, be turned through a greater angle than 45 deg. in order to produce equality of brightness, but the limit of accuracy is reached at about 80 deg., although theoretically intensities indefinitely high can be measured up to 90 deg.

Under these conditions the instrument cannot be used for temperatures much higher than about 1800 deg. since the lamp would have to be run at too high a degree of incandescence, which means short life and, therefore, recalibration. For measuring low temperatures, however, the limit is only reached by the loss of light, which makes a setting very difficult.

In the case of any pyrometer a few preliminary trials must be made in order to determine its range.

Table 1 was constructed as follows:

TABLE I.

t	ϕ	log tan ϕ
787	10	— 1.51
864	20	— 0.88
922	30	— 0.48
972	40	— 0.15

1020	50	+ 0.15
1084	60	+ 0.48
1105	70	+ 0.88
1315	80	+ 1.51

A series of values of ϕ were put in the table, as shown, and then the corresponding values of the log $\tan^2\phi$ were found from a table of trigonometric functions. For each value of ϕ the corresponding value of t was then found from equation (2).

For $\phi = 10$, $\log \tan \phi = 10 - 1.51$

Hence

$$t = \frac{9000}{7.55 + 1.51} - 273$$

$$= 787^\circ \text{ C.}$$

For $\phi = 60$, $\log \tan \phi = 10 - 0.48$

Therefore,

$$t = 1084^\circ \text{ C., etc., etc.}$$

Calibration of Le Chatelier Pyrometer.

The wave-length for the red glass used on a Le Chatelier pyrometer was found to be 0.649μ. The constant K_2 then becomes

$$K = \frac{14{,}500 \times 0.4343}{0.649} = 9700$$

In this case $J = \left(\frac{1}{s}\right)^2$, where s is the length of one side of the iris diaphragm. (See Fig. 8 in my article on page 337 of June issue.) In order to measure a very high temperature the diaphragm must be made small in order to obtain a photometric balance. s then becomes small and obviously J increases. Evidently an extremely high temperature could not be measured by simply making the diaphragm minutely small, for the error introduced in measuring such a small diaphragm would be large and, furthermore, there are optical difficulties that render the use of very small apertures impractical.

The upper limit of s is reached when the full aperture of the lens is used and that particular value of s corresponds to the lowest temperature that the instrument will measure without further modification.

For a particular instrument, it was found, by means of a few rough measurements, that a diaphragm reading of 24.2 corresponds to a temperature 1012 deg. C. Suppose we assume that $s = 25$ when $t = 1000$ deg. C. From a logarithmic table

$$\log (1/s)^2 = \log (1/25)^2 = -2.80.$$

Hence

$$K_1 - \log J + K_2 T$$

$$= \log \left(\frac{1}{s}\right)^2 + K T$$

$$= -2.80 + 9700 \times 1273 = 4.82.$$

Therefore

$$t = \frac{9700}{4.82 - \log (1/s)^2} - 273.$$

or

$$t = \frac{9700}{4.82 - 2 \log (1/s)} - 273 \qquad (3)$$

Various values of s were substituted in equation (3) and the corresponding values of t calculated. Thus for $s = 20$,

$$t = \frac{9700}{4.82 - 2 \log (1/20)} - 273 = 1033$$

TABLE II.

s	t
25	1000
20	1033
15	1080
6	1247
4	1337
2	1513

To completely standardize this instrument it is only necessary to direct it toward some incandescent body whose black-body temperature is known. Suppose this temperature is 1247 deg. C., from Table II we see that this corresponds to a diaphragm have equal intensity. If a fiducial mark, such as a fine platireading of 6, and setting the diaphragm to 6 it is only necessary now to adjust the flame until the two photometric fields num wire is made for the tip of the flame the latter can always be brought to the same intensity without the use of any auxiliary standard. If gasoline from the same can is always used the calibration will hold indefinitely.

If the instrument is used for different distances, it must be focalized each time. In this case the length of the draw-tube, containing the diaphragm, must be taken into account in the calculation of J and this makes the calibration rather complicated. It is not impossible, however, to always use the pyrometer at the same distance from the radiating body and if this distance does vary 50 cm or so the variation will not produce a sensible error in the value of the temperature.

Calibration of Holborn-Kurlbaum Pyrometer.

The H-K pyrometer is generally calibrated empirically by means of a number of black-body temperatures. Some form of an electric furnace is usually employed, but a pyrometer comparison lamp (Fig. 2) will do just as well. The pyrometer is directed toward the incandescent body in question and the

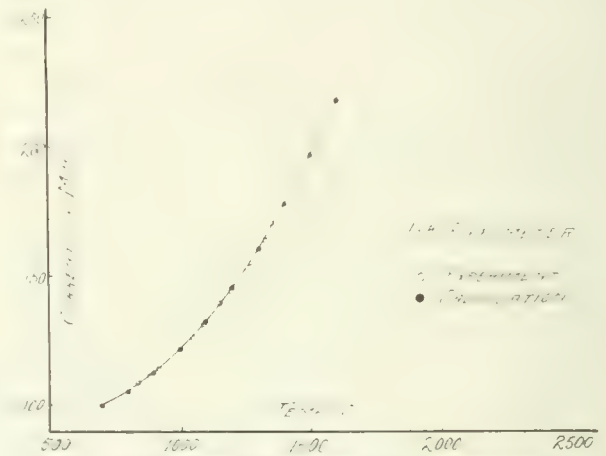

FIG. 3.—CALIBRATION CURVE FOR A H. K. PYROMETER.

current through the H-K lamp is varied until the filament disappears against the bright background. A curve is then plotted co-ordinating black-body temperature (deg. C.) and current values (milliamperes).

It has been shown by experiment that the relation between the current through the comparison lamp and its black-body temperature can be expressed sufficiently well by a quadratic formula of the form

$$I = a + bt + ct^2. \qquad (4)$$

where I is the current in milliamperes and a, b and c are constants which can be determined if three temperatures are known.

This method is especially applicable when for any reason the temperature range used for calibration is limited, for instance, when comparison is made by means of a platinum strip whose temperature is measured by means of a Wanner pyrometer. The Wanner will not read accurately much lower than 900 deg. C., while the lower limit of the H-K is about 600 deg. C.

When a number of points have been determined under such conditions, the best method is to draw a smooth curve through all the points and from the curve select three temperatures which will represent a good average and from these determine the constants of equation (4).

For example, the points marked o on the curve, Fig. 3, were determined by sighting the H-K pyrometer upon a platinum strip whose black-body temperature was determined by means

of a Wanner pyrometer. A smooth curve was drawn through these points and the following data taken from the curve:

Temperature, degrees C.....	900	1100	1300
Current, milliamperes	112	132	160

Substituting these values in equation (4) three independent equations were obtained from which the general equation was determined.

$$I = 121 - 0.100\,t + 0.000100\,t^2. \qquad (5)$$

Various values of t were then substituted in equation (5) and the corresponding values of I determined as in Table III.

TABLE III.

t_0 I_0 by experiment.
t I by calculation.

t_0	I_0	t	I
838	109.0	500	96.0
882	111.0	600	97.0
....	.....	....	.....
1330	163.6	1500	196.0
1355	170.0	1600	217.0

A method for calibrating an H-K pyrometer by means of only one known temperature has been worked out by Mendenhall and may be applied as follows: Suppose we have but one known temperature, say the meeting temperature of palladium,

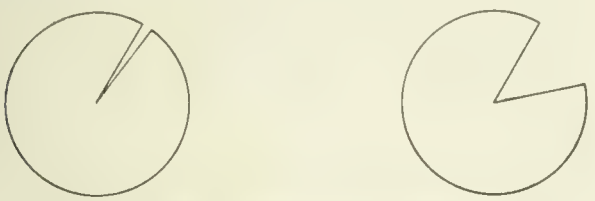

FIG. 4.—$R = 360 \div 30$ = 120 AND $R = 360 \div 50 = 7.2$

1549 deg. C., then by means of a number of rotating sector disks, having apertures of ½, ¼, ⅛, 1/20, 1/60, 1/120, a range of temperatures can be obtained from about 1030 deg. to 1450 deg. If it is desired to construct a curve by means of equation (4) using three temperatures, then two disks will be sufficient. The melting point of palladium can be taken as one temperature and the two disks will give values corresponding to two more temperatures.

If a disk has a sector of 3 degrees, Fig. 4, then it only transmits 1/120 of the incident radiation. The incident intensity, then, is 120 times the intensity of the radiation transmitted; that is, it is 120 times the apparent intensity that would be indicated by a photometer.

Suppose the radiation incident upon the objective of an H-K pyrometer is cut down by means of a rotating disk. Let

J' = intensity of the incident radiation.

J = the value as indicated by the instrument, when the rotating sector is used.

Then

$$J' = JR \text{ or } R = J' \div J, \qquad (6)$$

where R = absorption factor of the disk. Let T' represent the absolute temperature of the radiating body in question, in this case 1549 deg. + 273 deg., and let T represent the temperature as determined by the pyrometer when the absorption disk is used.

From (1)

$$\log J' = K_1 - K_2/T' \qquad (7)$$

and

$$J = K_1 - K_2/T \qquad (8)$$

Subtracting (8) from (7)

$$\log (J'/J) = K_2 (1/T - 1/T')$$

From (6)

$$\log J'/J = \log R$$

Therefore,

$$\log R = K_2 (1/T - 1/T')$$

Whence

$$(\log R)/K_2 = K = 1/T - 1/T'$$

$$1/T = 1/T' + K \qquad (9)$$

Equation (9) gives the apparent temperature of the palladium in terms of the actual temperature.

Since

$$T' = 1549 + 273 = 1822$$

$$1/T' = 0.00055$$

For a particular H-K instrument $K_2 = 9700$ and for a 3-degree sector $R = 120$. Therefore,

$$K = (\log 120) \div 9700 = 2.079 \div 9700 = 0.000214$$

Hence

$$1/T = 0.00055 + 0.000214 = 0.000764$$

Therefore

$$T = 1303 \text{ and } t = 1030$$

In a similar manner for 50-deg. disk, $t = 1290$.

Therefore from one original known temperature we have derived three, namely, 1549, 1290, 1030, which may be used to construct a calibration curve.

These temperatures are, of course, the true or thermodynamic temperatures, and this means that the palladium must be brought to its melting point in a uniformly heated enclosure, such as an electric furnace.

In order to make a temperature observation the furnace is slowly heated up to the desired temperature at the rate of a few degrees a minute. The pyrometer may be sighted upon a central diaphragm of the furnace, near which is placed the specimen of palladium and the instant of melting is determined either directly by means of a microscope or by the interruption of an electric circuit. The palladium might be brought to its melting point by means of a surface radiator, but in this case the black-body temperature must be known.

Now while the black-body temperature of a radiating surface can be measured with considerable accuracy, the true temperature, at the instant of melting, is difficult to measure, due to the changes of the surface, such as oxidation and crystallization, etc. Hence, the relation between the two temperatures, at the melting point, is very uncertain. Furthermore, the black-body temperature, alone, is useless unless we know the wave-length at which the observation was determined.

The black-body temperature of the melting point of palladium for three different wave-lengths is as follows:

Wave-length	0.662μ	0.547μ	0.462μ
Melting point	1386°	1425°	1450°

If a thin platinum strip is bent into the form of a narrow wedge, Fig. 5, and heated to incandescence, the radiation from

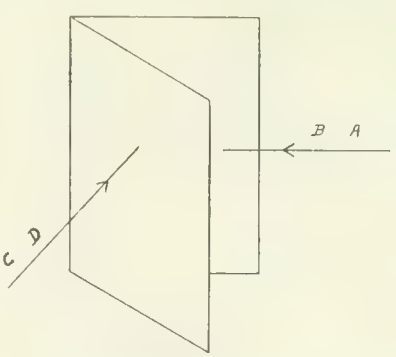

FIG. 5.—WEDGE-SHAPED CAVITY.

the interior will be observed to be quite different from the radiation emitted by the exterior surface. Hence if a temperature observation is made, by means of an H-K pyrometer, in the direction AB the pyrometer will indicate the true or thermodynamic temperature of the strip. However, when an observation is made in the direction CD the instrument then indicates the black-body temperature of the strip.

By means of such a wedge-shaped cavity the relation between the black-body and the true temperature of a metal can be experimentally determined. Such a wedge used in a hori-

zontal position may serve as a sensitive meldometer for the determination of melting points of salts between 700 deg. and 1600 deg. C.

Finally, *any radiation pyrometer calibrated by means of known black-body temperatures indicates the black-body temperature of an incandescent object unless the object sighted upon is itself a black-body in which case it indicates the true or thermodynamic temperature.*

When black-body conditions are not realized, as, for example, in the determination of the temperature of an incandescent sheet of metal, the temperature can only be expressed as *black-body temperature* unless we know the departure from black-body radiation for the particular metal.

Except in the case of a few metals, like platinum and palladium, very little is known at the present time concerning the departure from black-body radiation.

Direct and Indirect Reduction in the Blast Furnace*

By M. Levin.

Direct reduction in a blast furnace may be defined as the reduction of the iron ore by the solid fuel, whereby the fuel is charged into CO, while *indirect reduction* is the reduction of the ore by CO which was previously produced by direct reduction, whereby the CO is changed into CO_2. Since in the lower part of the blast furnace CO_2 cannot exist, only direct reduction will occur there so that indirect reduction is limited to the middle and upper parts of the furnace.

Assuming that the iron ore is FeO, we have the following equations:

Direct reduction $FeO + C = Fe + CO$ (1)

Indirect reduction $FeO + CO = Fe + CO_2$ (2)

The reaction (1) of direct reduction can and does occur independently of all other reactions, while indirect reduction (2) is always dependent on the formation and presence of CO. Now the presence of CO may either be due to previous direct reduction (1) or to the combination of the fuel with atmospheric oxygen in the air blast:

$$C + O = CO. \quad (3)$$

If CO formed by direct reduction is the reducing agent in the indirect reduction process we have the following equations:

Case A: Mixed Reduction.

Direct reduction $FeO + C = Fe + CO$

Indirect reduction $FeO + CO = Fe + CO_2$

$$2\,FeO + C = 2\,Fe + CO_2 \quad (4)$$

If on the other hand the CO is obtained from combustion of fuel by the air blast, the equations are:

Case B: Pure Indirect Reduction.

$C + O = CO$

$FeO + CO = Fe + CO_2$

$$FeO + C + O = Fe + CO_2 \quad (5)$$

Case A in which we have direct combined with indirect reduction may be called *"mixed reduction,"* while in case "B" we have combustion without any direct reduction and we may speak in this case of *"pure indirect reduction."*

The amount of C consumed and the amount of CO_2 formed is the same in equations (4) and (5), but "mixed reduction" A yields twice the amount of Fe which is produced by "pure indirect reduction" B per unit of fuel.

It will now be shown that the analysis of blast furnace gases is a simple means of determining whether in a blast furnace pure indirect reaction takes place or not.

The air blast contains 26.5 volumes of oxygen (O_2) per 100 volumes of nitrogen. The oxygen combines with carbon and forms fifty-three volumes of CO per 100 nitrogen.

In the lower part of the furnace this amount of CO, due to the air blast burning up carbon, may be increased by CO formed by direct reduction, while in the upper part of the furnace the amount of CO may be reduced in two ways, one of which is indirect reduction (2) and the other decomposition of CO by the reaction.

$$2\,CO = C + CO_2 \quad (6)$$

If we now assume that the N_2 from the air blast ascends through the furnace in unvarying quantity, it is obvious that a proportion of more than fifty-three volumes of CO per 100 volumes of N_2 proves that in the lower part of the furnace more CO has been formed by direct reduction (1) than has been consumed in the upper part by indirect reduction (2) or changed into C and CO_2 by the decomposition (6) of CO.

If the ratio of the volumes of CO to 100 N_2 is fifty-three, these reactions in the lower and upper parts of the furnace are in balance so that the same amount of CO leaves the furnace as has been formed by the burning of the fuel by the air blast.

In other words, if in the latter case indirect reduction (2) or decomposition (6) of CO has taken place, an amount of CO equal to that thus consumed must have been formed in the lower part by direct reduction (1).

We have therefore reached this result: *If in a blast furnace gas the CO content is greater than or equal to fifty-three volumes per 100 volumes of nitrogen, only direct or mixed reduction but not "pure indirect reduction" takes place in the whole furnace.* If the amount of CO is below fifty-three volumes per 100 volumes N_2, more CO is being consumed in the upper part of the furnace than was formed in the lower part by direct reduction and this consumption of CO in the upper part may occur either by indirect reduction or by decomposition of CO into C and CO_2. Part of the carbon monoxide consumed in the upper part must, therefore, have derived its oxygen from the air blast, so that in this case we may have pure indirect reduction.

However, since we do not know how much of the consumption of CO in the upper part is due to indirect reduction and how much to decomposition of CO, we cannot conclude from the concentration of carbon monoxide what the exact amount of the pure indirect reduction is. We can only conclude what the maximum amount of pure indirect reduction is which could possibly have taken place, and which corresponds to the condition that there has been no decomposition whatever of carbon monoxide into C and CO_2 in the upper part of the furnace.

Hence, *if in the blast furnace gas the proportion of carbon monoxide to nitrogen is less than 53 to 100, there exists the possibility of pure indirect reduction in the furnace and half the difference between fifty-three and the volumes of CO per 100 volumes. N_2 is the maximum amount of oxygen which can have been removed from the ore by pure indirect reduction.*

In two particular cases Levin and Niedt have shown that the decrease of CO in the upper parts of the furnace was essentially due to indirect reduction and not to the decomposition of CO. In these cases the calculation just sketched gives directly the value of oxygen removed from the ore by pure indirect reduction.

Now the percentage of CO_2 in the gas may be used as a basis for calculating the extent of indirect reduction.

If the concentration of CO is below fifty-three volumes per 100 N_2, all oxygen abstracted from the ore leaves as CO_2, but besides this we have other CO_2 which is driven off from the carbonates in the charge. This latter amount of CO_2 depends greatly on the composition of the charge and especially on the amount of limestone in it. Nevertheless the CO_2 content can be used to get an idea of the minimum amount of indirect reduction.

If a is the percentage of CO per 100 volumes N_2 and a is smaller than 53 and if b is the percentage of CO_2 per 100 volumes N_2, then the maximum percentage i of O_2 which can have been removed from the ore by pure indirect reduction, in per

*Translated slightly in abstract, from *Metallurgie*, vol. 8, Oct. 8, 1911, [illegible]

cents of the oxygen contained in the carbon dioxide in the blast furnace gas, is

$$i = \frac{53 - a}{2} \cdot \frac{100}{b}$$

Examples:

Wedding in his "Handbuch der Eisenhuttenkunde" (vol. III, p. 200 and following pages) gives twenty-one determinations of CO in blast furnace gas made in the years 1839 to 1873. The volumes of the CO per 100 volumes N_2 varied between 12.5 and 65.1, the average being 43.5 volumes CO per 100 volumes N_2, and the average percentage of the CO_2 was 18.35 volumes per 100 volumes N_2. From these figures we can calculate the maximum percentage of oxygen which have been obtained from the ore by indirect reduction.

$$i = \frac{53 - 43.5}{2} \cdot \frac{100}{18.35} = 25.8\%$$

or not more than one-fourth of the oxygen contained in the CO_2 of the blast furnace gas can have been obtained by indirect reduction.

C. Brisker (Berechnung des Eisenhochofens, p. 8) gives 12 data from a coke blast furnace, the average figures being as follows:

$CO = 42.2$ volumes per 100 volumes N_2.

$CO_2 = 19.5$ volumes per 100 volumes N_2.

$$i = \frac{53 - 42.2}{2} \cdot \frac{100}{19.5} = 27.7\%$$

that is, not more than 27.7 per cent of the oxygen in the carbon dioxide in the blast furnace gas can have been obtained from the ore by pure indirect reduction.

O. Simmersbach (Die Eisenindustrie, p. 63) gives five analyses from charcoal furnaces, viz.:

$CO_2 = 17.9$ volumes per 100 volumes N_2.

$CO = 50.4$ volumes per 100 volumes N_2.

$$i = \frac{53 - 50.4}{2} \cdot \frac{100}{17.9} = 7.3\%$$

In this case less than 10 per cent of the oxygen in CO_2 is obtained from the ore by indirect reduction.

The following figures give the results of analyses of the gas of six modern blast furnaces of one and the same works, each figure being the average of 21 analyses:

Furnace.	CO per 100 N_2	CO_2 per 100 N_2	Amount of O_2 from indirect reduction in % of O_2 in CO_2.
I	40.1	18.75	10.38
II	51.0	19.2	5.2
III	49.4	18.3	9.83
IV	50.6	17.55	6.83
V	50.4	19.65	6.62
VI	48.2	18.8	12.77
Average	49.8	18.71	8.6

Niedt and Levin in a previous article (*Metallurgie*, Vol. 8, p. 515, 1911) give the following data from two different modern furnaces in Silesia and Rhineland:

	CO per 100 N_2.	CO_2 per 100 N_2.	Amt. of O_2 from indirect reduction in per cent of O_2 in CO_2. "i" is not corrected.	"i" corrected.
Silesia	51.2	13.8	6.5	9.3
Rhineland ..	55.9	10.2	..	...

In the second case no indirect reduction took place. In the first case the CO_2 derived from carbonates in the charge amounted to 29.5 per cent of the carbon dioxide in the blast furnace gas. By taking this into consideration* we get the above corrected figure of i. Since in this case there was no decomposition of carbon monoxide into dioxide and carbon the figure of i gives not only the maximum limit, but the actual proportion of the oxygen obtained by pure indirect reduction in per cent of the oxygen of the carbon dioxide in the furnace gas.

Gillhausen (*Metallurgie*, Vol. 7, 1910, p. 421) gives very accurate data from gas analyses from modern practice, each being an average of sixty determinations.

Test No.	CO per 100 N_2	CO_2 per 100 N_2	CO_2 from carbonates in % of total CO_2 in the gas	O_2 from pure indirect reduction in % of O_2 in CO_2. "i" uncorrected	"i" corrected
I	49.9	20.4	38.8	7.6	12.4
II	52.2	14.4	21.9	2.5	3.6
III	47.2	21.7	26.1	13.4	18.1
IV	58.2	14.1	55.7		
Average	51.9	17.8	34.4	...	.

In Test II there was very little pure indirect reduction and in Test IV none at all. The oxygen due to pure indirect reduction in per cent of the oxygen derived from the ores, can have been at the highest 12 per cent and 18 per cent in the other two cases.

These figures indicate that in the older blast furnaces the maximum amount of oxygen obtained by indirect reduction was in the average about 25-30 per cent of the oxygen in the carbon dioxide in the furnace gas, while in more modern blast furnaces pure indirect reduction is of small importance and sometimes negligible.

Heat Balance.

The reaction heats of the direct and indirect reduction processes play an important part in blast furnace operation. We will calculate those of the mixed and pure indirect reduction and compare them with those of direct and indirect reduction.

As a basis for the calculation we use the following data:

(7) $Fe + O = FeO + 64.6$ calories.

(3) $C + O = CO + 29$ calories.

(8) $C + 2O = CO_2 + 96.96$ calories.

The chemical symbols are gramatoms and the calories are kilogram calories. C is amorphous carbon, and O, CO and CO_2 are gases.

By subtracting (3) from (8) we get

(9) $CO + O = CO_2 + 67.96$ calories.

By subtracting (7) from (3) we get the equation for "direct reduction"

(1) $FeO + C = Fe + CO - 35.6$ calories.

By subtracting (9) from (7) we get the equation for "indirect reduction"

(2) $FeO + CO = Fe + CO_2 + 3.36$ calories.

Direct reduction, therefore, results in a big loss of heat, indirect reduction produces a small amount of heat. Since the conditions are similar in the reduction of the higher oxides of iron, indirect reduction is generally considered the more economical reaction. (Ledebur, Handbuch der Eisenhüttenkunde, Leipzig, 1899, p. 286.)

For "mixed reduction" we have:

direct reduction (1) $FeO + C = Fe + CO - 35.6$ calories.

indirect reduction (2) $FeO + CO = Fe + CO_2 + 3.36$ calories.

For "pure indirect reduction" we have:

(3) $C + O = CO + 29.0$ calories.

(2) $FeO + CO = Fe + CO_2 + 3.36$ calories.

(5) $FeO + C + O = Fe + CO_2 + 32.36$ calories.

Mixed reduction requires, therefore, an expenditure of 32.24 kg calories per gram atom of carbon consumed, while pure indirect reduction generates 32.36 kg calories per gram atom of carbon consumed. Calculated per kilogram of oxygen removed from the ore there is an expenditure of 1005 calories for mixed reduction and a generation of 2020 calories for pure indirect reduction.

This shows the importance of the origin of the CO which takes part in the indirect reduction, the reaction heat per kg of oxygen removed from ore being greater by 3025 calories for pure indirect reduction than for mixed reduction.

The following is a summary of the reaction heats of the dif-

*0.295 × 13.8 = 4.1 CO_2 per 100 N_2 are formed from carbonates. Hence instead of b = 13.8 we have b = 13.8 − 4.1 = 9.7, hence

$$i = \frac{53 - 51.2}{2} \cdot \frac{100}{9.7} = 9.3$$

ferent kinds of reduction in kilogram calories per gram atom of iron reduced:

Direct reduction: $FeO + C = Fe + CO - 35.6$ calories.

Mixed reduction: $FeO + \frac{1}{2}C = Fe + \frac{1}{2}CO_2 - 10.12$ calories.

Pure indirect reduction: $FeO + C + O = Fe + CO_2 + 32.36$ calories.

These results show that mixed reduction is more economical than direct reduction, since it consumes only half of the carbon and less than half of the energy per unit of iron reduced.

In all three equations the quantities of FeO reduced and Fe produced are the same, so that the differences in the reaction heats must be due to the different quantities of carbon consumed and the difference in the degree of oxidation of the carbon.

This is proved by the following equations:

mixed minus direct reduction $\frac{1}{2}(2CO) = \frac{1}{2}(C + CO_2) + 19.48$ calories.

pure indirect minus mixed reduction $\frac{1}{2}(C + O_2) = \frac{1}{2}(CO_2) + 48.48$ calories.

pure indirect minus direct reduction $CO + O = CO_2 + 67.96$ calories.

Finally, attention may be called to the fact that according to these equations the differences between direct reduction, mixed reduction and pure indirect reduction are independent of the nature of the metal (iron in the above case) which is being reduced from its oxide. The same is true for the difference between indirect and direct reduction, for which we have the equation:

$$2CO = C + CO_2 + 38.96 \text{ calories.}$$

Iron and Steel Metallurgical Laboratory,
Institute of Technology,
Aachen, Germany.

The Mexican Mining Journal, published at Mexico City, sustained a complete loss of its plant by fire on April 20. The May issue of the *Journal* was in press and was destroyed. Through the courtesy of local printers the owners of the *Journal* have been enabled to continue publication until a new plant can be obtained.

Variation of the Electrical Resistance of Oxides with Temperature

By A. A. Somerville

Since studying the effect of temperature upon the resistance of many of the so-called electrical conductors found in a laboratory, the writer has found an interesting field for work in the investigation of the non-conductors under ordinary conditions, if these materials are subjected to higher temperatures.

Also as most metals and alloys oxidize when subjected to higher temperatures in air, it seems just as natural to investigate the products of oxidation as to try to prevent oxidation by excluding oxygen.

For these reasons the work has been begun of trying to measure the resistance as a function of temperature of the oxides.

As a rule, oxides at room temperatures are non-conductors. As the temperature is increased, the resistance decreases until at 1000 deg. C. most of them may be classed as conductors.

The oxide in the form of a powder is placed in a porcelain or quartz tube [illegible] inches in diameter and [illegible] in

[illegible] OXIDE POWDER

length. Nickel rods are machined to fit into the ends of the tube against the ends of the column of oxide, which is about 5 cm. in length. Two to 4 lb. pressure is put on the ends of the nickel rods by means of weights in order to effect constant pressure and constant contact on the oxide. The oxide in its containing tube is heated in a tubular resistance furnace. The temperature is measured with a platinum resistance thermometer. Electrical contact is made with the ends of the nickel rods for measuring the resistance of the oxide. A Wheatstone bridge is used for this purpose.

There is a marked similarity in the way in which the resistance of the different oxides varies with temperature. The

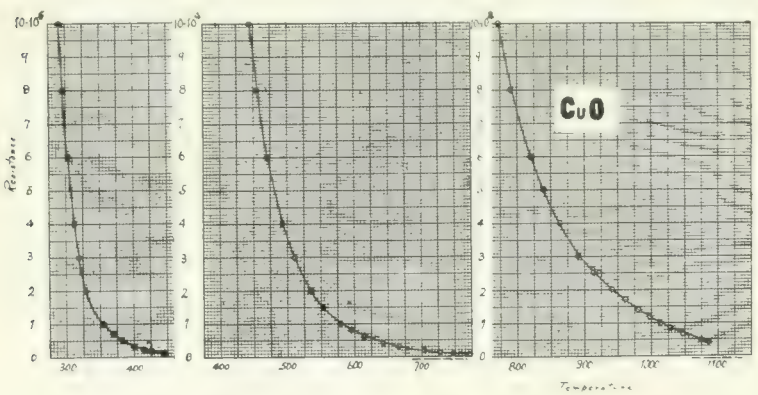

FIG. 2.—CURVES FOR CuO (FIRST HEATING).

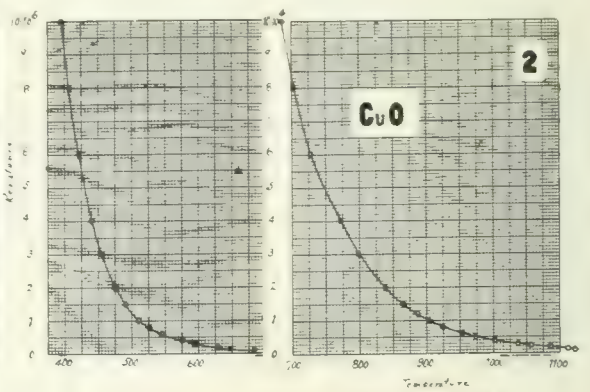

FIG. 3.—CURVES FOR CuO (AFTER ONCE HEATED).

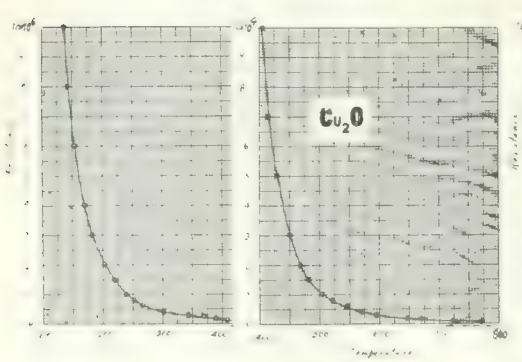

FIG. 4.—CURVE FOR Cu_2O (FIRST HEATING).

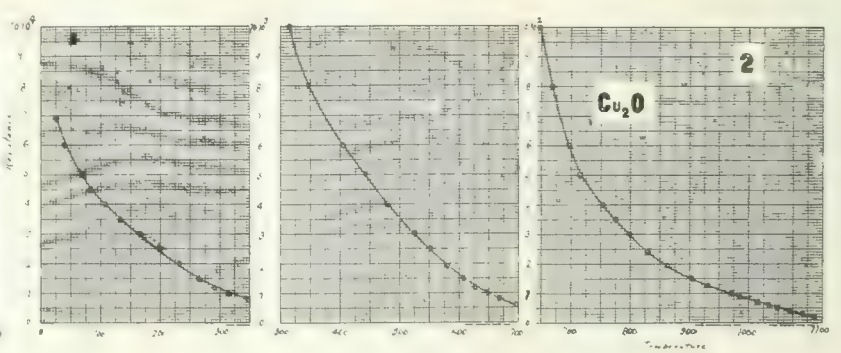

FIG. 5.—CURVE FOR Cu_2O (AFTER ONCE HEATED).

maximum resistance reading made is 10,000,000 ohms. This reading occurs at different temperatures in different oxides. However, the general form of all the curves is nearly the same.

The materials that have been studied to date are:

Zinc oxide	ZnO.
Ferric oxide	Fe_2O_3.
Cupric oxide	CuO.
Cuprous oxide	Cu_2O.
Magnesium oxide	MgO.
Manganese dioxide	MnO_2.
Aluminium oxide	Al_2O_3.

The same cross-section and length of each has been used, that is, 1 cm. diameter and 5 cm. length. Variations from this

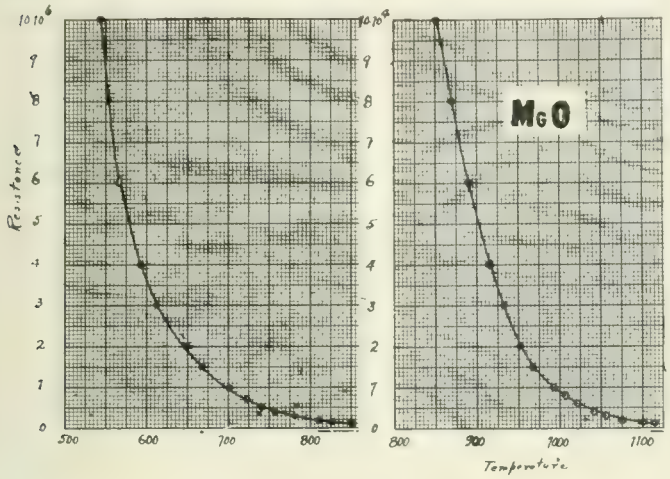

FIG. 6.—CURVE FOR MgO.

have been made only to show that contact resistance is negligible.

The temperature at which each measures 10,000,000 ohms is here indicated. Temperatures are in Centigrade degrees.

ZnO	393 deg.	
Fe_2O_3	252 deg.	
CuO	290 deg.	(First heating.)
CuO	395 deg.	(After once melted.)
Cu_2O	137 deg.	(First heating.)
Cu_2O	After first heating measures 90,000 ohms at 0 deg. C.	
MgO	545 deg.	
MnO_2	120 deg.	
Al_2O_3	?	

The resistance of these materials at a temperature of 1100 deg. C. near the maximum of the furnace is the next most

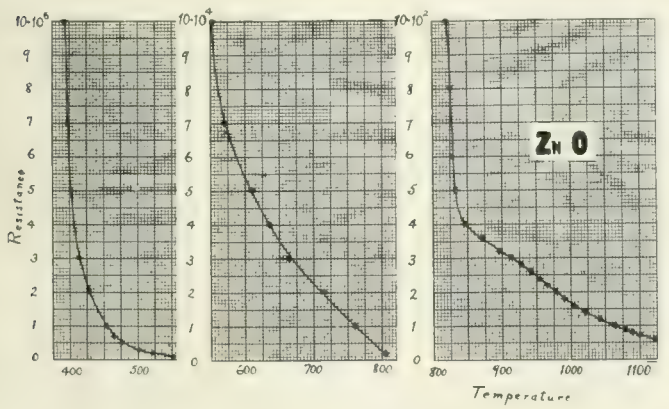

FIG. 7.—CURVE FOR ZnO.

interesting thing learned. The resistance is given in ohms.

MgO	1200.
Cu_2O	Changed to ($Cu + CuO$) at about 800 deg. C
Cu_2O	18. (After first heating.)
CuO	35 at 1084 deg. C. (Melting point.)
CuO	1600. (After once melted.)
MnO_2	70.
ZnO	72.
Fe_2O_3	80
Al_2O_3	? (Infinite.)

The curve sheets, Figs. 2 to 8, are scaled to various powers of "tens" in order to show the entire curve to the best advantage.

Black copper oxide, CuO, melts at 1084 deg. C. and contracts to about one-half its former volume. The surface ten-

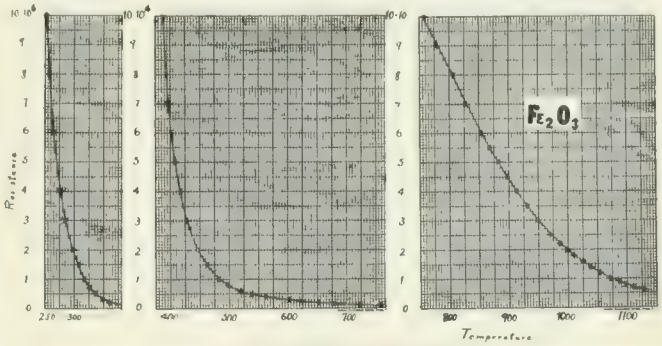

FIG. 8.—CURVE FOR Fe_2O_3.

sion is such that it retains its cylindrical form. The value of the resistance is at all temperatures greater after the oxide has been once melted.

Red copper oxide, Cu_2O, undergoes a change at about 800 deg. C. here indicated. $Cu_2O = Cu + CuO$. The metallic copper then begins to unite with the oxygen of the air to form more black copper oxide, CuO. Only the metallic copper at the surface, however, is exposed to the air and the copper in the interior remains metallic, being protected from the oxygen

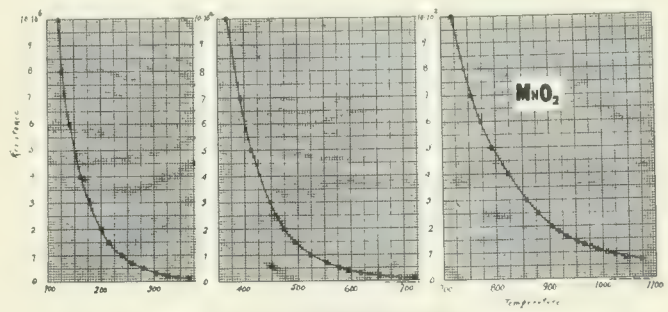

FIG. 9.—CURVE OF MnO_2.

of the air by the outer layer of oxide. The metallic copper formed tends to make the resistance of the mixture lower than it had been at any corresponding temperature before the formation of the metal occurred.

Aluminium oxide appears to be one of the best insulators. Magnesium oxide is also used as a non-conductor.

Ithaca, N. Y.

The average tenor of zinc and lead sulphide concentrates in different states is shown in the following table, which has been compiled from statistics of the United States Geological Survey for 1911:

Notes on Chemistry and Metallurgy in Great Britain.

(From Our Special Correspondent.)

The National Physical Labratory.

The report for the last year, which has just been issued, is a fairly satisfactory document. In many respects the severest critics of the laboratory can take no exception to a great deal of its activities. A feeling of soreness, however, in regard to its doing commercial testing is still a point of irritation to many men in private practice. That, however, is by the way, because the chief interest to your readers will be in what the laboratory has achieved rather than in our domestic quarrels. There has been an enormous increase in work, and issues of certificates have been as follows:

Physics Department, Electrical Measurement Section	200	as against	172
Electrotechnic Section	2203	"	1810
Photometry Section	920	"	480
Thermometry Section	582	"	400
Optics	5100	"	5308
Metrology	2074	"	1860
Engineering Department	283	"	150
Observatory	37,145	"	30,395

The financial situation is as follows: The income again shows a satisfactory growth, having risen from £28,076.12.1 in 1910 to £30,336.15.8 in 1911, an increase of £2,260.3.7. This is mainly due to an increase in the receipts for work done, which have risen from £15,363.0.9 in 1910 to £17,398 3.7 in 1911. The receipts for 1910, as here given, include one-half year's dividends from the Gassiot Fund, amounting to £234.13.7 and also a payment by the Meteorological Office of £200 for one-half year's work done. Both these payments lapsed as from July, 1910, and the increase in 1911 in receipts for work done, excluding the meteorological work now transferred to the Meteorological Office, is therefore really greater by these two amounts than would appear from the totals. On the other hand the total for 1911 includes the sum of £687.3.2 for work done by the Tank Department, which this year contributes to the receipts for the first time. The sum received from the Institution of Naval Architects on account of the Guarantee Fund for the Tank has been £1,316.15.0 as against £1,327.5.0 in 1910.

The total expenditure for the year 1911 has been £30,571.14.10, exceeding the receipts by £234.19.2. This expenditure includes a sum of £640.6.0 spent on general equipment, with a further sum of £63.7.11 for accessories to the Lorenz Apparatus. The sum of £352.6.1 was also provided out of the General Maintenance Account toward the expenses of the William Froude National Tank, while a further amount of £111.3.0 was spent on certain items of equipment for the Tank.

Space in this letter only permits of reference to part of work done in 1911. The processes of analysis in use in the Division of the Department of Metallurgical Chemistry have continued to give complete satisfaction. Special attention has been given to the whole question of carbon determination in steel by the two processes of direct combustion in oxygen and the previous separation of the carbon by means of copper-potassium chloride. As a rule it has been found—over a very large number of samples—that the two methods give identical results, but in a certain group of steels, which were tested by both methods at the request of a steel-maker, serious discrepancies were found, the copper-potassium-chloride method giving distinctly higher results. It was subsequently discovered that these high results were due to the presence of organic impurities (probably dissolved cellulose) in the copper potassium chloride solution. Although such cellulose is precipitated when the solution is acidified, the quantity is too minute to be seen and remains present as a finely-divided flocculent precipitate. This contamination was found to be present in the "pure" variety of the double chloride supplied by a chemical manufacturer of high standing, so that care in the use of this reagent is obviously needed. This experience has served to strengthen the view held as the result of experience at the laboratory, that the method of direct dry combustion is the most uniformly reliable for carbon steels.

In the new electrochemical room provided in the New Building, a beginning has been made in setting up apparatus and methods for a more extended use of electrochemical methods of analysis.

Investigatory Test Work.—A considerable amount of this class of work has been carried out by the Chemical Division of the department.

A series of samples of pitch and bitumen have been examined and tested for Colonel Crompton on behalf of the Road Board; a room in the new building set aside for this work (together with cement analysis) affords special facilities for the investigation of such materials. A report on methods of testing such substances has also been drawn up.

The chemical properties of a series of samples of optical glass have been determined, interesting results as to the relative durability of such glasses of British and Foreign manufacture being obtained.

The special investigation on the inflammability of flake charcoal mentioned in the previous report has been continued and is now nearly completed. These experiments show clearly the danger of fire which is involved in using sulphur dioxide for disinfecting purposes in places where charcoal is used in the walls. The behavior of decayed wood has also been studied from the point of view of spontaneous combustion, but as far as the samples yet tested are concerned, this material appears to be markedly less inflammable than charcoal—i. e., its temperature of spontaneous combustion is very decidedly higher.

Alloys of Aluminium and Zinc.

At the meeting of the Institution of Mechanical Engineers on the 19th of April, the Alloys Research Committee's tenth report was presented by Dr. W. Rosenhain and Mr. S. L. Archbutt. The authors attributed the usual rapid corrosion of commercial samples of these alloys to the impurities in the spelter used in preparing them; and found that pure zinc gave alloys with much less tendency to corrosion or to cracking on cooling. They claim to have discovered that a compound Al_2Zn_3 is formed. The results of dynamic tests in conjunction with those of tensile tests indicated that the most useful binary alloy was that containing 20 per cent of zinc.

In the course of the discussion Sir Gerard Muntz objected that the results given in the report were obtained from alloys prepared with pure zinc. It was not necessary to use zinc of such a high degree of purity as had been employed for these investigations; the commercial quality was good enough and would be used in practice.

Sir H. F. Donaldson remarked that he had obtained results varying considerably from those given in the report; but as nearly all his alloys contained about 1 per cent of copper a strict comparison could not be made.

Mr. L. Archbutt, Jr., said that the authors had used sea water for the corrosion tests. He thought that the substances employed for such tests should be selected according to the purpose the alloy was to be used for, and suggested that it would be preferable to ascertain the action of oils and fatty acids.

The meeting was then adjourned until Friday, the 3d of May, when Professor Arnold is expected to resume the discussion.

It is difficult to reconcile some of the statements in the text of the report with the figures in the tables referring to the same question, viz., the effect of ageing; and the contradictions are so manifest that the authors will most probably be asked to give an explanation at the adjourned meeting.

At the meeting of the Institution of Mechanical Engineers on the 3d of May, the discussion on the tenth report of the Alloys Research Committee was resumed by Mr. S. L. Archbutt, one of the authors, who remarked that sometimes the yield point was a little higher when zinc of commercial quality was used for the alloys; but with pure zinc the ultimate stress was invariably much higher. The thermal expansion of alloys containing from 5 to 15 per cent of zinc was about twice that of steel.

Professor Arnold regretted that the authors had not paid greater attention to mechanical tests. The decision of the engineer was final; and it was necessary that he should have these results. It appeared that the endurance of the alloys under alternating stress was only from one-eighth to a quarter of that of good mild steel, and that was a vital matter. In research of this class the collaboration of the practical metallurgist was necessary to insure its full value to mechanical engineers.

Mr. W. Mills said that he was one of the first to deal practically with aluminium-zinc alloys, and directed attention to the difficulties encountered in making castings. He had obtained the best results with an alloy the composition of which closely approximated to that which had come out best in this research. There was, however, a demand for a lighter alloy with almost the same specific gravity as aluminium.

Mr. F. W. Harbord remarked that the impurities mostly existing in commercial zinc were iron and lead; and it would be useful to ascertain which of these caused the difference between alloys containing commercial zinc and those with pure zinc. He quite agreed with Professor Arnold on the question of practical tests.

Mr. E. F. Law said the authors referred to two undesirable properties in these alloys, namely, the tendency to crack on cooling and abnormal corrosion; and they then dismissed these aspects somewhat perfunctorily. They admitted that these views were widely held by practical men; and he thought it desirable that such men should present their opinions. With regard to the use of pure zinc, practical founders were asked to make much more complicated castings than those described, and they were not presented with chemically pure zinc by Sir John Brunner. A point to which he desired to draw attention was that the authors stated on p. 9 that no signs of change were observed after fifteen months ageing; and yet the table on p. 32 gave decisive evidence of the effect of ageing; for the ultimate stress and yield point had risen in every case. The authors seemed to have misinterpreted their own results.

Mr. R. F. Graham spoke as a practical man on the subject of castings, and urged the necessity of very carefully regulating the casting temperature as an essential condition for the production of sound castings with aluminium-zinc alloys.

Mr. P. Armstrong, on the question of ageing, said he had found it necessary to season the castings before machining or threading them. The electrical conductivity of these alloys was about the same as that of aluminium.

Dr. Rosenhain, in his reply, said it had been necessary to make a selection out of a great diversity of methods of research; and those which seemed most generally desirable had been adopted. With reference to Mr. Fowler's remarks as to the desirability of testing the alloys under practical working conditions, he suggested the construction of a railway bridge.

International Aluminium Syndicate.

There is some probability that the International Syndicate which dissolved in the autumn of 1908 will be re-constituted in about three months' time. A conference of the French, English, American and Swiss makers was recently held in Paris, and it is reported that an agreement was arrived at as to the establishment of a basis for combined operation. Negotiations are expected to reach their conclusion in June or July and to result in the speedy establishment of the syndicate. The fact that continental prices have risen eight or nine shillings per cwt. during the past six months is in some quarters attributed to anticipation of the successful resuscitation of the combination.

Engineering Imports and Exports.

The returns issued by the Board of Trade for the four months ended April 30th give the value of imports of iron and steel, including manufactures, as £3,683,797, a decrease of £60,541 from the figures for the same period in 1911; but the exports show an increase of £249,369 with a total of £15,007,223. Other metals, including manufactures, were imported to the amount of £9,909,819, an increase of £1,009,752; and were exported to the value of £3,628,757, also an increase of £46,219. The imports of electrical goods reached £530,812, and the exports £1,443,277; showing increases of £62,638 and £540,597 respectively. Imports of machinery are put at £2,214,538, a rise of £179,477; and exports at £10,370,236, a rise of £275,432. Imports of new ships amounted to only £11,597, a decrease of £33,303; while exports valued at £1,716,933 improved by £18,505. The figures for the month of April only are not altogether satisfactory. Both imports and exports of iron and steel decreased, the respective falls amounting to £173,655 and £1,041,557. Imports of other metals fell £48,959 and exports also fell £113,538. Imports of machinery improved by £9,533; but the exports were £57,153 lower. There was an increase of £8,927 in imports of electrical goods, and an increase of £47,881 in exports.

The Stassano Electro Steel and Furnace Company has not proved a commercial success and is voluntarily winding up. Mr. Augustus Hobbs, of Highbury, has been appointed liquidator.

Market Prices, April and May, 1912.

Copper has kept pretty much the same level during April. Opening at £70.10 it fell to £69.5, on the 10th, recovered, and remained over £70 till the 19th, when the price declined slowly to £69.10. On the 24th the price again recovered to over £70, and has remained in the neighborhood of this price, closing at £70.12.6.

Copper opened in May at £70 and after a slight decline to £69 rose steadily to £74 (17th). Since then it has continued to appreciate, general activity of Continental and Colonial trade assisting the withdrawals from stock. Closes at £76.0.0.

Tin was considerably affected in April by shortening stocks, and has shown a strong upward tendency throughout the month. Starting at £198 it touched £196 during the second week, rose to £203 in the fourth and closes at £211.10.

In May tin opened at £211, dropped to £208 on the 6th, again rose to £212 on the 13th, and £212.15.0 on the 16th, afterwards fell sharply to £205 (22nd), since recovered to £208, but closes £204.0.0.

English Lead was quiet in April, with upward tendency, opening at £16.10, and closing £16.17.6.

In May English lead has shown an upward tendency; starting £16.17.6 and closing £17.2.6.

Pig Iron, Scotch, rose sharply after Easter, opened at 58/-; had reached 60/- by the 10th; afterwards fell away slightly, but recovered ultimately to 60/- (Glasgow settlement).

In May pig iron, Scotch, has kept in the neighborhood of 60/-, with dip to 59/4 on the 9th. Closes at 59/10½.

Cleveland jerked up in the same way as Scotch Pig, opening 51/10, rose to 54/- at mid-month, declined during the following week, and closes at the same price, 54/-.

In May Cleveland has kept up in the neighborhood of 54/-, opening at that price, touching 53/3 on the 9th, and closing at 53/10½.

Haematite, after rising from 65/10 to 69/- (commencing its strong movement on the 11th) held up, and ultimately closed at 69/0.

In May Haematite has been strong, opening at 70 -, touching 69/6 on the 9th, and closing at 71/-.

The following prices are for May 1912:

	£ s. d.
Alum lump, loose, per ton	8 15 0
Antimony, black sulphide powder, per ton	20. 0.0
Borax, British, Refined Crystal, per ton	16.10.0
Copper ore, 10 to 25%, per unit	13/- to 13.6
Copper sulphate, per ton	25. 0.0
Carbolic acid, liquid, 97 to 99%, per gal.	1.7
Creosote, ordinary good liquid, per gal.	3¼
Camphor, 1 oz. tablets	1.7¼
Caustic soda, ash 48% ordinary, per ton	5.10.0
Hydrochloric acid, per cwt.	5.0
India rubber, Para, fine, per lb.	4.6¾
Mica, small slab, original cases, per lb.	6d to 2.6
Naptha, solvent, 90%, 160 deg. C., per lb.	9¾
Petroleum, Russian spot	8½
Quicksilver, per bottle	8. 5.0
Sal ammoniac lump, firsts, delivered U. K. per ton	44. 0.0
Sulphate of ammonia, f.o.b. Liverpool, per ton	14.17.6
Sulphur, recovered, per ton	5. 0.0
Shellac, standard T. N. Orange spots, per cwt.	4. 4.0
Tin ore, 70 per cent, per ton	£135 to 137. 0.0
Zinc, Vielle Montagne, per ton	29. 7.6
Platinum, nominal, per oz.	9. 5.0

The differences on the month of May are thus:

Higher.

	£ s. d.
Copper ore unit	7½
Copper sulpate, ton	10 0
Creosote per gal.	⅜
Naptha, per gal.	¾
Sulphate ammonia, ton	7.6
Tin ore, per ton	6. 0.0
Copper, ton	6. 0.0
Lead, ton	5.0
Haematite	1 3

Lower.

	£ s. d.
India rubber, lb.	1¼
Tin, ton	7. 0.0

Zircon exists in sandstone deposits near Ashland, Va., and samples taken from deposits on a number of farms show considerable percentages of the mineral. Should the demand for zircon prove sufficiently great it is probable these deposits could be worked at a profit. A combination of wet dressing and magnetic separation could be used to separate the mineral.

The production of phosphate rock in the United States continues to increase steadily. The United States Geological Survey reports that in 1911 the production was 3,053,279 tons, valued at $11,900,693. New ground was prospected in Kentucky last year, and it is probable that phosphate eventually will be produced in that state. Continuation of work on Western deposits has increased the estimates of tonnage, and has discovered some new deposits in Montana. The Western deposits are now estimated to contain more than 2,500,000,000 tons of minable rock carrying 70 per cent or more tricalcium phosphate.

The output of gold from the Transvaal in 1911 is estimated to constitute about 38 per cent of the world's production for that period.

The average value of copper rock treated in Michigan in 1911 was $2.50 per ton. The recovery of refined copper per ton of rock treated was 20 lb. The quantity of silver recovered was 497,281 fine ounces, of which 513 ounces were recovered as pickings, and 496,768 ounces from electrolytic treatment of 13,755,777 lb. of copper.

The Elmore oil-vacuum concentration process in use at the mines of the Sulitelma Company, Norway, produced 975 tons of copper concentrates in May, 1912.

The Western Metallurgical Field.

New Montana Mills.

The Butte Central Copper Company is erecting a combination concentration-cyanidation mill at the foot of South Dakota Street, Butte, Mont. The mill is being constructed in units of 100 tons each, and for the present an initial capacity of 200 tons will be completed. The arrangements are such that a plant of 500 or 600 tons capacity per day can be erected. The various steps in the process are as follows: Mine ore will be crushed to ¾-in. size and stored in the main mill bins, from which it will be fed to Chilean mills fitted with 24-mesh screens. At this stage in the crushing the pulp will be concentrated to remove coarse sulphide mineral, which contains lead, copper, iron, zinc. The tailing will be classified by Akins classifiers, producing sand and slime, the former being reground in a 5-ft. by 22-ft. tube mill. The slime will be thickened and again subjected to concentration on Deister tables, care being taken to eliminate all minerals that would be detrimental to the subsequent cyanide treatment. From 60 to 65 per cent of the value of the ore will be recovered by this double concentration.

Preliminary to cyaniding the tailings from concentration they will be dewatered to a comparatively dry state. Cyanide solution will be added, and the mass agitated in a continuous system of Rothwell-Akins agitators for a period of thirty hours. Experiment has shown that an extraction of 86 per cent of gold and silver can be obtained by this procedure. Portland continuous vacuum filters will be installed to separate solution and slime, and zinc shavings will be used for precipitation. A feature of the cyanide treatment will be the application of the continuous counter-current system which was described in this journal by Mr. John E. Rothwell, July and September, 1911, pages 373 and 439.

The sulphide minerals obtained in the double concentration will be subjected to further dressing to separate the lead, copper, iron and zinc into suitable shipping products. Careful preliminary tests have preceded the plan and construction of this mill, and it is believed that the system can be successfully adapted to the treatment of the low-grade silver ores of the Butte district.

Flotation at Butte & Superior.—The new zinc concentrating mill of the Butte & Superior Company, at Butte, Mont., was designed as a result of long experimentation, including commercial treatment of the ore at the old Basin Reduction Works. An important feature of the treatment employed is the use of a flotation system. No data are given out by the company regarding the work at the mill, but some idea of the flotation process can be gained from the description given in patent papers. The patentee is James M. Hyde, of Basin, Mont.

The process makes use of acid and oil, but does not involve the use of a vacuum. A coagulant, such as ferrous sulphate, may be used to facilitate the settlement of colloidal matter. The ore is first mixed with acid before thickening, as it has been found that this reduces the amount of acid required. The pulp is then thickened and pumped to a series of connected agitation and flotation tanks. In the first of these oil is added and the entire mass agitated. Concentrated mineral floats and is removed, while the remainder of the pulp is removed and pumped to a second agitator and flotation tank similar to the first. Here a second concentrate is produced, and the tailings may be re-treated in a third tank, from which tailing is finally discharged. The concentration from the several foregoing flotations are now combined and cleaned in a second series of similar tanks.

The process is applicable to fine material, an example of which follows: A slime pulp consisting of quartz, blende, and granite, in which the feldspars were largely kaolinized, contained 30 or more parts of water to one of dry slime. Before thickening, it was treated with from ¼ to ½ lb. sulphuric acid per ton of ore. The thickened pulp was heated with live

steam and mixed with "candle makers' red oil." The original pulp carried 23.3 per cent zinc, the concentrate 51.4 per cent, and the tailing 3.2 per cent, showing a 91 per cent recovery. In the first treatment the concentrate contained from 38 to 42 per cent zinc, and this percentage was raised, as above shown, in the second treatment.

In addition to the use of flotation, the Butte & Superior system makes use of classifiers, jigs and tables. Jigging begins at 6 mesh, and the oil flotation is used on 100-mesh and finer material.

Timber Butte Mill.—W. A. Clark has organized the Timber Butte Company to build a concentrating plant to treat the zinc and copper ores from the Elm Orlu Mine. This plant will replace the old concentrator at the Butte Reduction Works, which was burned last year. The new mill will be located on Timber Butte, about 2 miles south of Butte, and will have a capacity of 350 tons per day.

Increasing Activity in Colorado.

The long talked of mill at the old Newhouse tunnel, now known as the Argo tunnel, at Idaho Springs, is to be erected this summer. Following the general plan of the Hudson mill, which was described in this journal for January, 1912, the new plant will be adapted to make recovery by amalgamation, concentration and cyanidation, and will be operated as a custom plant. The great variety of ores encountered in this district makes it impossible to reply on any one system of metallurgy to recover the valuable minerals, hence the combination above mentioned. A sampling plant of 300 tons daily capacity will be erected in connection with the mill, but for the present only one unit of the mill of 100 tons capacity will be erected. This capacity will be increased to 300 tons as needed. It is expected that the erection of this mill will permit an increased production of low-grade ores, which at present are not mined, as well as an increased profit from other ores which are now sold at a disadvantage.

It is reported that the El Paso Consolidated Mining Company, one of the large producers in the Cripple Creek district, has interested additional capital in its operations, and that a mill will be erected in the district for the local treatment of low-grade ore. While the details of the mill have not been announced, it is probable that the metallurgical process to be employed will follow the general plan which has proven so successful in the Stratton's Independence and Portland mills.

The suit of the Smuggler-Union Mining Company against the Liberty Bell Mining Company, both of Telluride, was tried in the Federal Court in Denver during the first week in June. The former company alleged trespass and unlawful extraction of 74,000 tons of ore which was treated in the Liberty Bell mill. The damage asked amounted to $600,000, and the verdict awarded the sum of $403,000 to the plaintiffs. Toward the end of the trial the defendant admitted innocent trespass and placed the amount of ore extracted at 53,000 tons. The plaintiff was granted twenty days in which to file a motion for a new trial.

New Work in Utah.

Increased capacity at the smelter of the International Smelting & Refining Company, Tooele, is being provided to accommodate the growing shipments of lead ore. A new lead furnace will be erected, making the third, and four sinter roasters will be installed. In the copper smelting department four of the five reverberatories are in commission, and the combined lead and copper furnaces are treating about 1000 tons of ore per day.

The Columbus Consolidated, which is an old producer in the Alta district, is planning to remodel its concentrating plant and bring it to a high state of efficiency in accordance with modern practice. Recent development of new bodies of concentrating ore has made this step advisable, and the necessary alterations will be made as rapidly as possible in order to make the new discoveries profitable.

Consolidated Mercur, which was one of the first companies in this country to make successful application of the cyanide process and vacuum filters, has about reached the end of its profitable existence. The company notified stockholders of a 3-cent dividend last month, and stated at the same time that unless unusual developments resulted in the next few months operation would be discontinued. The stockholders were requested to take action which would permit the directors to dispose of the salable equipment, in order that the affairs of the company might be wound up with as little expense as possible. During the past few years the company has sought other properties where its present equipment might be of service, but it has been unable to find anything suitable.

Inspiration Consolidated Mill.

This company, which owns a large acreage of porphyry copper ground in the Miami district, has decided on the site of its new 7500-ton concentrating mill, and has commenced construction work. The mill will be located about one mile north of the town of Miami, and one mile east of the mine. The ore-dressing system has been developed by J. M. Callow, of Salt Lake, and will be along the line developed in the mills of the Utah Copper Company. The mill will be erected in six units of 1250 tons capacity each.

Culture in the Education of Engineers.*

By William L. Saunders.

At one of the meetings of the American Institute of Mining Engineers, held in the hall of the Sheffield Scientific School at New Haven, a discussion arose as to whether or not sufficient importance was given to cultural studies in our scientific schools. A diagram was exhibited showing graphically the relative proportion that culture bore to other studies in the various colleges. In some there was a wide distribution of cultural work, in others the proportion was small, and in a few cases it was shown that these studies were entirely omitted in the curriculum. During recess a group of students were discussing the subject; one of them, a senior, said, "I don't see why they should *learn* a person culture in a scientific school." This remark, made in my presence, so impressed me as a concrete example of neglect in true educational lines that it has been chosen as a text for what is to follow.

Education in its broadest sense is mental and moral training. High schools and colleges differ from common schools in that they aim at higher planes of mental and moral life. The small boy is taught by stuffing, as one puts sawdust in a doll; this is because his mind has not grown to the stage when it can think for itself. Impressions are received and transfixed by memory; the process is one of mental photography; the moral code is learned by rote as though it were the multiplication table. Not so with the older, the college student; his highest aim in education is to learn to think for himself. "If you are a student force yourself to think independently; if a teacher compel your youth to express their own minds," writes Dr. Osborn of Columbia; and again, "The lesson of Huxley's life and the result of my own experience is that productive thinking is the chief *means* as well as the chief *end* of education."

Now what is productive thinking? Let me answer this question by giving you Huxley's definition of culture: "The pursuit of any art or science with the view of its improvement." The storage process is of paramount importance only when applied to elementary education. It is but the auxiliary of the scholar who has passed from the junior to the senior stage of student life, and who aims to do things in the world. The pursuit of facts is a mathematical study. We learn of things that exist as a result of divine and human creation. The earth is round and it is composed of land and water. Water is

*Address delivered at the 38th Annual Commencement, Colorado School of Mines, Golden, Colo., May 24, 1912.

hydrogen and oxygen combined. The square of the hypothenuse of a right angle triangle is equal to the sum of the squares of the other two sides. How elementary are these facts! It is important that we should know them; but even a large volume of facts when stored in the human mind is powerless to add one cubit to progress. It is like putting a pair of legs on the Encyclopedia Britannica and expecting it to do something. Knowledge is power, but reason is power in action.

Dr. James Gayley, of the United States Steel Corporation, told me recently that the professor at Lafayette College who taught him how to think made so deep an impression upon him that it has lasted throughout his life. Mr. Gayley is distinguished for what he has done as a metallurgical engineer. His life has been one of productive thinking; he has pursued science with the view of its improvement. That teacher, Mr. Gayley said, once gave him a solution containing iron, and instead of instructing him how best to precipitate the metal he told him to try three or four ways of doing it and report which was best. This led directly to thought and reason and built up a master mind among engineers. We may still heed the voice of old Carlyle crying from the heathery hills of Dunscore: "Produce! Produce! Were it but the pitifullest infinitesimal fraction of a product, produce it in God's name! 'Tis the utmost thou hast in thee; out with it, then."

Where among all the professions do we get the results that come through productive thinking as from engineering? The engineer is the architect of the world's progress. Transportation in railways and ships, in motor cars and aeroplanes, is the productive thinking of mechanical engineers woven into our industrial life. The men who did these things were students of science, not that they might be mere storehouses of knowledge, but that they might produce. Civil, electrical, chemical and mining engineers are fields which afford infinite opportunities for research and progress. If you men of the future do not rise to your chances in these lines it is not because the fields are not still open for cultivation and growth, but rather through your own inefficiency or perhaps your top-heaviness.

"In vain our toil,
We ought to blame the culture, not the soil."

Even Huxley feared that men might be over-fed scientifically when he said: "An exclusively scientific training will bring about a mental twist as surely as an exclusively literary training. The value of the cargo does not compensate for a ship's being out of trim; and I should be very sorry to think that a scientific college would turn out none but lop-sided men."

All this bears upon culture in its broadest sense. Productive thinking is the most important form of culture. It makes for power, refinement, progress, knowledge, taste, civilization. The subject, you see, is a very broad one; the obligation upon you as students of science is equally broad. Take care that you be not "lop-sided men." A graduate of the Colorado School of Mines, like all graduates of the higher institutions of learning, misses his opportunities and discredits his college if he does not carry throughout all his walks of life the imprint of the educated man. Noblesse oblige is a degree and an obligation which is uniformly conferred upon all college men. To carry this obligation properly one should study culture in all its phases and in its broadest sense. Study it as an undergraduate and study it still harder and more fully through all your post-graduate life. To this end let us accept and profit by that definition of culture given us by Matthew Arnold: "Acquainting ourselves with the best that has been known and said in the world." A professor at Wellesley College defined culture to the students as that which is left after all else learned at college is forgotten.

Virtue and moral training belong to cultural work in the education of engineers. It is a mistake to suppose that schools and colleges are places for mental training only. Physical exercise through athletics is just as much a part of one's college life nowadays as the study of mathematics; the one helps the other. Emerson said, "Archery, cricket, gun and fishing rod, horse and boat, are all educators, liberalizers." To the engineer physical training is of value in order to fit him for outdoor work. Moral training is of even greater importance. Locke has placed virtue first in defining the objects of education. Wisdom he puts next, and then good breeding; last of all learning. It is more the province of the teacher than of the student to safeguard and train the character by precept and example, for, after all, "the foundation of culture, as of character, is at last the moral sentiment. This is the foundation of power."

It is a common saying that manners make the man. Good manners afford us easy weapons with which to win friends and to conquer enemies. Manners adorn the gentleman and smooth the way of the educated man through the world. Manners are never born in men; but they are bred by association and study. Like oil on the journals of an engine, they avoid friction and aid efficiency. There are many reasons why we should be polite, but the best reason is because it pays; it costs nothing. It is said of William Earl of Nassau that he won a subject from the King of Spain every time he put off his hat. So engaging were the manners of Charles James Fox that Napoleon said of him on the occasion of his visit to Paris in 1805: "Mr. Fox will always hold the first place in an assembly of the Tuileries." "My gentleman," said Emerson, "will outpray saints in chapel, out-general veterans in the field and outshine all courtesy in the hall. He is good company for pirates and good with academicians; so that it is useless to fortify yourself against him; he has the private entrance to all minds, and I could as easily exclude myself as him."

Good speech is a rule of manners. It always avoids exaggeration. Moderation in language and tone is the trademark of good breeding, and good breeding is after all mainly a matter of self culture. Madame de Staël valued conversation above everything, and so engaging was she in that art that a prominent lady of France said of her: "If I were Queen I should command her to talk to me every day." The man of education mixes with the right kind of people and reads good books. Books lead us into pleasant paths of culture and happiness. Read that you may avoid worry; read that too much hard thinking may not dull the edge of intelligence and sap the roots of memory; read that you may know what has been done in the world; read that you may acquire that power which comes from knowledge; read that you may learn to value the example of great men's lives; that through them you may know that the grave is not the goal of life. Montaigne had a passion for books and never traveled without them; he said that reading roused his reason and employed his judgment rather than his memory.

But of greater importance than good speech and reading, of higher value to the engineer than manners, is ability to write good English. Engineers are not given to public speaking; they pride themselves in being workers; they compare themselves with General Grant who did things. It is very true that the engineering profession is one of practical work; but no one can hope to achieve prominence in this profession who cannot write good understandable English. An engineer may not talk, but he must make reports; he must write letters; he should draw specifications and plans. To do these things properly he must command and know how to use the tools of language. Lord Bacon tells us that "reading makes a full man, conversation a ready man and writing an exact man." Engineering is an exact science; accuracy is the one column on which the whole structure is reared. To write clearly and accurately can hardly be called an accomplishment; it is really a necessity. No college course is complete, whether it be a classical, scientific, medical or law course, without a thorough training in English. No graduate is worthy to be called an educated man who does not speak and write good English. It lifts a man above the common; it makes him bigger than his business or profession; it trims the ship of knowledge and puts oil on rough places; it makes the man.

Margaret Fuller said that the object of life is to grow, and James Freeman Clarke has written a lecture upon this subject, "Man's Duty to Grow." A post-graduate course in self-culture will tend to upward growth. Such a course is open to every one. The greatest opportunities for that education which unfolds the whole nature of man are those which are opened when we close the college door behind us. Graduation only marks the beginning of education to one whose face looks forward and upward. Let us build high; "they build too low who build beneath the stars." Build so that life and strength and growth may vitalize the whole structure; build on lines that are straight; build so that every root and branch of the tree of knowledge lends support and does not add a twist to the whole; build that men may see in you not alone skill and wisdom, but honor, culture, manhood, example; study to improve self—

"For virtue only makes our bliss below,
For all our knowledge is ourselves to know."

Synopsis of Metallurgical and Chemical Literature.

Iron and Steel.

Utilization of Waste Heat of Open-Hearth Furnaces in Boilers.—In an article by A. Pfoser in *Stahl und Eisen*, p. 405 (March 7, 1912) it is pointed out that the temperature of flue gases of open-hearth furnaces ranges usually between 600 and 700 deg. C. (1100 and 1300 deg. F.), so that the heat lost by the flue gases is quite considerable. Mayer, in his book on open-hearth furnaces* gives the following approximate heat balance sheet for an open-hearth furnace:

Total net efficiency	27 per cent
Radiation losses of furnace and regenerators	29 per cent
Flue gas losses	31 per cent
Combustibles left in producer ashes	3 per cent
Radiation losses of producers	10 per cent
Total	100 per cent

By utilizing the heat now lost in the flue gases the furnace efficiency could, therefore, be increased quite considerably, but at the present time no means are available to recuperate them in the furnace system. The idea of enlarging the dimensions of air and gas regenerators in order to increase the preheating effect, is impractical, since the temperature of air and gas when leaving the checkers is already as high as the temperature of the flue gases. The heat available in the flue gases must therefore be used for other purposes outside of the furnace.

If it is possible to utilize the heat in the waste gases which is rendered available by reducing the temperature from 600 or 700 deg. C. (1100 or 1300 deg. F.) down to 300 deg. C. (about 570 deg. F.), a furnace of 34 to 35 tons capacity with a coal consumption of 1350 kg (2970 lb.) coal per hour (7200 calories per kilogram or 13,000 B.t.u. per lb) is able to yield 1800 kg (3960 lb.) steam per hour at 10 atmospheres (or 147 lb. per square inch). Under the assumption of evaporating 8 lb. water per pound of coal during 300 days a year and with a coal price of $4.00 per ton of 1000 kg or 2200 lb., the saving per year will be $6360, or in other words, there will be a net saving of 225 kg (495 lb.) coal per hour or since the present coal consumption is 2970 lb. per hour, the net saving will be 4950 ÷ 297 = 16.7 per cent.

The heat balance of such an open-hearth furnace would now appear as follows:

Total net efficiency (27.0 + 16.7)	= 43.7 per cent
Radiation losses of furnaces and regenerators	= 29.0 per cent
Flue gas losses (31.0 — 16.7)	= 14.3 per cent
Combustibles left in producer ashes	= 3.0 per cent
Radiation losses of producers	= 10.0 per cent
Total	100 per cent

With a flue gas temperature of 600 to 700 deg. C. (1100 to 1300 deg. F.) the pound of coal (with a calorific value of 13,000 B.t.u. per lb.) produces therefore 1.33 lb. of steam of 147 lb. gauge pressure. Some difficulties, however, have to be overcome since the furnace draft would be injured by such a boiler installation. It is important to maintain a good draft at the stack base, but with the additional frictional losses in the boiler arrangement the ordinary height of the stack of 144 ft. will not be able to overcome this. The height of the stack would have to be increased considerably, which, in most cases, would hardly be practical. The use of artificial draft, however, is quite practicable and the installation would be paid for in 1½ or 2 years by the gain figured above. With artificial draft and with an economizer the waste gases can be cooled down even further to 300-400 deg. F., so gaining an additional 20 per cent steam production. The author, A. Pfoser, has already successfully put in operation such flue-gas boilers in connection with zinc and glass melting furnaces where they have given excellent results in practice, in spite of the much lower flue-gas temperatures. He concludes that for open-hearth furnaces the system would be even more profitable.

*Dr. F. Mayer, Die Warmetechnik des Siemens Martin-Ofens, 1908.

Nickeliferous Pig Iron.—An abstract in *Stahl und Eisen*, 1912, p. 708, gives results of two melts made by H. Thaler, one with a carbon content of 3.5-4 per cent, the other with 1.5-2 per cent carbon, the nickel varying from 0 to 48 per cent. In high-carbon iron a nickel content of 1 per cent was sufficient to separate half of the carbon as graphite; this segregation increases with the nickel content and reaches its maximum at 47.78 Ni, where 85.71 per cent C has segregated as graphite. The freezing point of the high-carbon set rose from 1122 deg. C. to 1240 deg. C., in the low-carbon series it remained at about 1350 deg. C. The perlite point, however, drops, while nickel is increased up to 6.4 per cent from 710 deg. to 550 deg. The structure of the white pig iron is considerably changed by a nickel content of only 1.08 per cent. The perlite structure is hard to notice; the carbon is segregated as graphite. This segregation increases with the content of nickel and the perlite disappears more and more. Instead of perlite fine needles of cementite appear, surrounded by troostosorbitic seams. (The original paper by Thaler was published in *Giess. Zeitung*, 1912, Feb. 1 and March 15.)

Gold and Silver.

Principles of Agitation.—In a review of the development of agitation as applied to cyanidation of slime pulps, Mr. L. C. TRENT, of Los Angeles, Cal., gives some ideas on the proper method of application and quantity of compressed air which will give the best results. His article is found in the June, 1912, issue of the *Mexican Mining Journal*.

While air is indispensable to the perfect action of the cyanide process, only a limited quantity can serve a useful purpose in aiding dissolution of the precious metals, and the author is of the opinion that any excess over this amount not only does no good, but is absolutely a detriment on account of the various reactions which it brings about between the chemicals in the cyanide solution. Alkalinity is destroyed by the action of oxygen on the sulphides in the ore, and by the reaction between carbon dioxide in the air and calcium hydrate, forming calcium carbonate. Cyanide is oxidized and rendered unfit for further solution of gold and silver. The author likens the action of the air-lift agitator to a Bessemer converter, in which the great volume of air blown through the charge creates a number of chemical reactions, most of which are not useful in dissolving the precious metals, but merely cause loss of expensive chemicals. He believes, therefore, that it is quite as essential to regulate the quantity of air used in cyaniding as to regulate the use of any chemical reagent that is employed in the reaction.

Instead of applying air in large volume and allowing it to pass through the solution in large bubbles or masses, it should

be applied in a finely divided condition, so that it can be retained in the mass of the pulp as long as possible. The author therefore prefers methods of mechanical agitation, in which a necessary amount of air is admitted to the solution circulating through the pump, instead of using compressed air for agitation. He claims that the latter method chills the charge by expansion of the compressed air, thus extracting heat useful in causing solution. Atomized air sent into the charge with the circulating pulp does not chill the charge because the compression essential to entering is obtained from the liquid, and the heat of compression is retained, rather increasing the temperature.

It is the opinion of the author that the science of agitation offers numerous avenues for research.

Slime Treatment in Victoria, Australia.—In the *Mining & Engineering Review* (Melbourne) for April 3, 1912, W. J. Nicol describes the treatment of current and accumulated slime at the Lord Nelson mine. The former assays from 24 to 40 grains per ton, and the latter averages 31 grains per ton. This gives a gold value ranging from $1 to $1.65 per ton for current slime, and about $1.30 for the old material, and it is apparent that there is not a wide margin for profit after deducting operating expense and allowing for loss in tailings. The old slime is mixed with barren cyanide solution in a vortex mixer, and combined with current slime which has been dewatered as much as possible. This mixture is agitated in mechanical agitator tanks fitted with four-arm stirrers running at 7 r.p.m. There are five of these tanks of 31 tons capacity each, and three of them are filled and emptied daily. The agitated pulp is pumped to filter tanks, each containing twelve leaves 9 ft. by 5 ft., having an effective filtering area of 1080 sq. ft. These leaves are manifolded in the usual way, and connected with wet vacuum pumps. With the three-tank system of filtration the flow of slime and wash water to the tanks approximates continuous operation, and the discharge of residue is much more nearly continuous than with single tank arrangement. At any one time, one tank is filled with slime and a cake is being formed, another tank is filled with wash water and the cake is being washed, while the third is either discharging residue or waiting for another slime charge. The capacity of the filters is determined by the time required to satisfactorily wash the cake, which varies from 45 to 60 minutes. The cake averages 13 lb. dry slime per square foot of filter area, and allowing 50 minutes for washing, the capacity of the plant if about 7 tons per hour. Precipitation is by zinc shavings. The solution is strengthened immediately before precipitation as a strength of not less than 0.03 per cent KCN is found necessary for good precipitation. No figures are given as to cost of operation, but the plant had been in operation for about eight months when these notes were contributed. Operation was undertaken only after the completion of numerous tests.

Lead and Zinc.

Magnetic Separation of Pyritic Blende Concentrates.—It sometimes happens that plants erected for the treatment of ore must be altered on account of an unexpected change in the character of the ore. Such was the case at the Pierrefitte Mines, Hautes Pyrenees, France, where the original ore was argentiferous galena with blende, but which later became more and more pyritic in character. The manner in which this difficulty was overcome is described by E. C. Hugon in *Bulletin* No. 92, I. M. M. (London).

The choice of methods for separating the pyrite from the blende seemed to lie between electrostatic separation on the one hand, and either wet or dry magnetic separation on the other. The former was soon eliminated on account of the varying character of the ore and the difficulty of getting reliable data or having tests made. Samples of the ore were submitted to two firms manufacturing wet magentic separators, and to one firm making separators working on roasted ore. The results obtained were as follows:

		Zinc			
		%	%	%	%
Wet, No. 1	[illegible]	32.6	19.5	41.0	79.2
Wet, No. 2	[illegible]	33.7		41.9	90.2
Wet, No. 3	[illegible]	33.7		40.7	93.0
Roasted Ore	[illegible]	34.5	18.4	46.4	98.0
Roasted Ore	[illegible]	34.5	18.4	45.4	97.0

Apparently the roasting process gave much better results, both as to grade of zinc concentrate produced and percentage recovery. The better enrichment by this process allowed for marketing blende containing silicious matter, thus avoiding regrinding and further treatment loss, at the same time offering the opportunity of getting a higher price per unit of zinc in the ore. The selling price per ton of zinc in blende rises rapidly with the increased percentage of zinc, while the loading and transport charges per ton of zinc is decreased materially with the higher grade of cencentrate.

Accordingly a plant was installed to treat the pyritic blende product from the wet concentrator. The roasting furnaces installed are of the McDougall type, with five hearths; the cooler consists of sixteen water-jacketed tubes arranged circularly around a hollow cast-iron axle rotated by worm gearing. The inner tubes through which the ore passes are 3 in. in diameter, and the outer tubes 4 in., thus providing an annular space of 1 in. for water jacket. The cooled ore is screened and the undersize treated on a magnetic separator, making but two products, blende and pyrite concentrates. The capacity of the two furnaces is 50 tons in 24 hours; of the cooler, 40 to 50 tons, and of the separator, 70 tons.

Flotation of Minerals.—In our issue for August, 1911, p. 426, we reviewed the work of an Australian investigator in the principles of flotation. In the *Australian Mining Standard* for April 11, 18, 25 and May 2, 1912, the same author, Kenneth A. Mickle, publishes a continuation of his researches in flotation.

The flotation processes which have become such a factor in concentration, particularly of zinc ores, depend for their success on differential gas and liquid attaching phenomena. The sulphides are floated by the agency of gases alone or by oily substances.

Attachment of Gases and Liquids.—Pure water on being agitated shows little tendency to form a froth, or, in other words to show an attachment of gas particles to itself. In order to determine an approximate measurement of the attachment of air to water and to other liquid mixtures, the author added to a given quantity of water (60 cc.) a drop of various oils and agitated the mixtures vigorously with air, noting the amount of froth produced. The following list of oils is arranged in the order of their froth producing qualities, the first giving the greatest froth; (1) saponine; (2) turpentine, phellandrene, residue from eucalyptol; (3) refined petrol, acetic acid; (4) eucalyptol, crude shale oil, cotton seed oil; (5) oleic acid, combustion engine oil; (6) shale residual oil, shale turpentine substitute, Austral machine oil; (7) kerosene; (8) alcohol, oil of wintergreen, naphtha, gasoline, petroleum ether, sulphuric ether. The opacity of these mixtures was also noted as an index of the attachment of oil and water particles. The following list gives the results of the opacity tests, the oils being arranged in the order of the intensity of opacity produced: (1) oil of wintergreen; (2) turpentine, cotton seed oil; (3) residue from eucalyptol; (4) Austral machine oil; (5) phellandrene; (6) kerosene; (7) naphtha.

In the case of the other substances a clear solution was obtained as the result.

Absorption of Oil.—In an effort to get some measure of the degree to which various sulphide minerals would absorb various oils, the author agitated various quantities of different ores with 200 cc. water and 5 grams of oil, both with and without 0.5 grams sulphuric acid. While it is impossible to give here the details of all the tests made, we present the author's conclusions as to the effect of oil and acid on sulphide and gangue minerals.

(1) Gangue minerals in oil and water exhibit a mild tendency toward attachment of oil and mineral in preference to the attachment of oil and water. In acidulated solutions this tendency is lessened.

(2) Sulphide minerals in oil and water absorb varying amounts of oil. Large proportions of oil tend to form magma, and smaller proportions plastic masses and coherent aggregates. The character of these oily magmas depends on the amount and character of the oil used. Thick oils give viscous, coherent products and thin oils less coherent masses. Oily magmas with considerable proportions of oil will entangle and hold gaseous bubbles with a degree of persistency which depend on the viscosity of the oil. Sulphides carrying an absorption of about 5 per cent of oil tend to attach gaseous bubbles, and this tendency increases as the proportion of oil diminishes until a certain limit is reached, which is 0.5 per cent or thereabouts. Absorption is more pronounced with sulphides than with gangue minerals. The amount of oil absorbed depends on the surface exposed.

(3) Sulphide minerals in acidulated water and oil act as above, but the adsorption of oil by the gangue minerals is decreased. The maximum amount of oil absorbed by sulphides in a stable manner when crushed to 80 mesh is in the neighborhood of 10 to 15 per cent of their weight. Such a small quantity of oil as 0.1 per cent cannot be separated from the mineral by any mechanical means, and such quantity may be regarded as through adsorption. When more oil is present it is probable that a secondary envelope becomes attached to the primary film.

Adsorption of Gases.—Investigation was made of gas absorption by the following experiments. Pieces of copper and silver foil were cleaned by boiling in caustic soda, washing in water and drying. Cleaned and uncleaned pieces of foil were then placed in a vacuum flask in (a) ordinary distilled water, (b) air-free distilled water and (c) ordinary tap water, and subjected to reduced pressure of 26 in. mercury. In the case of the cleaned foil, a few bubbles collected on it in the distilled water, while in the tap water enough bubbles collected to float the foil. In the case of the uncleaned foil enough bubbles collected on it in the ordinary distilled water and ordinary tap water to float the foil, but in the air-free distilled water very few bubbles were formed. On repeating these experiments in water to which a drop of oleic acid had been added and agitated, in all cases the cleaned and uncleaned foils floated by reason of the attached gas bubbles. These experiments show that the persistence of attachment of bubbles is increased when the surface of the foil is contaminated by some oily substance.

Cleaned and dried needles would not float on the surface of freshly drawn distilled water, but when either the needles or water was allowed to stand in contact with the air for some time the needles would float.

Cleaned and uncleaned pieces of iron wire were submerged in a saturated solution of carbon dioxide, with the result that the cleaned pieces collected very few bubbles on their surfaces, while the uncleaned ones were shortly covered with a fine frost of bubbles and caused to float to the surface. This shows that gas attachment is enhanced by a superficial coating of oily matter.

Some Broken Hill jig tailings were cleaned with acid and distilled water and submerged in a solution of carbon dioxide. Gas bubbles collected on the sulphide mineral, but except in the case of a few pieces of garnet the gas did not collect on the gangue minerals.

The gas collected from sulphide mineral which had been separated by an oil process gave the following analysis: Nitrogen 72 per cent, oxygen 2 per cent, carbon dioxide 26 per cent. The gases collected by subjecting dry minerals to reduced pressure showed varying, but large, quantities of carbon-dioxide. It was also shown that more gas was collected from the sulphide minerals than from calcite and quartz. That this gas is not derived from the decomposition of carbonates during the experiment is shown by the negative results obtained from calcite and cerussite. There is apparently a condensation of carbon dioxide on the surface of sulphide minerals, and the fact that slime mineral shows this tendency to a greater degree than coarse grains would indicate that the phenomenon is a surface action.

Recent Metallurgical and Chemical Patents.

Continuous Vacuum Filter.—In Fig. 1 we show a sectional elevation of a form of filter for cyanide pulps which has been patented by HARRY E. KIER, of Colorado Springs, Colo. It consists of an endless chain of filter sections or pallets traveling around sprocket wheels placed at the apices of an imaginary isosceles triangle. Each section is connected by a flexible tubing 23 with the circular valve which occupies a central position behind the sprocket wheel 26. This valve has one long port connecting with a vacuum pump, and one short port connecting with a source of compressed air. In operation the chain of filters moves in the direction of the arrow, and pulp is fed onto the filters from the launder 20. At this time the

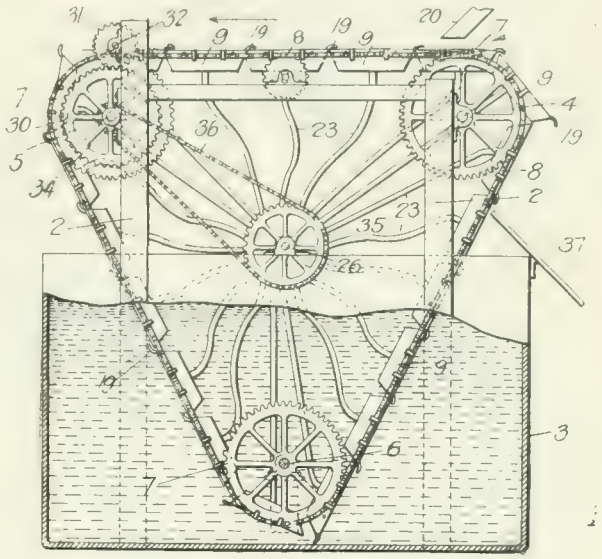

FIG. 1.—CONTINUOUS VACUUM FILTER.

valve connection is such that vacuum is applied to remove the valuable cyanide solution. This suction continues until the sections traverse the other two sides of the triangle, passing through the tank 3 containing wash water. On reaching the upper right hand sprocket the suction is cut off and compressed air applied to force the cake from the filter section, whereupon it drops off onto the deflectors 37 and falls into a suitable car. Apparently no provision is made to keep separate the pregnant solution separated from the original pulp and the washings which pass through the cake during its travel through the water tank. (1,026,917, May 21, 1912.)

Gold and Silver.

Precipitation by Atomized Lead and Zinc.—In this journal, March, 1912, p. 180, was described mechanical means for producing finely divided, or "atomized" metals, such as lead and zinc. In a later issue, May, 1912, p. 305, we mentioned a patent granted on the process of atomizing. More recently another patent has been granted to James M. Neil, of Toronto, Canada, on the process of precipitating precious metals from cyanide solutions, by means of atomized metals. The inventor has discovered that when finely divided lead and zinc are added to a cyanide solution of gold and silver, these metals are precipitated more efficiently and rapidly than when zinc dust is used. In carrying out his invention, atomized lead and atomized zinc are used, in the proportion of about one part lead

to one or more parts zinc. The best method of adding the metals is to use them separately in the following manner: Cyanide solution is run into a suitable tank fitted with agitating apparatus. Atomized lead is then added to the solution in the proportion of about 100 lb. lead to 10,000 gal. cyanide solution. This mixture is then thoroughly agitated, and while

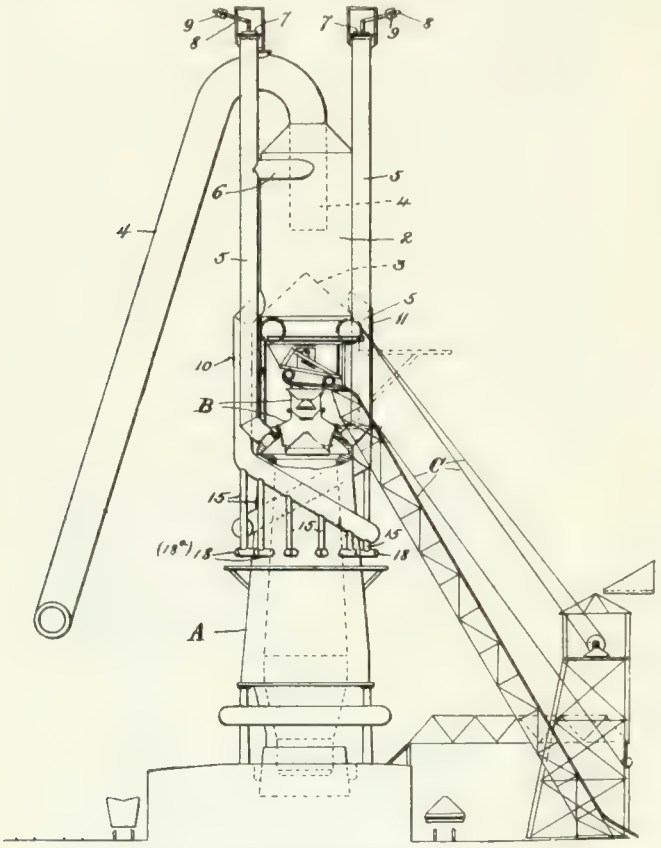

FIG. 2.—DUST CHARGING DEVICE FOR BLAST FURNACE.

in agitation it receives successive charges of atomized zinc until the usual tests indicate complete precipitation. The mixture may then be allowed to settle, the barren solution drawn off and the precipitate recovered. Or, a new quantity of solution may be added to the precipitate of lead and precious metals, and after agitation, successive quantities of zinc as before.

The added zinc goes into solution, replacing the precious metals, but the lead remains as finely divided metal, and is useful in the subsequent process of refining. The inventor claims a precipitating efficiency of over 95 per cent of the zinc used (1,023,524, April 16, 1912.)

Iron and Steel.

Charging Fine Ore and Dust.—To overcome the objections to charging fine ore or dust into the blast furnace at or above the stock line or into the crucible with the blast, JOHN W. DOUGHERTY, of Steelton, Pa., has designed a charging device which can be used for this purpose. Fig. 2 illustrates a blast furnace with the device attached. The gases rising out of the furnace *A* pass into the pipes 5, of which there are four, and continue through branch pipes 6, being discharged tangentially into the dust collector 2 having a conical bottom 3. By this means little dust passes on through the down-comer 4 which extends some distance into the dust collector.

Connected with the bottom of the dust collector are delivery pipes 10 and 11 which conduct the accumulated dust by gravity to vertical supply pipes or pockets 15 that supply the dust to the charging devices, one of which is illustrated in Fig. 4. This is a screw conveyer placed in alignment with an opening in the furnace below the stock line. As dust accumulates it is forced into the furnace at a point from which it cannot well be blown out by the blast, and where it probably will be sintered and form part of the charge. Should dust accumulate too rapidly to be handled by the charging screws, it can be conducted by suitable connections to a storage receptacle and later returned to the dust collector. If the latter should be-

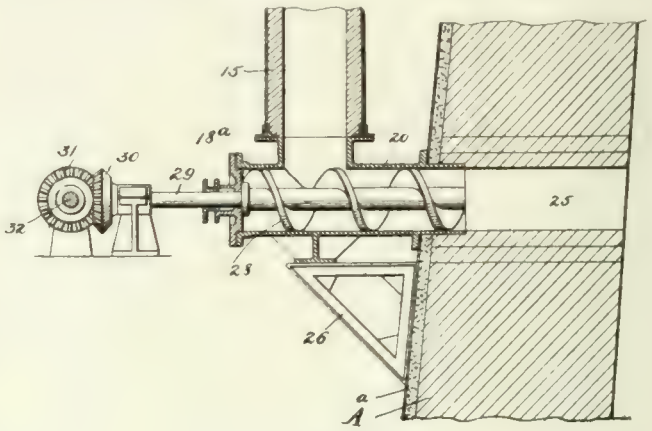

FIG. 4.—DUST CHARGING DEVICE.

come filled with dust and prevent the gas from passing through it, the bell bleeder valves 7 on top of the pipes 5 will automatically release the gas coming from the furnace. (1,024,623, April 30, 1912.)

Merton Roasting Furnace.—In all rotary rabbled rectangular roasting furnaces hitherto in use, the rabbles are so positioned as to cut deeply into each other's field, the result being that a portion of partly roasted ore is carried back toward the feed end of the furnace by the circular travel of the rabbles, where it mixes with green ore discharged onto the hearth. In a roaster designed by THOMAS D. MERTON, of Grove Mill, Watford, England, this undesirable feature is overcome, and the hearth, or hearths, of the furnace is divided into zones in which the ore is retained until it has received the complete treatment, after which it may progress into the next zone, but never backward into a zone from which it has come.

The furnace is illustrated in sectional end elevation and in plan of hearth in Figs. 3 and 4. Referring to Fig. 3, it will be seen that the rabbles are arranged in series, 1, 2, 3, 2, 1, forming zones or areas on the hearth. Ore enters the furnace at *M* and is engaged by the first rabble, and spread over the

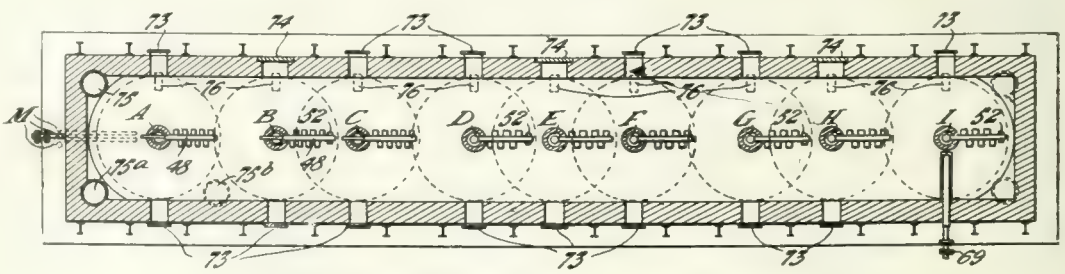

FIG. 3.—HEARTH PLAN MERTON ROASTING FURNACE.

area covered by the circle which the rabble describes. On the end of the arm of the second rabble is an oblique-shaped plow

which cuts slightly into the zone of rabble No. 1, and removes from the first zone a certain amount of ore at each revolution. This ore is then spread over the area covered by the two rabbles in the second zone, where it is mixed and stirred without any part of it being allowed to return into the first zone. In similar manner the ore is cut into the third zone, then into the fourth and fifth. It will be observed that the rabbles in the second, third and fourth zones cut deeply into each other's field, thereby causing thorough mixing of the ore and exposure to the roasting influences. In the fifth zone the ore is caused to travel in successively reduced circles to a central point of discharge, from which it may be allowed to pass completely out of the furnace, or fall onto the next hearth below for further treatment, traveling in the opposite direction.

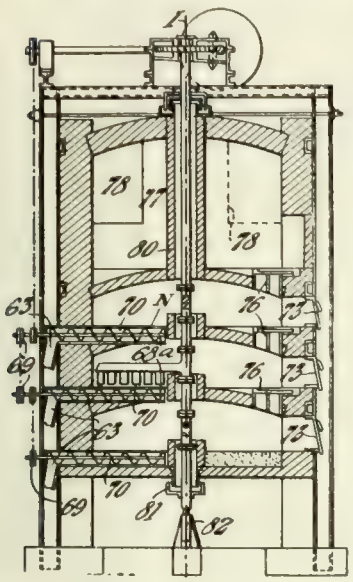

FIG. 4.—SECTIONAL END ELEVATION, MERTON FURNACE.

The manner of discharge is illustrated in Fig. 4, where an Archimedean screw revolving in a cast iron case is shown connected with the point of discharge. This screw may be made to deliver the ore from the furnace; or by means of perforated slides in the screw casing, the ore may be passed onto the hearth below. (1,022,961, Apr. 9, 1912.)

Lead and Copper.

Smelting Furnaces.—In this journal, December, 1910, p. 671, was described the essential points of the so-called Partridge smelting furnace. A patent recently issued to the inventor, ALLEN R. PARTRIDGE, of Denver, Col., covers practically the same points as given in the foregoing reference. The principal points about the furnace are the utilization of the heat of the slag in pre-heating the air blast, and the substitution of a complete circular opening between crucible and furnace shaft in place of the usual tuyeres. Fig. 5 in the adjoining column shows the application of these points. The water-cooled furnace shaft is shown at *B'*, with the crucible *D* enclosed in a crucible box *C*. The slag flowing from the crucible falls onto a train of slag cars *K* which revolve about the central support *N*. Air enters the enclosed slag box at *T*, passes over the hot slag and rises to the crucible chamber, where it enters the stack through the narrow circular slot between crucible and shaft. (1,025,922, May 7, 1912.)

A similar device has been patented by ALFRED D. LEDUC, of Rouen, France, in which the inventor makes use of a slot between upper and lower water jackets as a continuous tuyere, preferring this arrangement to the customary individual tuyeres. (1,025,531, May 7, 1912.)

Refining Scrap Lead.—The treatment of old storage battery plates and waste material from lead accumulators is the subject of patent granted to JULIUS ASBECK, of Krantscheid-Westerwald, Germany. He claims that pure lead can be obtained from such material by melting it at a low temperature with a flux of caustic soda and sulphur or a sulphur compound as sodium thiosulphate, sodium sulphide or sodium polysulphide. Appropriate mixtures consist of 3 parts of caustic soda to 1 part sulphur; or equal parts caustic soda and sodium thiosulphate; or 3 parts caustic soda and 1 part sodium sulphide or polysulphide. A temperature of only 400-500 deg. C. is necessary. (1,025,050, May 14, 1912.)

Refining Copper.—A method of refining molten copper has been devised by WALTER A. ROCKEY and HILLIARY ELDRIDGE, of New York, N. Y. To carry out the process the copper is first fused and then poured into a fused bath of boron trioxide, or one containing that compound. The inventors prefer to carry out the process by causing the copper to flow downward into the flux, through the flux and upward out of the flux. During this time of contact the temperature is maintained at the required point to expel all or a majority of the occluded gases and to permit solution of the oxides by the fused boron trioxide. (1,027,769, May 28, 1912.)

Sintering Ores—Additional patents have been granted to ARTHUR S. DWIGHT, of New York, N. Y., in connection with his method of roasting and sintering ores for blast furnace

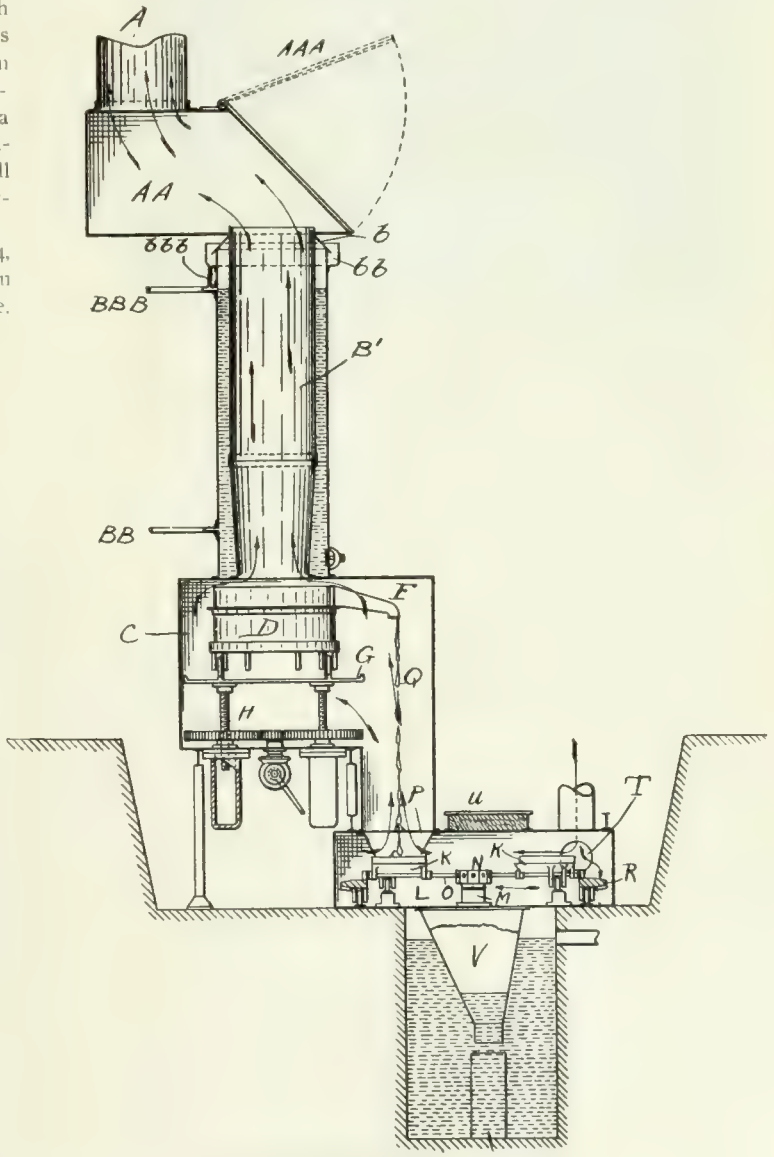

FIG. 5.—HOT-BLAST SMELTING FURNACE.

treatment. These machines have been described in this journal February, March and May, 1912, pages 87, 162 and 320, respectively. (Reissue 13,423-4, May 28, 1912, and 1,027,110, May 21, 1912.)

The Parral Tank System of Slime Agitation.

By Bernard MacDonald.

For the efficient treatment of ores amenable to cyanidation, it has been found, in the majority of cases, especially with silver ores, that the "all-sliming" method of preparation is essential. When the ore is pulped in water to *a slime* the finest particles of the gold and the silver compounds in it are liberated from the enclosing vein matter, and thus freed and

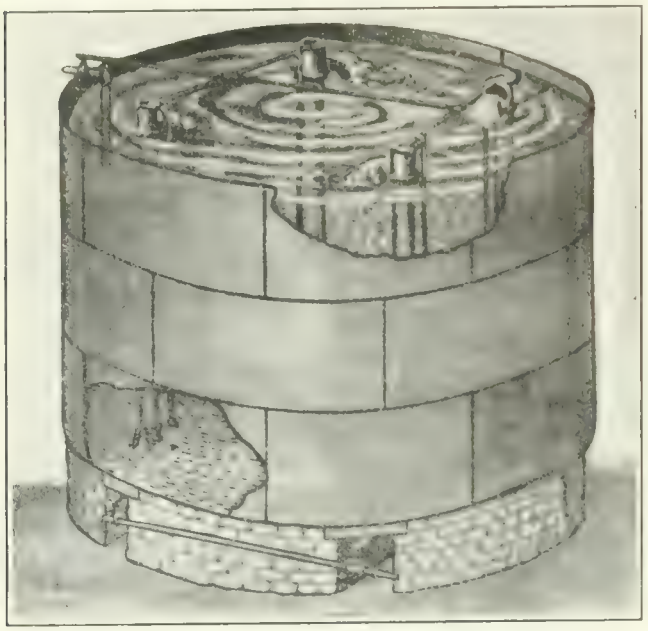

Fig. 1.—PARRAL TANK.

themselves reduced to impalpable slime, they are in the most favorable condition to be dissolved by the cyanide solution.

The cyanide solution, which is the water constituent of the slimed ore, contains dissolved in it the cyanide and other chemicals required for the treatment and is mixed with the slime in ratios ranging from 1 to 2 by weight (approximately 2½ to 5 by volume) according to requirements.

The ideal condition of the slime for treatment is to maintain its solid and solution constituents in proper proportional mixture, that is, to have each infinitely small particle of the solids surrounded by 2½ to 5 times its own volume of solution at all times during the treatment period, incidentally giving it such free contact with the air that it may absorb the amount of oxygen required for the chemical reactions.

The operation by which this condition is maintained is called "agitation" and is carried on in tanks which contain the pulp. Tanks have no other function in a cyanide plant than to serve as economical and convenient containers or receptacles for holding the pulp, solution or water used in plant operation and they may be built of wood, steel or concrete and be of such shape or size as may be suitable for the quantity of pulp to be treated daily or the method of agitation employed.

Various methods or systems have been designed for agitation, and these may be installed and operated at various costs and degrees of efficiency and economy. In a paper read at the San Francisco meeting, October, 1911, of the American Institute of Mining Engineers, which now appears in the *Transactions* of the Institute, I have described the characteristic features of the more prominent of these systems, and therefore it is not necessary to repeat what has been said there in this respect.

The object of all the systems of agitation is, of course, to maintain the solid and solution constituents of the pulp undergoing treatment in proper proportional mixture, providing at the same time the aeration necessary for the chemical reactions. The more efficiently and economically this object can be obtained by any system the higher that system will rank commercially.

The Parral Tank System.

During the past eight years the writer has been almost exclusively occupied in the design and construction of cyanide plants in Mexico, and a considerable portion of this time has been devoted to the design and development of a system of slime agitation in which the defects of other systems would be eliminated and which would effect the object of agitation more efficiently and economically. The result has been the Parral tank system which I have installed in several plants in Mexico, where it has been in successful operation and has proved to be superior to any other system in the following particulars:

1. It costs less for construction by 60 per cent.
2. It is more economical in operation, using only about one-third the horse power.
3. It requires neither repairs nor renewals in plants, using it for the past 14 months.
4. It maintains the pulp constituents in proper proportional mixture during the treatment period.
5. It obtains a higher extraction of the values.

In elaboration of these characteristic features it may be said in order with respect to them:

1. That the comparative low cost of construction is due to the fact that the apparatus of the system will operate efficiently in tanks of any diameter and any height, leaving to be chosen such shape of tank as will have the greatest holding capacity

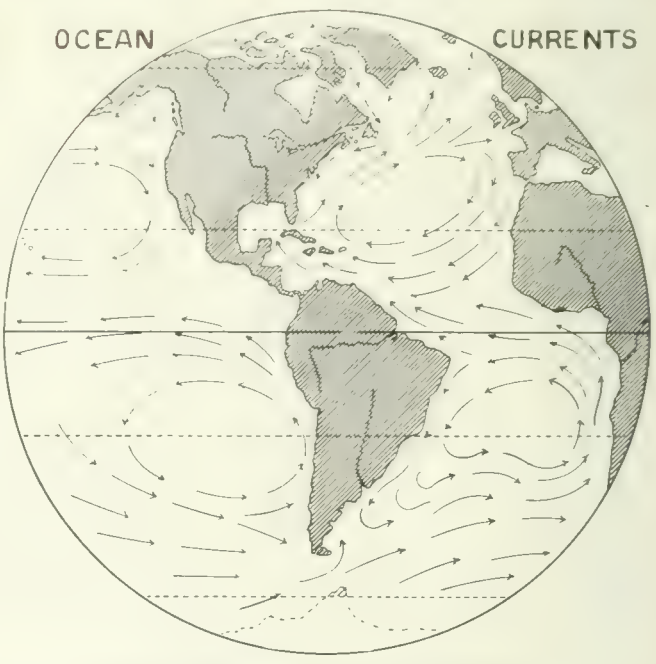

Fig. 2.—COMPARISON WITH OCEAN CURRENTS.

per pound of steel or material of which it may be constructed. Thus, in tanks for this system of approximately the same holding capacity as the standard tank of the Pachuca tank system, 157 lbs. of steel will be required for each ton of 2:1 pulp, whereas in the Pachuca standard tank 400 lb. are required. In other words, the cost of the raw material, freight and erection, is only about 40 per cent. of that for the Pachuca tank used for the same purpose. The same ratio holds with respect to other systems, which, like the Pachuca tank, require a tall, narrow shape of tank for their method of operation.

2. On account of the comparative low height of the Parral tank and the rotary flow which the plurality of transfer pipes peculiar to the system sets up in the tank-charge, only about one-third the horse power that is required for the Pachuca

tank is required for its operation. Other systems of agitation, which, in operation, require the settlement of the solids in the pulp to the bottom of the tank and draw the clear solution from the top of the tank and to effect agitation, force the clarified solution into the settled solids at the bottom, are operated at variance to the fundamental principles of agitation, and their high consumption of horse power and frequent renewals of parts are uneconomical.

3. In the Parral tank system of agitation there are no wearing parts except the air nozzle ball valve which has been in operation continuously for 14 mouths without showing any signs of wear or loss of efficiency, and, while these valves will naturally wear out some time, they may last several years. Side by side in the same plant there was used the rubber sleeve which protects the air nozzle in the Pachuca tank; this wore out in six weeks and in the meantime gave no end of trouble in starting up after the air was shut off for any reason, while the ball valve would start promptly without trouble under the same conditions.

4. In the Parral tank system the agitation is effected by a plurality of transfer pipes of comparatively small diameter through which the continuous transfer of the pulp from the bottom to the top of the tank is brought about by compressed air. The discharged ends of the transfer pipes are horizontal and so directed that the discharging pulp will spout in the same direction with respect to the interior side of the tank and in line with segment cords thereto. This method of discharge sets up a rotary current in the tank charge which flows round and round within the tank and keeps the whole charge in rotary motion from top to bottom of the tank. This rotary flow is one of the important features of the system, as it carries the heavier pulp particles in suspension in the solution and breaks up the colloidal agglomerations in the slime. In other systems of agitation, except that using stirring arms, the solid particles settle vertically out of the solution, and, of course, when separated from the solution, they escape reaction with the chemicals dissolved in it.

5. In the same plant under identical conditions the Parral tank system showed a three per cent. higher extraction of values than the Pachuca tank. This I attribute to the rotary motion in the charge which maintains the solids and solution in proper proportional mixture, effects the breaking up of the colloidal agglomerations and causes the friction of the solids *inter se* or in the revolving flow of the solution.

Fig. 1 illustrates a tank equipped with the apparatus of this system and how the rotary flow is created and maintained by the spouting of the transfer pipes raised a few inches above the surface of the tank charge.

It is difficult to comprehend how the discharge force of the pulp from the transfer pipes with a few inches of fall is sufficient to keep the entire charge revolving within the tank and prevent dead accumulations of the solids on the bottom.

But the fact is that it does. Indicating the sensitiveness of water to slight force, we have examples in the great ocean currents which, generated by the trade winds, revolve continuously between the shores of continents thousands of miles apart.

Fig. 2 shows the path of the Gulf stream in the North Atlantic, which is said to sweep the coral rocks on the sea bottom between Florida and Cuba as clean as a floor. Such is the effect of the rotary flow in the Parral tank system; there is no accumulation of solids on the bottom of the tank, and the solid and solution constituents of the pulp are kept in the proper proportional mixture, while the spouting of the pulp at the surface of the charge gives the aeration required for the chemical reactions.

FIG. 3.—EXTRACTION CURVES PLOTTED FROM RECORDS OF OPERATIONS IN PACHUCA AND PARRAL TANKS.

In addition to the points of superiority of the Parral tank system over others briefly referred to above, is the fact that the comparative low height of the tank practically removes the necessity for the elevating or pumping of the pulp into the tank, consequently the cost of elevators or pumps and their operation is done away with entirely or reduced to a minimum, and the pressure of the compressed air required for the operation of the transfer pipes is correspondingly lowered.

Fig. 3 is a reproduction of a diagram from the San Francisco paper, delivered before the American Institute of Mining Engineers above referred to.

It gives extraction curves plotted from records of operations in Pachuca and Parral tanks, samples taken every six hours and analyzed.

In explanation of the percentage column of the above chart, it may be said that more than 62 per cent of the head-values were extracted during the first six hours' agitation.

South Pasadena, Cal.

A Centrifugal Gaswasher.

Purification and Cooling of Blast-Furnace and Producer Gases—Recovery of Metal Dust from Gases of Lead and Copper Smelting Plants—Extraction of Tar from Coke Gases.

By Walther Feld

In another article published in this issue my new process is described for the direct production of ammonium sulphate from ammonia and hydrogen sulphide in coal gas without the use of sulphuric acid. Mention is made there of the Feld centrifugal washer by means of which the ammonia and hydrogen sulphide are washed out of the coal gas, but which is in general and successful use for any and every purpose in the treatment of gases or vapors with liquids. With the advantages of high efficiency due to the most intimate mixing of gas and washing liquid, and of low water consumption, the Feld gas washer combines such a high degree of simplicity and robustness of construction that it requires practically no repair and that clogging is practically impossible.

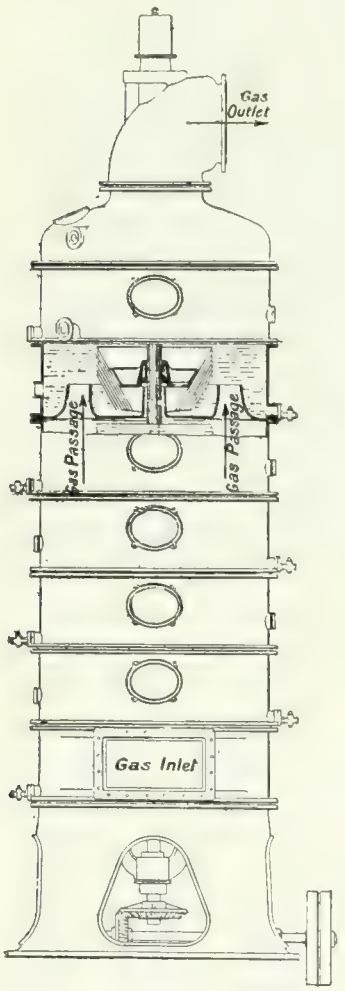

FIG. 1.—CENTRIFUGAL WASHER.

Twelve of these centrifugal washers with an aggregate capacity of 8,627,500 cubic meters (305,000,000 cubic feet) of gas per day are now in successful use for dust removal and cooling of gases; sixteen washers jwith 3,900,000 cubic meters (138,000,000 cubic feet) daily capacity are in use for washing out tar; three washers with 480,000 cubic meters (17,000,000 cubic feet) daily capacity for washing out napthalene; three washers with 420,000 cubic meters (15,000,000 cu. ft.) daily capacity for washing out cyanogen; eighteen washers with 4,695,000 cubic meters (166,000,000 cubic feet) daily capacity for washing out ammonia; nine washers with 1,050,000 cubic meters (37,000,000 cubic feet) daily capacity for washing out simultaneously ammonia and hydrogen sulphide according to the process sketched above; three washers of 420,000 cubic meters (15,000,000 cubic feet) daily capacity for washing out benzene, and seven washers of 840,000 cubic meters (30,000,000 cubic feet) daily capacity for fractional lignite distillation.

The washer which is shown diagrammatically in Fig. 1 is constructed on the centrifugal principle, and is composed of a set of chambers (Fig. 2)—say, three to six, according to the desired gas-treating capacity—placed one above the other. There is a central shaft, running on ball-bearings at the top of the apparatus, which shaft revolves at the rate of about 120 revolutions per minute. In each of the chambers there is a set of cones, each set consisting of three to six attached to the vertical shaft by means of a cast-iron hub. The lower ends of the cones dip into the dish shaped channel below, which contains the water or other liquid.

Through the rotation of the shaft the water is drawn up on the inside of the cones, and is thrown off at a tangent at the upper edge across the open space against the wall of the chamber. A thick body of mist, so thick that it presents a foam-like appearance, is thrown off from the tops of the cones at great velocity, and circulating in its fall with immense rapidity through the general impellent forces at work within the washer. The thought arises that the passage through successive thick seething sprays of this kind might have detrimental effect on the gas pressure; but, as a matter of fact, the

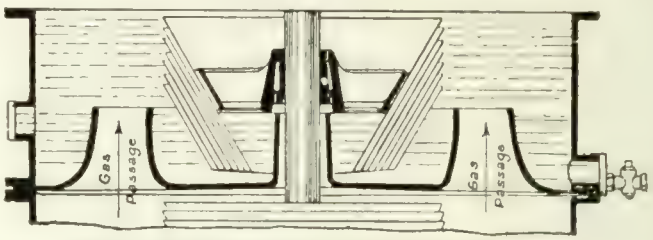

FIG. 2.—ENLARGED VIEW OF ONE OF THE CHAMBERS.

gas is sucked up and carried upwards by the whirling motion in such manner that the loss of pressure is surprisingly small.

The dish-shaped liquid container in which the sets of cones dip is provided, as stated above, with four gas-ways, which allow the gas to escape through the finely-sprayed liquid. The supply of water enters at the top, and the gas passes upwards from chamber to chamber, their courses thus being in opposite directions. The outflow of the liquid from the washer is regulated entirely by the inflow, plus what is taken from the gas. From this it will be seen that any concentration of liquor can be worked to by simply controlling the admission of the water and using the content of the washer over and over again.

The washer can be employed equally well with turbid liquids as with clear ones, and through the constant and rapid

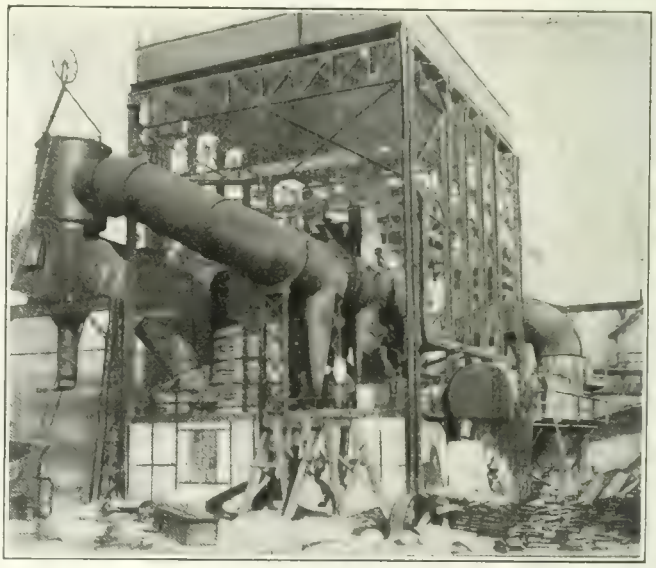

FIG. 3.—FELD CENTRIFUGAL GAS WASHER PLANT AT POMPEY STEEL WORKS.

rotation there can be no sedimentation. The washing liquid passes down from chamber to chamber; and the bottom of the apparatus is so devised that no settling can take place there. All of the liquid contents passes away at the bottom, and the gas, as mentioned, at the top.

The power required to drive the washer is very moderate. The smallest size washer, capable of treating about ¼ million

cubic feet of gas per twenty-four hours, can be driven by ½ horse-power, and so on up to the largest size, capable of dealing with 45 millions cubic feet a day, for which not more than 25 horse-power is needed. The washer can be driven by belt from a small steam or gas engine, or where there is an electric generating plant on the works by an electric motor.

Treatment of Blast-Furnace Gases.

The purification and cooling of blast-furnace gases gets more and more important in view of their high value for power production in gas engines. In Germany and France there is hardly a steel plant which does not use the surplus of gas for this purpose, thus deriving from these gases, which formerly

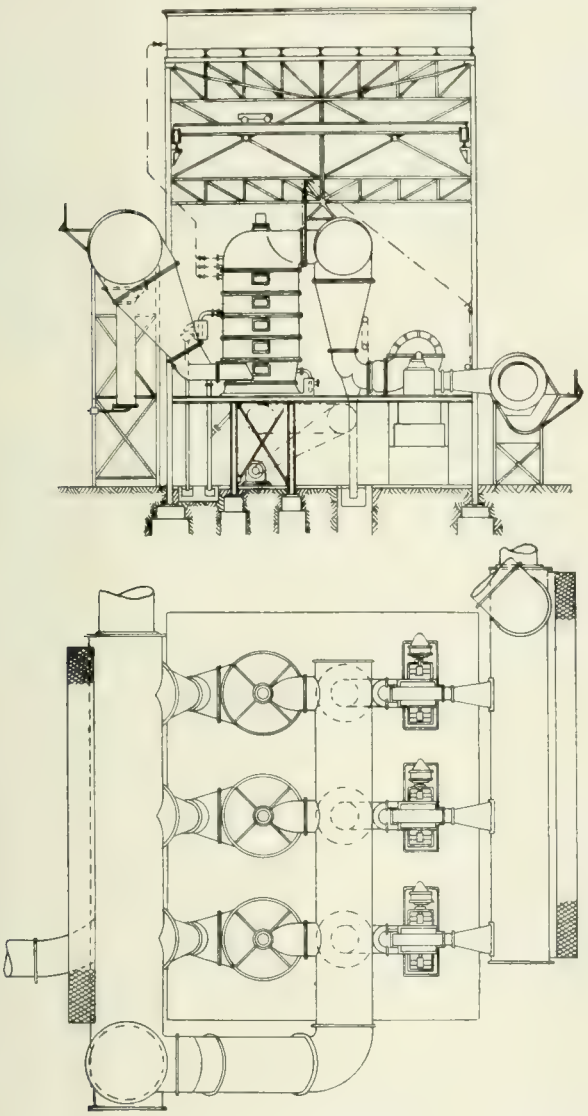

FIG. 4.—ARRANGEMENT OF THREE CENTRIFUGAL GASWASHERS.

went partially to waste, spoiling the surrounding atmosphere with their sinister fumes, an important additional profit. For this purpose the gases must be thoroughly purified from the dust contained therein and cooled.

Fig. 4 shows a Feld plant for the purification and cooling of 3½ million cubic meters (or 125 million cubic feet) of blast-furnace gas per day. This plant was started two years ago and has since been in continuous operation in the steelworks of Pompey, France. No repairs and no cleaning of the apparatus has been required in this period. Three parallel erected Feld washers are in operation, each with a maximum capacity of 1,250,000 cbm. per day (44,000,000 cubic feet per day).

The purification and cooling is done in the same apparatus. More than 97 per cent of the dust, etc., are extracted from the gases by passing one washer. The gases are supplied to the washers at the high temperature with which they come from the furnaces and the cooling is completed down to a temperature not higher than 5° C. above the temperature of the cooling water. The consumption of water is less than 20 per cent above the amount theoretically necessary.

The back pressure of the gases in the washer is lower than 50 mm. and therefore the consumption of power is very low. All three washers do not require more power than 60 hp.

Recovery of Metallic Dust from Lead and Copper Smelting Furnaces.

The recovery of metallic dust from gases of lead and copper smelting plants is accomplished by similar plant. In most of these works the fumes from the smelting furnaces are passed through chambers and long flues before they go to the chimney. In these chambers about 70 to 80 per cent of the metallic dust is separated from the gases, while the rest passes with the chimney gases into the atmosphere. There is no necessity to refer here further to the endless troubles which have arisen on this account, resulting in court injunctions of farmers against smelters, while the periodical cleaning of the dust chambers is a great danger to the health of the workmen.

On a daily consumption of 50 tons of lead, about 1,000,000 cubic meters (or 35,000,000 cubic feet) of gas are produced with about 8 grams of lead per cubic meter (or ½ lb. per 1000 cubic feet). The volume of the waste gases increases in the chambers and flues, by leakage through the brickwork, to about 2,000,000 cubic meters (or 71,000,000 cubic feet), and these gases, leaving the chimney, contain up to 1 gram of lead per cubic meter (or 1 ounce per 1000 cubic feet). The total loss may be estimated to be about 2 tons of lead per day.

Tests with the Feld washer on a big scale have proved that, in erecting a Feld washer immediately behind the ovens, before the gases enter the flues, more than 99 per cent of the metallic dust can be immediately recovered in form of a wet cake, containing about 70 per cent of lead. Thus the storing of and the dangerous work with the dust, and all periodical cleaning up is avoided. The value of the lead additionally recovered is about $100 per day, against about a cost of $50 per day for the operation of the Feld plant, including depreciation of plant and repairs.

The profit, in applying the Feld process to copper smelting works, will, of course, be considerably higher.

The treatment of the gases is the same as in the purification of blast-furnace gases, but, as it is not necessary to cool the gases, the water for purification can be used over and over again, and thus no waste water, containing free acids extracted from the gases, is obtained.

Tar Extraction.

For tar extraction from coal gas and producer gas the washer is equally in use with very satisfying results. More than 15 tar washers are now in operation. The following figures are obtained in a coke works at Monceau in Belgium, in treating the gases with a Feld washer at temperatures as high as 60° and 90° C.:

Temperature of the Gas.	60° C.
Tar entering washer	23.03 grams per cu. meter. = 1.44 lb. per 1000 cu. ft.
Tar leaving washer	0.1 gram per cu. meter. = 0.1 ounce per 1000 cu. ft.
Percentage of tar recovered in washer	99.6 per cent.

	90° C.
Tar entering washer	30.04 grams per cu. meter. = 1.88 lb per 1000 cu. ft.
Tar leaving washer	0.2 grams per cu. meter. = 0.2 ounces per 1000 cu. ft.
Percentage of tar recovered in washer	99.4 per cent.

This plant treats about 75,000 cubic meters (2,600,000 cubic feet) of gas per day and has been in continuous operation for the past eighteen months without requiring any cleaning of the apparatus.

The Feld washer is built by Walther Feld, Gasabteilung, in Linz am Rhein, Germany.

New Armored Stoneware Vessel.

By Percy C. Kingsbury.

In many industries the need has been felt for a vessel of large capacity that is unaffected by acids or other materials it may contain, and that can also be subjected to a considerable range of temperature without damage. Copper or iron vessels employed to meet these conditions are often an unsatisfactory makeshift for the lack of something better. Where the corrosion is rapid, the walls of the vessel have to be made exceptionally thick and often where the action on the metal is not enough seriously to affect the life of the apparatus, the slight corrosion may impair the quality or purity of the product.

For work on a small scale, chemical stoneware has obvious advantages but this valuable material has its limitations as vessels of a larger capacity than 150 to 250 gallons cannot safely be subjected to sudden variations in temperature.

A solution of the problem is offered by the Gehman-American Stoneware Works, of 50 Church Street, New York City, who have recently introduced a novel form of vessel that has found extensive application in Europe.

A cylindrical jacket having a rounded bottom, all of sheet iron is held together by cast-iron flanges so designed that by tightening up the bolts the whole is drawn together in a perfectly uniform manner. Into this jacket is built a lining of chemical stoneware tiles, each tile being carefully ground on all four edges so as to make a perfect joint with those adjacent to it. A special acid-proof cement forms a backing into which the tiles are laid and serves to take up the difference in the co-efficient of expansion of the two materials. When all the plates are in position and while the cement is soft, the flanges are drawn together placing the lining under strong and even compression and completely closing all the joints.

ARMORED STONEWARE VESSEL.

It is obvious that this method lends itself readily to the construction of vessels of very large capacity. The possibility of corrosion is completely eliminated, the vessels being internally for all practical purposes one homogeneous piece of stoneware with, however, one important difference. A large stoneware vessel to resist sudden changes in temperature cannot be highly vitrified and the acid-proof quality of such vessels is, therefore, largely dependent on the glaze, but in these armored vessels the plates forming the lining can be made as hard and dense as possible without risk or fracture from rapid expansion or contraction.

A frequent source of expense and danger eliminated by the new construction is the fragile nature of stoneware. Crystals may be chipped away from the walls of these armored vessels without risk and they cannot be damaged by the most careless treatment. The stoneware tiles are made from an iron-free clay, giving to the interior of the vessel a white glazed surface. The contents may be heated by the injection of steam or hot air or by heating coils. Connections can be made through the side or bottom of the vessel as desired. They are now made in nine standard sizes, varying from 130 to 2650 gallons capacity but can be supplied to special dimensions if required.

The vessels have a wide application, but their advantages should appeal particularly to dyeworks, and those interested in the manufacture of certain organic acids.

Sq.Ft. of Boiler Surface per Boiler Horse Power Developed.

Heat Transmission Through Conducting Surfaces

The Rationale of the Present Tendency of Reducing the Heat-Conducting Surface per H. P. in Boilers.

The cost of generating steam consists of two main elements, one the expense for fuel, and the other the expense for interest, depreciation, labor and other fixed charges upon the boiler, boiler setting, grate, draft apparatus, and fittings. If the amount of boiler surface employed to develop a boiler horse-power, that is to evaporate 30 lb. of steam per hour, be increased, the amount of heat recovered from each pound of

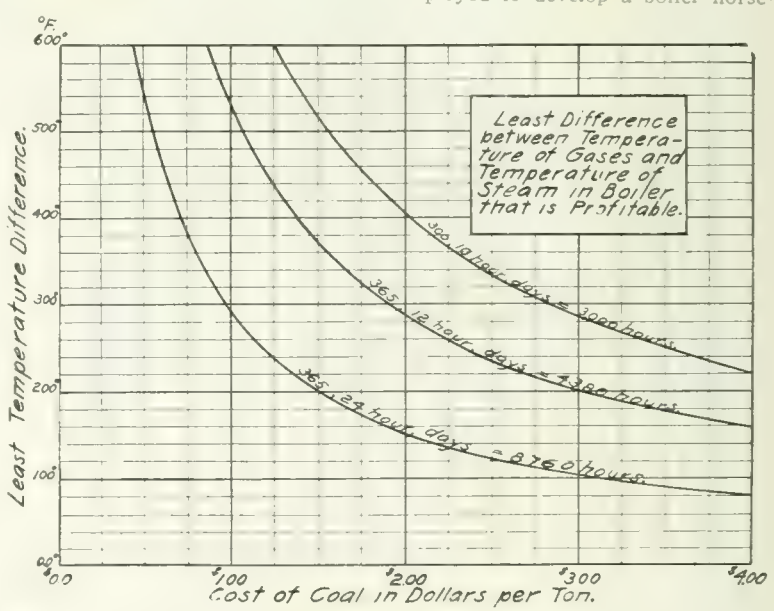

FIG. 2.—CHART SHOWING POINT AT WHICH BOILER SURFACE CEASES TO PAY PROFITS FOR DIFFERENT CONDITIONS.

fuel will, within the limits of ordinary operation, also increase. That is, more heat will be absorbed, and the gases will be discharged to the stack and to atmosphere at a lower temperature as shown graphically in Fig. 1.

At the same time, however, that the cost of steam is being reduced by increasing the efficiency of heat absorption, the

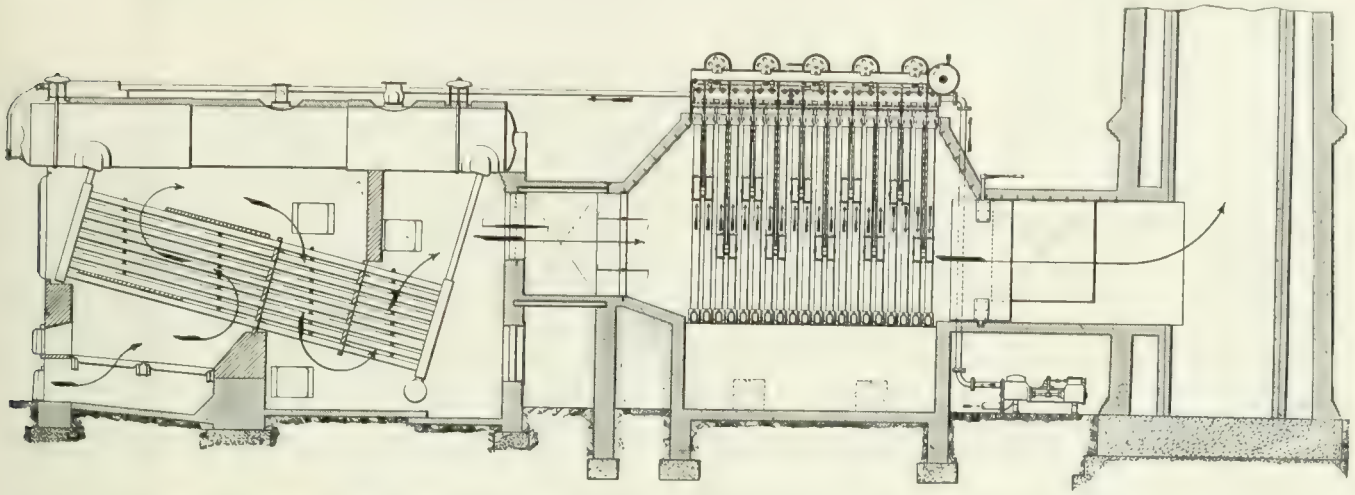

FIG. 3.—THE COUNTER CURRENT PRINCIPLE IN STEAM GENERATION AS EXEMPLIFIED BY GREEN'S ECONOMIZER INSTALLED IN CONNECTION WITH A WATER-TUBE BOILER. THE COAL GASES SERVE TO HEAT THE COLD WATER, WHILE THE HEATED WATER ABSORBS HEAT FROM THE HOTTEST GASES.

element of cost due to the fixed charges on the boiler and its appurtenances is rising. The rate at which heat is absorbed by any element of the boiler surface depends directly upon the difference between the temperature of the contents of the boiler, and the temperature of the gases of combustion in contact with that part of the boiler. If the amount of heat absorbed by that particular part of the boiler is worth more than the fixed charges corresponding, that particular element of heating surface is paying for itself, but as the temperature of the gases falls and approaches the temperature of the steam and water within the boiler, a point must soon be reached where the heat absorbed will no longer pay the fixed charges upon additional boiler surface.

Just where this limit is will, of course, depend upon the price of fuel, the charges upon boiler surface and the proportion of the whole time that the boiler surface is being used. Referring to Fig. 2, it will be seen that for plants operating 10 hours per day, 300 days per year, and using $3.00 coal, the limit is reached when the gases are reduced to a temperature 285 deg. F., above the temperature of the steam.

If we assume steam at 150 lb. pressure gauge, which corresponds to a temperature of 366 deg. F., it will be seen that the lowest temperature to which it will pay to reduce the flue gases under the above conditions is 650 deg. F., showing by reference to Fig. 1 that it will not pay to put in more than 4 or 5 sq. ft. of boiler heating surface per boiler horsepower developed.

However, as is at once apparent, considerable heat would be wasted under these conditions. If we assume a coal containing 14,000 b.t.u.'s per pound, burned with 26 lb. of air per pound of coal, and the boiler room temperature at 70 deg. F., the temperature in the fire will be about 2230 deg. F., and if the same gases of combustion are discharged at 650 approximately 27 per cent of the total heat of the fuel will be lost in the chimney gases.

If there were no body colder than the water and steam within the boiler by which the heat from these gases might be taken up, this loss would be inevitable, but fortunately, there is a use for this heat, viz.: in warming up the cold water which is to be fed to the boiler. This water may have an initial temperature of anywhere from 50 deg. or 60 deg. F., in case the water is taken from a well or stream, up to 200 deg. or 210 deg. F., in the case of returns from heating and drying coils or water heated in an exhaust steam feed water heater. Taking water at 200 deg. F., for instance, it will be seen that between such water and flue gases at a temperature of 650 deg. F. there is a difference of 450 deg., under which conditions the provision of additional heating surface would again become profitable.

If the water, however, be sent directly into the boiler, it is at once heated up to the boiler temperature by the steam and water already there, and has no opportunity to perform the service of absorbing heat economically from gases of combustion. The remedy, obviously, is to divide the process of steam generation into two parts, one of which consists of heating the water up to the boiling point, and the other the evaporation of boiling of the water; that is, to apply the counter-current principle, which has proved most economical in heat transferring apparatus of all kinds.

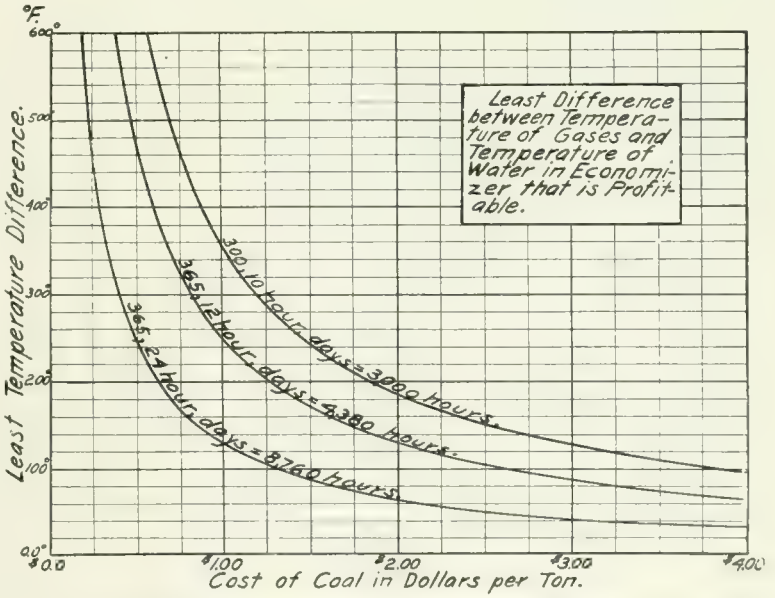

FIG. 4.—CHART SHOWING POINT WHERE ECONOMIZER SURFACE CEASES TO PAY DIVIDENDS FOR VARIOUS CONDITIONS.

The apparatus in which the feed water is heated is ordinarily

called an economizer, and the boiler and economizer, connected as shown in Fig. 3, become in effect a counter-current apparatus for the transfer of heat from hot gases of combustion to water which is to be turned into steam. The economizer costs somewhat less than the boiler per square foot of heating surface, and the temperature difference at which it ceases to be profitable is therefore lower, as will be noted from Fig. 4.

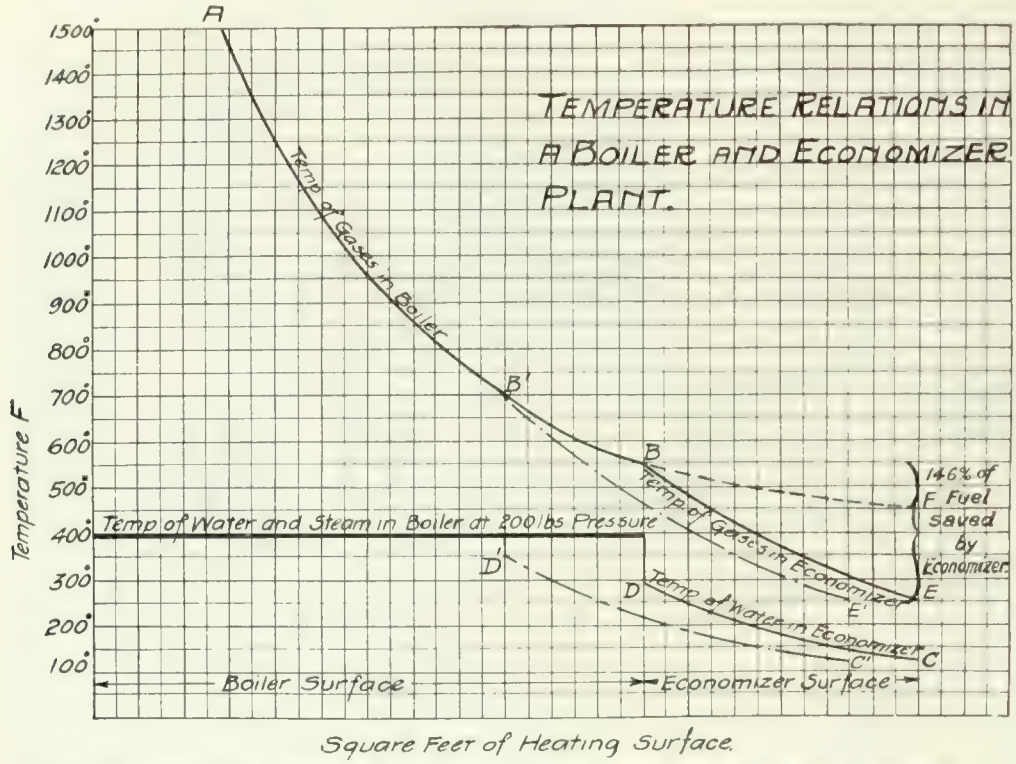

FIG. 5.—CHART SHOWING RELATIONS BETWEEN TEMPERATURES OF GASES AND WATER AND STEAM IN A BOILER AND ECONOMIZER INSTALLATION.

As an example, suppose that fuel costs $3 per ton and the plant is operated 300 days per year and 10 hours per day. It will be seen that the lowest economical temperature difference is about 110 deg. F. If the initial temperature of the water entering the economizer is 200 deg., as just assumed, this will give as a final temperature to the flue gases 310 deg. F., which is still hot enough to produce sufficient draft with a good chimney.

The temperature relations within the boiler and economizer are indicated in Fig. 5. It has been here assumed that the boiler is operated at 200 lb. gage pressure, giving a steam temperature of 388 deg. F. If 6 to 7 ft. of boiler surface be installed, as is usual in recent practice, the gases will leave the boiler at 550 deg. F., and if the water enter the economizer at 110 deg. F., as from the hot well of a surface condenser, 3 to 3½ sq. ft. of economizer surface will suffice to heat it to 290 deg. F. at the point where it enters the boiler, saving 14.6 per cent of fuel. As shown by the dotted lines, however, it would be possible to curtail the boiler surface to between 4 and 5 sq. ft. per boiler horsepower, leaving the gases at 700 deg. F. at the point where they leave the boiler and enter the economizer, and with these hot gases, 6 or 7 sq. ft. of economizer surface would suffice to give the same final gas temperature as before and maintaining the same efficiency of heat absorption. In other words, approximately 1 sq. ft. of economizer surface would replace 2 sq. ft. of boiler surface without impairing economy, and since economizer surface is cheaper than boiler surface per square foot, this change would result in a considerable overall saving in fixed charges.

In the design of large steam power plants, such as central stations for electric light and power in the large cities, power stations for electric traction systems, etc., this principle has been recognized and is being applied; that is, the boiler sur-

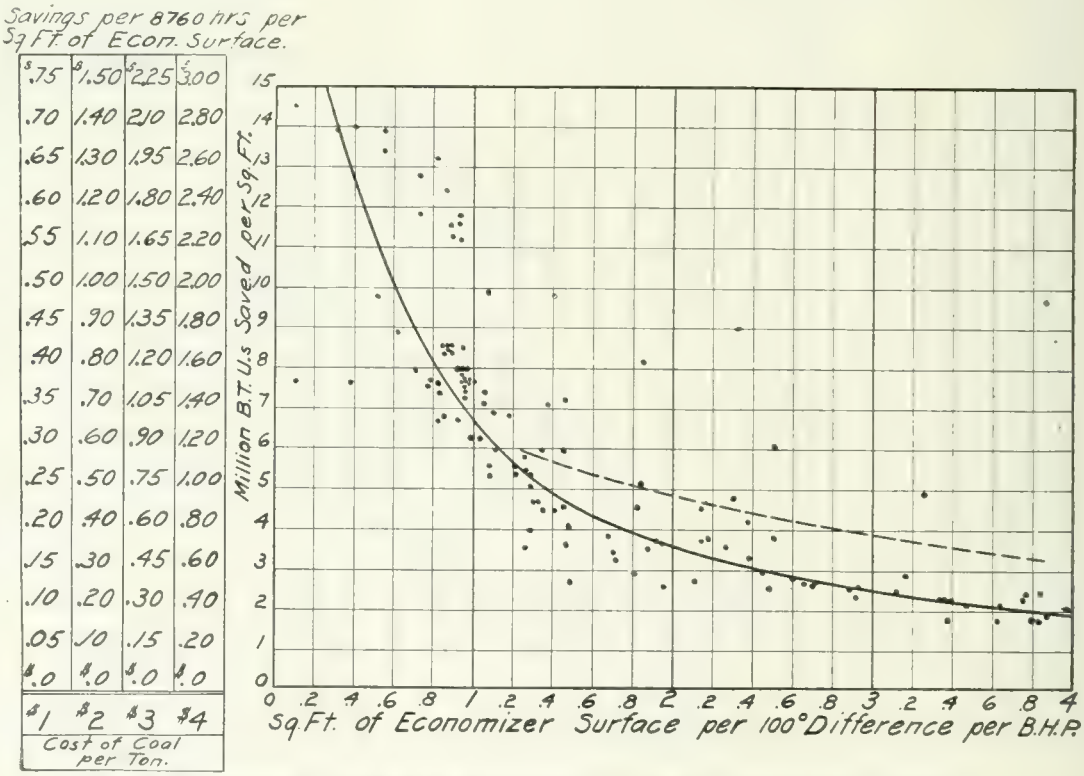

FIG. 6.—HEAT AND MONEY SAVED EACH YEAR BY 1 SQ. FT. OF ECONOMIZER SURFACE.

face is being considerably curtailed, while the efficiency of heat absorption is maintained or even improved by substituting the cheaper and more effective economizer surface.

In addition, there are other causes leading to the increased adoption of economizers. For one thing, there is a tendency toward higher and higher pressures, 200 lb. per square inch being not uncommon in steam turbine plants. As will be evident

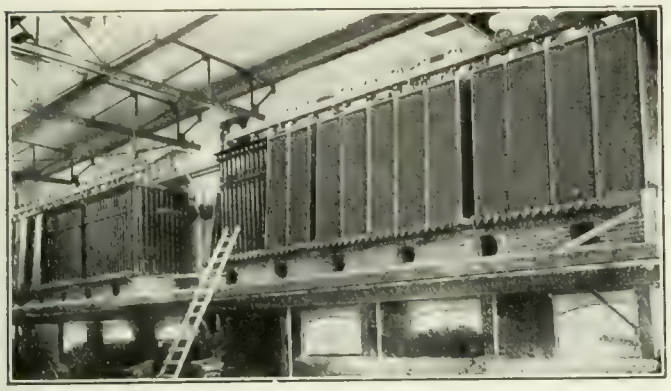

FIG. 7.—GREEN'S ECONOMIZERS INSTALLED IN POWER PLANT OF DAN RIVER POWER & MANUFACTURING COMPANY.

from the preceding arguments, any increase in the steam pressure, with accompanying increase in the boiler temperature, renders boiler surface correspondingly less efficient in the absorption of heat from the gases of combustion, since it reduces the available heat "head" causing the flow of heat from the gases to the water or steam. This leaves a greater duty to be performed by the economizer, and makes the latter correspondingly more profitable.

Another factor working in favor of the economizer is the greater efficiency obtainable from auxiliary apparatus, such as boiler feed pumps, circulating pumps, fan engines, stoker engines, etc. The less the steam consumed by these appliances, the less exhaust there is available to heat the feed water in exhaust heaters, so that instead of obtaining 200 deg. or even 210 deg. F. with some exhaust to waste, it is not uncommon to find plants in which there is difficulty in maintaining a temperature of 160 deg. F. in the water leaving the heater. Naturally the colder the water entering the economizer, the greater will be the activity of the surface in transmitting heat from the gases.

Another factor of special importance in many plants is the large heat and water storage capacity of the economizer, giving it the ability to deliver large quantities of hot water in a short time, as when water is drawn from the boilers for filling dye and wash tubs, or when excessive drafts are made for steam for any purpose. While in the latter case the economizer does not supply the steam directly, it assists the boiler surface by supplying to it water upon which part of the work of steam making has already been performed, reducing thereby the proportion of work which must be performed by the boiler in transmitting heat to the water.

The fuel saving to be expected from the installation of economizers may be estimated roughly at the rate of 1 per cent for each 10 deg. F., through which the water is raised in temperature; or, in the average plant, 1 per cent for each 20 deg. F., by which the temperature of the flue gases is reduced. Inasmuch, however, as the determination of the number of degrees that the water will be heated or the gases reduced in temperature by an economizer of given size involves considerable calculation and some knowledge of economizer engineering, it is more convenient to use the chart presented in Fig. 6, which is based upon the actual results secured in some 200 plants where economizers have been installed. Suppose, for instance, that $3.00 coal is being used, as before, and that it is decided that the economizer should show a gross saving of 30 cents per square foot per year. If the plant is operated 10 hours per day, 300 days per year, or 3000 hours per year in all, it will be in operation only a little over one-third of the time for which the chart has been made out, namely, 24 hours per day, 365 days per year, or 8760 hours. Therefore to earn 30 cents per square foot for the year as a whole, a square foot of surface must earn at a rate approximately three times as great, or 90 cents, on the basis of the time for which the chart is figured. Finding 90 cents in the $3.00 coal column, run horizontally until the curve is encountered, from which it is seen that 1.1 sq. ft. of surface should be installed per boiler horsepower developed, for each 110 deg. F. difference between the temperature of the flue gases and the temperature of the water entering the economizer. Supposing as before that the former is 650 deg. F. and the latter 200 deg. F. giving a difference of 450 deg. F., it will be seen that 5 sq. ft. of economizer surface should be installed for each boiler horsepower developed; that is, each 30 lb. of water turned into steam per hour.

Oxy-Acetylene Welding.

By W. I. REICH.

A review of the oxy-acetylene welding process shows that the business has grown beyond expectations from a few hundred installations in 1908 to over 10,000 blow-pipe equipments at the end of 1911.

The great impetus for this industry was the large improvement in the manufacture of oxygen, which was 5 cents in the year 1907 and is now 1½ cents per cubic foot, compressed in

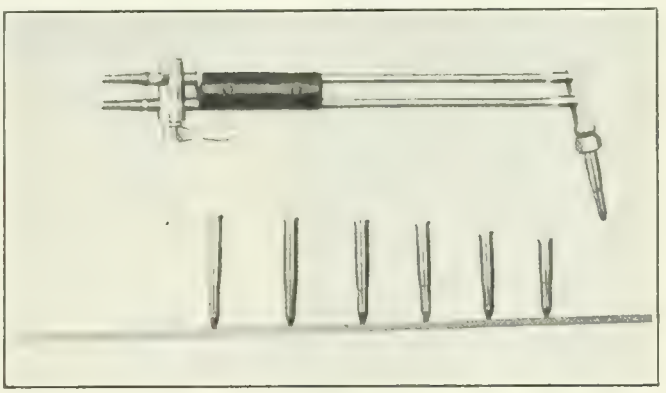

FIG. 1.—BLOW PIPE.

steel cylinders. The dissolved acetylene is still expensive, as there is no competition in this line, and the same applies to the manufacture of carbide.

However, these two "good" trusts are doing something for us for which we have to be thankful, that is, they produce materials of very good quality, far better than in Europe, where competition in this line is very keen. The price of carbide at $70 per ton is still too high in the writer's opinion and the hope may be expressed that with the extinction of the original Wilson patents this year we will get a cheaper carbide.

Some of the Uses of the Process.

The industry has spread very nearly to all classes of manufacturing. We find them in the foundry, to repair castings; in the pipe shop, to weld on tees, flanges; in tank factories, for seamless pressure tanks; in shipyards and in railroad shops for manufacturing and general repairing; in the automobile field, for welding cast iron, aluminium, steel and copper parts; in the hospital furniture industry to weld the joints without fittings, and last but not least is the development of the steel cutting business, which was well noticed last year in New York City, when the main streets were widened, and the vault I beams in the sidewalk had to be shortened. The process became so

common that the operators in the street were not annoyed any more by spectators.

Development in Blow Pipes.

The writer brought out last year a new "no backflash" blow pipe, as shown in Fig. 1. Fig. 2 is a section through the head in large scale.

In the sketch we can see both gases conducted separately to the head, the oxygen in the center, the acetylene surrounding it. The acetylene is screened off by a perforated plate *a*, the plurality of orifices in this screen are covered by a check valve *b* which moves freely, its stroke being determined by the nut *n*. The check valve will admit acetylene freely during normal operation of the blow pipe, but will close the acetylene channels when any backfire occurs.

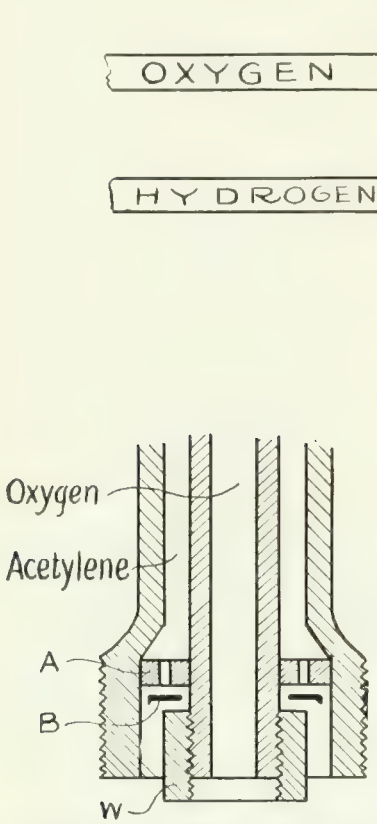

FIG. 2—SECTION THROUGH HEAD OF OXY-ACETYLENE BLOWPIPE.

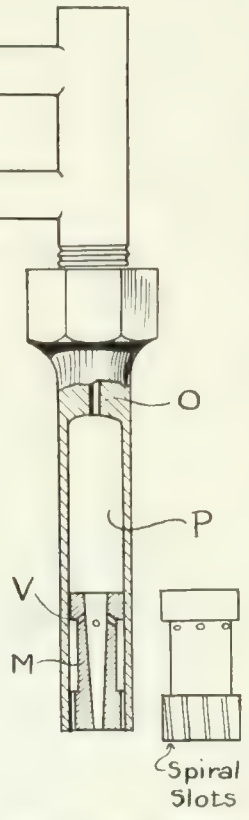

FIG. 3 OXY-HYDROGEN BLOWPIPE.

The blow pipe is furnished with a number of interchangeable tips for all sizes of welded joints. Each tip represents an individual blow pipe, in as much as length, size of uniting chamber, oxygen inlet, and acetylene orifices change.

This blow pipe does not require a metal bundle filled with pumice stone to check the backflash. Therefore, the bundle is made of insulating material, light in weight and adjustable so that it can be moved nearer to or further away from the head. The control of gases is by means of a double cock, with a small bore for the oxygen and a large one for the acetylene, so that the oxygen can be shut off in turning the handle 15 degrees without contracting the acetylene supply.

Platinum Melting.

The writer has installed several platinum melting plants for which the above blow pipe was used. The fuel in this case was changed to hydrogen or illuminating gas.

The fuel gas should be under pressure and controlled by an automatic regulator. The blow pipe tip is made of heavy copper with a mixer as shown in Fig. 3, in which *o*, is a narrow channel and *p* the mixing chamber. At *m* is a mixer head. The gas mixture passes from the narrow channel *o* to a large mixing chamber *p*, where the speed of the gases is reduced to insure a good mixture. The mixer has a center channel and an annual channel into which part of the mixture is forced through the small opening *r*. From there a plurality of spiral slots allow the gas mixture to feed the center flame, preventing its blowing out. The spiral flames give the molten platinum a rotary motion, which is quite important in the art of platinum melting. With a small blow pipe about 50 ounces can be melted at a cost of 8 cents per ounce. Large blow pipes will melt easily 500 ounces at a much lower cost.

New York City.

A Modern Electrotyping Plant.

The top floor of the new seven-story building at the corner of Seventh Avenue and Fifteenth Street, New York City, erected by Messrs. Street & Smith to house their great publishing business, contains one of the most modern and adequate electrotyping plants in the country. Although as to the number of machines not the largest in the city, it is complete as an adjunct to or a part of a great publishing house equipment, comprising the most up-to-date methods and devices to save time, not only in the direct manufacture of the printing plates themselves, but in the different pressrooms which handle these printing plates.

It is an all important factor to the production of printing plates by the electrotype process to produce plates that "will print and print well," plates which when they are put on the presses need no further preparation but which permit of the almost immediate starting of the presses on their so-called "runs." This fact is particularly important with the last forms (usually the advertisement section), which must be printed before the issue of the publication. To cause a publication to be late on the news stands is "an unpardonable sin" in a publishing house. Consequently in the last rush hours even minutes are valuable.

The layout of this electrotyping plant was all contemplated and arranged before the erection of the building. The location of machines was plotted and every piece of apparatus was provided on plans drawn from the architect's plans of the building, so that when the plant was installed in accordance with these plans, each machine when placed on the floor was in a correct position with relation to the outlet through which the wires for the motors came through the floor, the metal conduits for the electric wires being put under the flooring, part of which is granolithic, when the building was constructed.

In plotting the layout squares of cardboard, in some instances rectangles, were cut to scale, showing the relative positions of both motor and starting box for the respective machine. These bits of pasteboard or miniature machines were all laid on the floor plan and arranged in what seemed to be the most advantageous layout and a tissue tracing made of the arrangement and then other arrangements were tried and checked. Finally what appeared the best grouping and arrangement was selected and adopted, the final plan being drawn and blueprints made for the different artisans who were to contribute to the laying out and installation of the plant.

The principal objects were convenience and the saving of steps to the more skilled and consequently higher priced employees. Most of the carrying of work in process, was planned to be performed by laborers or helpers. The arrangement was such as to have the work advance in progressive steps from one operation with a predetermined regularity around the room, to be completed nearly beside the point from which it started.

Not only was it necessary to provide for the general layout, but it was important to consider the proper care of certain wastes necessary in the electrotyping business. For instance, an iron oxide dust is used in one of the manipulations. This is liable to become extremely troublesome in the ordinary sewage pipes of a building having elbows or other turns and traps, as

it will deposit and harden upon the inside walls of a perpendicular pipe unless there is a continuous flow of water through the pipe. Special provision was made for this pipe, which is made of a special acid-proof tile, to obtain a straight, uninterrupted run through six stories to the basement, where it empties into a separating catch basin before entering the main sewer. This basin can be cleaned out as often as desired and the pipe is cleaned out several times each year by drawing up and working down through its entire length a round scraper

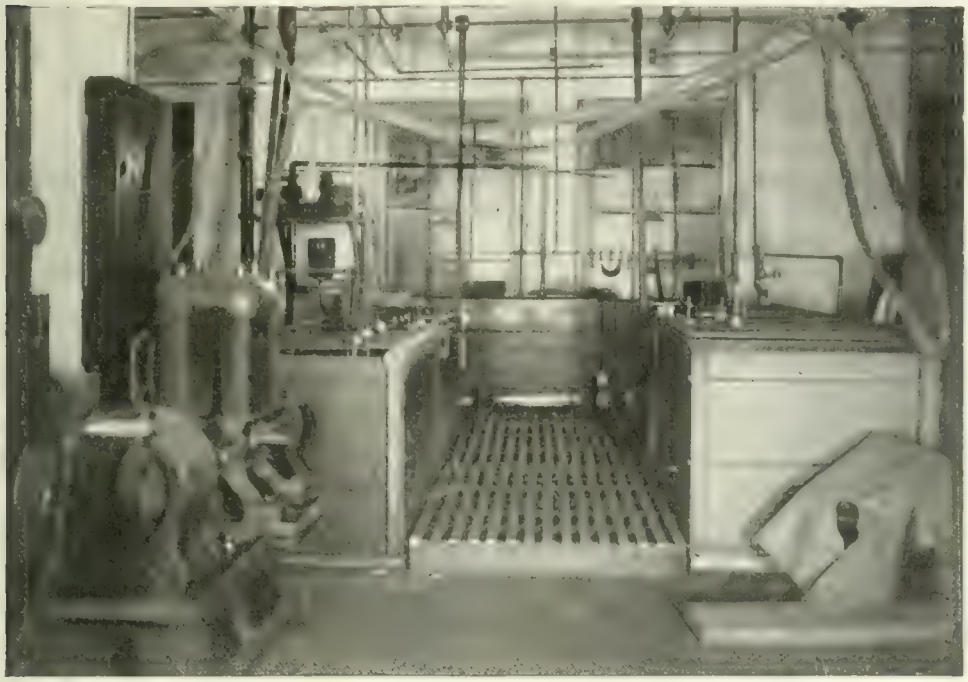

FIG. 1.—TUBS AND PART OF THE PLATING EQUIPMENT. THE ONLY SHAFTING IN THE SHOP OVER THE TANKS OPERATING FOUR CIRCULATING PUMPS IN THE PLATING TANKS.

device similar to the flue cleaners used within the steam boiler.

The process of making printing plates by the electrotype or galvanoplastic art as carried on in this establishment may be briefly described as follows:

The forms composed of reading matter or illustrations, represented by movable types or the so-called "linotype" slugs wherein the individual letters are cast into concrete and movable lines, and metallic plates bearing upon their surfaces the etched intaglio of the illustrative picture or design, are assembled and placed within a steel frame, secured with mechanically-operated wedges called quoins. This is the preliminary composing room operation.

The forms coming to the electrotyping department are washed, dried, placed upon the molding press, where the cleaned surface is lightly dusted over with powdered graphite which lubricates, preventing the form sticking in the wax into which it is pressed, giving a print in bas-relief of the form in the wax, and as a preliminary to the metallic coating which the surface of the wax must receive later, before it will take the deposit of metal in the electrolytic bath.

In taking these impressions in the wax it is necessary at times to develop pressure as high as 4500 lb. to the square inch of form surface pressed into the wax to a depth never greater than ⅛ of an in. To produce this pressure hydrostatic presses made of steel are employed. For lower pressures, not over 1000 lb., screw-actuated toggle presses are employed. This plant is equipped with both the hydrostatic and screw-actuated toggle presses.

The wax into which these forms are pressed is composed in the main of ozokerite, a petroleum residue, to which are added numerous gums or resins according to the fancy of the operator.

The composition is melted and mixed in large steam-heated kettles and poured while in the melted or fluid state over the surface of thin sheet metal backs. After cooling sufficiently a shaving is taken off the surface to insure greater evenness, the surface is dusted over with graphite and the form is pressed into the wax to the desired depth to give contour to the type and sharpness to the cuts.

The surface of the mold is thoroughly polished with graphite to insure perfect electrical conductivity to the surface of the mold, as it later becomes the cathode in an electrolytic operation.

Before the mold is placed in the electrolytic bath it has a very slight coating of copper precipitated over the surface of the wax owing to the chemical transposition which takes place when powdered iron is added to dilute sulfate of copper solution, which has been flowed over the graphited surface of the wax mold and agitated by means of a soft bristle brush. This coating becomes the base of the deposit which begins to build up simultaneously over the entire surface of the mold. Without this preliminary coating, the deposit of metal starts at the connectors at the edges of the molded surface and gradually spreads over the entire surface, which consumes about thirty minutes before the deposit begins to thicken and the extreme edges will be much heavier than the central portions.

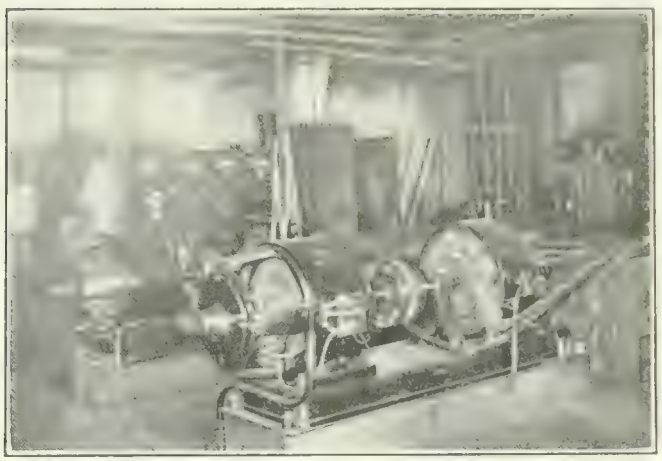
After the mold has been thoroughly rinsed off or washed out to remove any surplus graphite and powdered iron as well as to break up any oxidation, the mold is hung in the electrolytic bath, composed of a solution of the salts, of whatever metal is to be deposited, dissolved in water slightly acidulated with some acid, usually sulfuric acid. The printing-plate-making industry has only to do with the deposition of copper and nickel alloy, exhibiting properties which leads many to believe that the deposit is nickel-steel. Street & Smith employ copper wholly, as it has been found to withstand all the runs which they give their plates. Some have already given over a million impressions and are good for at least half as many more.

Particular attention is given in this establishment to the deposition of the copper shell, which is the wearing element of the printing plate. Toughness of the texture of the deposited metal is not sacrificed to hardness and the elemental condition of the electrolytic baths are maintained and never permitted to deviate from a fixed standard which insures a deposit of metal which is always the same. The temperature of the baths is kept at the same point both summer and winter, which is also an important factor in this work. The solutions are mechanically circulated in the tubs sufficiently to produce an even deposit at all points of the cathode.

The generating outfit consists of two 20-kw octipolar units built by the Jantz & Leist Company, Cincinnati, Ohio, each direct-connected through a flexible coupling to a 27-hp slow-speed multipolar motor, the armature making 600 revolutions per minute. Each generator is capable of generating 2000 amp at from 1 to 10 volts and maintaining a constant potential on all loads. This is a special feature of these particular machines due to the fact that their field coils are separately excited by the current operating the motor. A field rheostat per-

mits adjustment of the excitation of these coils, so that the voltage of the generator may be fixed as desired upon starting the machine, and thus be maintained throughout the entire time of running, without giving attention to the addition or removal of molds from the baths, since the voltage remains constant from one mold up to the full capacity of the generator.

The electrical and mechanical features of these Jantz & Leist sets deserve special mention. The armatures are of the gramme ring type, which is particularly adapted for the generation of very large currents, since better ventilation can be more easily obtained than with the drum type. The windings of the armature are in the form of copper bars, not wrapped with any insulating covering, each being separated by an open dividing space from its neighbor. There is a ventilating aperture communicating with the central opening within the armature outward, between the bars. When the armature rotates the centrifugal force drives the air out through or between the bars



TWO MOTOR DRIVEN PLATING GENERATORS SHOWING SWITCH BOARD AND CONNECTIONS TO TUBS.

and cools them. Owing to this fact, these generators are capable of overloads as high as 50 per cent. But as this concern does not believe in the economy or safety of overloads these generators have been built of sufficiently large capacity to do all the work required before they have been taxed to within 75 per cent of their rated capacity, leaving 25 per cent as a factor of safety and an additional 25 per cent as an emergency factor.

The commutator efficiency of these generators has been greatly increased by the adoption of a special arrangement of specially made carbon brushes furnished by the United States Carbon Brush Company. There are on each generator eight sets of four brushes each, three brushes in each set being made with particular consideration for their conductivity while the fourth contains sufficient graphite to provide perfect lubrication to the commutator surface which passes under it. These lubricating brushes are set staggering with relation to the other brushes around the commutator, thus lubricating the entire commutator surface without any form of grease or oil. They have now been in use two years and three months and during that time the commutators have not been touched either with sandpaper or any other substance or device to smooth them, neither have they had or required the application of any lubricant whatever on their surfaces.

Each set, motor and generator, is placed upon an 18-in. I-beam base carefully levelled and grouted in with Atlas cement 3 in. deep, poured inside, giving a perfectly solid, rigid foundation, bringing the machines up high enough to make the oiling and cleaning easy. The armatures are dusted out each day by means of a hose supplied with compressed air and particular attention is given to the brushing, wiping and oiling of these machines each morning before starting up.

Each machine supplies energy for two plating tubs connected in series, through 2½-in. solid copper conductor rods fastened directly to the terminals of the dynamos. Their circular area is ample to carry 2000 amp without heating.

Some carefully conducted efficiency tests made with one of these sets developed the following facts which are interesting but easily understood from the fact that the generators are generally used below their rated capacity.

With 45.83 sq. ft. of cathode surface exposed in the bath the generator developed 750 amp at 6 volts, while the motor consumed 27 amp at 230 volts (of 8.40 hp). The loss was therefore 27.54 per cent from the terminals of the motor to the terminals of the generator, hence the efficiency was 72.46 per cent in the conversion of electrical energy between motor and generator.

With the same exposure of cathode surface the generator was made to give 1120 amp at 9 volts, when the motor consumed 50 amp at 230 volts (or 15.41 hp) showing a loss of 12.35 per cent or an efficiency of 87.65 per cent for the set.

These figures illustrate the usual fact that as the maximum of the motor is approached there is a gain in the efficiency of conversion. However, it is more economical to work below the rated capacity than to go above it as is shown by the following test, made with a plating set in which the motor had a full-load capacity, 33 1-3 per cent below that of the generator.

The motor was a 7½-hp, 230-volt machine, driving a shunt-wound generator (direct connected) generating 800 amp at 6 volts. The motor on full rated load should draw 28.2 amp. With the same cathode surface as in the above tests, the motor drew 37.5 amp at 230 volts, so that there was an overload of 3.8 hp or 50.76 per cent, causing excessive sparking at the brushes and heating the commutator and armature. The generator gave 750 amp at 6 volts. Hence the loss was 47.84 per cent and the efficiency 52.16 per cent.

After the deposit of metal becomes sufficiently thick it is removed from the wax mold, thoroughly washed to remove all adherent wax, and has a soft metal backing sweated to it by being placed in a shallow pan, having sheets of solder foil laid over the back and melted. Molten backing metal is poured carefully over this melted solder foil, to the desired thickness and the whole is allowed to cool. The result is a soft metal plate with a copper, nickel or other metal face as may be desired or required.

The plates are cut into the required sizes, the surfaces are trued up to the same plane and the backs are machined perfectly parallel with the surface. Many of these plates are "curved" and are fitted to the cylinders of the large printing presses which print thousands of copies every hour.

Messrs. Street and Smith issue thirty-eight dated publications each month ranging from 32 to over 300 pages each, for which is required nearly 5,000,000 square inches of electrotype plate work during the year.

This branch is in charge of Mr. George E. Dunton who has a very wide reputation as an authority on the art of electrotyping, based not only on his contributions to the literature of the subject but to the more than twenty patents taken out by him for methods, devices, and mixtures which relate to improvements in the production of printing plates by the electrotype process.

NOTES.

The **American Rolling Mill Co.** of Middletown, Ohio, have issued a nicely illustrated pamphlet entitled "Public Opinion on American Ingot Iron," giving quotations from various authorities on the relation between purity of iron and its resistance to corrosion.

The **Rockwell Furnace Company,** New York, have opened an office in the Engineers Building, Cleveland, Ohio, for the sale of furnaces for heat treatment, annealing, tempering, etc. The office will be in charge of Mr. George B. Norcross, who will have associated with him Mr. Walter F. Johnson, formerly assistant treasurer of the King Bridge Company, Cleveland, Ohio, and Mr. E. W. Saunders, of the Carbon Steel Company.

Oil Furnace for Heat Treatment of Steel Forgings—The Rockwell Furnace Company, of New York City, has recently completed for the Heppenstall Forge & Knife Company, of Pittsburgh, Pa., and Bridgeport, Conn., three of their overfired type furnaces for the heat treatment of steel forgings, the largest furnace having a heat chamber 4 ft. wide and 50 ft. long. The fuel used is oil.

Mr. **P. E. Garretson** and associates, who have successfully placed upon the market an ore reducing machine, known as the National Pulverizer, have purchased from the Samson Manufacturing Company all rights, title, interest, good will, etc., for the manufacture of the Samson rock crusher. The company will not confine its business to the mining industry alone, as this crusher is adapted for all kinds of rock breaking, such as rock for concrete, road work, etc., lime, cement, coal and other products where a uniform product is desired. The business will be continued under the name of The Samson Manufacturing Company at 1738 Broadway, Denver, Col.

Pyrometers.—We have received from the Brown Instrument Company, of Philadelphia, their new illustrated 56-page catalog on Brown Pyrometers. This is very complete, covering both indicating and recording pyrometers. Section I deals with electric pyrometers and radiation pyrometers, section II with expansion pyrometers, mercurial pyrometers, and other types. While the immense strides in design and applications of pyrometers have chiefly been made in the last few years, it is interesting to note that this company originally commenced to manufacture expansive pyrometers in 1860 or over fifty years ago.

Optical Projection.—A recent bulletin, issued by the Technical Bureau of the Bausch & Lomb Optical Company, of Rochester, N. Y., on "A new balopticon for projection of large opaque objects" is unusually interesting as evidence of the rapid strides now being made in the development of optical projection and in general in design of special optical instruments.

Bolting Cloth.—"From Mulberry Tree to Mill" is the title of an illustrated pamphlet issued by the old firm of Dufour & Co. and sent to us by their agent, Mr. Paul O. Abbe, 30 Broad St., New York. It describes in an interesting general way the many operations in the manufacture of Dufour bolting cloth, the silk for which is spun from the best white cocoons which are raised. The factory of Dufour & Co. has been since 1833 in Thal, Switzerland.

Competition in Aluminium Manufacture.—French and Swiss capital is to be invested in an aluminium plant in North Carolina. L'Aluminium Français which has been organized in Paris with a capital of 15,000,000 francs, will be the parent company. The operating company is to be known as the Southern Aluminium Company and will have a capitalization of $8,000,000. The company has purchased the partly completed hydro-electric plant of the North Carolina Electric & Power Company, which is a reorganization of the old Whitney Company. There are large deposits of bunxite in the territory. The initial development, partly completed, is of 50,000 horsepower, while other power sites will supply an additional 50,000 horsepower. Dr. Paul Heroult is on the spot to supervise the erection of the works.

Electric Muffle Furnace for Heat-Treatment of Tool Steels.—Bulletin No. 10, just issued by the Hoskins Manufacturing Company, of Detroit, Mich., gives a detailed illustrated description of their type FC electric muffle furnace for the heat treatment of tool steel. The furnace is of the resistance type, the heating resistors being two piles of flat carbon plates, which can be compressed more or less by means of a screw, thus permitting an exceedingly easy and exact regulation of current and temperature. Another special feature of the furnace is a draft hole which extends from the top and rear of the furnace chamber to the top of the furnace and by means of which chemical nature of the atmosphere—whether oxidizing or neutral or reducing—can be controlled as desired. The furnace is in successful use in various large steel plants in this country.

Double-Chamber Furnace for Melting Cyanide Precipitate.—Bulletin 33 of the Rockwell Furnace Company of New York describes their double-chamber melting furnace for melting copper, brass, bronze, aluminium, ferrosilicon, ferromanganese and other alloys. It is operated by gas or fuel. The essential feature is the provision of two chambers so arranged that they can be used alternately. The exhaust heat from the active or primary chamber passes into the other chamber, thereby simultaneously melting in one chamber and preheating to near the melting point in the other chamber with one burner and no additional cost. An interesting special application of this furnace is the melting of cyanide precipitate, for which purpose it has proven very successful in various cyanide plants.

"Smokeless Chimneys" is the title of a twelve-page pamphlet issued by the Furnace Gas Consumer Company, Matteawan, N. Y., describing the furnace gas consumer, which consists of a bank of fireclay tubes installed in the space back of the bridge wall, underneath the boiler. It is claimed that these tubes become white hot or incandescent and that they serve to reheat the distilled gases and air, so that when the two mingle in the space back of the tubes complete combustion takes place before the gases again strike the cold surface of the boiler, and there is perfect combustion without formation of smoke or soot. The device, therefore, really represents a means of heat storage in the furnace, storing heat when the fire is bright and utilizing the same heat for the combustion of the gases distilled when fresh fuel is spread over the incandescent fuel bed. Other advantages claimed for this device are that it makes it possible to secure perfect combustion with a smaller excess of air and that the heat-absorbing capacity of the boiler is increased, due to the increased absorption by radiation, the white-hot tubes radiating into the boiler almost as rapidly as does the incandescent fuel bed, therefore leaving less heat absorption by convection to be performed by the flues.

High-Vacuum Pump and Pressure Blower.—The Abbé Engineering Company, 220 Broadway, New York, have put on the market a patented rotary vacuum pump for a high vacuum. This pump, the Abbe Engineering Company claim, will maintain a vacuum to within one-tenth of an inch of the barometer. It runs as quietly as a motor and is simple in construction, having no valves, packing or springs. The internal parts of the pump are automatically oiled, thereby doing away with oil cups. The pump has already found great favor with chemical factories and laboratories and for other purposes where a high vacuum is required. These pumps are built in twelve different sizes, having displacement of from 6 to 1000 cu. ft. of air per minute. The Abbe Engineering Company are also putting a patented rotary pressure blower on the market. This blower requires no air tank as a steady pressure can be pumped up of from 1 to 12 lb. pressure, direct from blower. A relief valve is furnished so that the pressure can be easily regulated. These blowers are fitted with outboard bearings, tight and loose pulleys, and ring oiler bearings.

Laboratory Apparatus Blue Book.—The "Blue Book" just issued by the Scientific Material Company, of Pittsburgh, Pa., is certainly one of the most complete and up-to-date catalogs of laboratory apparatus ever published. It contains an enormous amount of valuable information and data regarding almost every piece of apparatus which might be regularly used in chemical, metallurgical, and biological laboratories The most interesting feature of the book is the large number of new apparatus for producing better results, saving time, saving labor—in short all those apparatus which have been the outcome of the modern tendency of applying scientific management methods in the laboratory. It is a pity that it is impossible to give at this place a list of such apparatus which would show how great the activity of designers has been in recent years along these lines. The book contains 537 pages,

about 10,000 different items, and perhaps 2200 illustrations, and is bound in a light blue flexible cloth. The Scientific Materials Company offer the book free of charge to chief chemists, metallurgists, and professors, and make a charge, which seems quite reasonable, of $1.50 to others.

Personal.

Dr. **Victor C. Alderson** has been reelected president of the Colorado School of Mines for the ensuing school year.

Mr. **E. J. Carlyle** has gone to Argentina to take charge of the smelter of the Famatina Corporation at Chilecito.

Mr. **W. Ray Cox,** of Colorado, has been appointed professor of mining and geology in the Pei Yang University, Tientsin, China, and will assume the duties of his position this summer.

Mr. **J. Ross Corbin,** of Philadelphia, has received notification of his appointment as professor of chemistry in the Pei Yang University, Tientsin, China.

Mr. **N. H. Emmons** has resigned as general manager of the Tennessee Copper Company and has opened an office as consulting, mining and metallurgical engineer in the Union Oil Building, Los Angeles, Cal.

Mr. **Oscar Faller** of the Rapid Evaporator Company, Detroit, Mich., recently returned from Munich, Germany, where he has spent the winter. He is at Ludington, Mich., for the purpose of conducting some experiments for his company.

Dr. **Hans Goldschmidt,** of Essen-Ruhr, Germany, with his daughters, Miss Lucy Goldschmidt and Miss Marga Goldschmidt, sailed on June 15 for Europe after a two months' stay in this country in the interest of his celebrated thermit process.

Mr. **Franklin Guiterman,** New York, who is in charge of technical investigations for the American Smelting & Refining Company, visited Denver recently. He resigned as trustee of the Colorado School of Mines on account of his permanent removal from Denver to New York.

Mr. **H. W. Hardinge** left New York on June 1 for Norway to investigate the operation in some of the iron plants of the Northern districts.

Mr. **James A. Jones,** Lansingburgh, N. Y., has been appointed Eastern sales manager of the Brighton Firebrick Company, of New Brighton, Pa.

Mr. **C. P. Karr** has been appointed metallurgist to the Standard Chemical Company, Pittsburgh, Pa. The company manufactures uranium and vanadium products.

Mr. **John H. Kennedy** has left the employ of the Punxsutawney Iron Company, Punxsutawney, Pa., and has taken charge of the blast furnace department of the Rogers-Brown Iron Company, operating the Susquehanna furnaces at Buffalo.

Dr. **Chas. F. McKenna,** consulting chemist and chemical engineer, announces the removal of his laboratories from 221 Pearl Street to 50 Church Street, where in the specially designed suite of the top floor of the new extension they have been combined with his offices and enlarged as research and testing laboratories.

Prof. **Robert H. Richards,** of the Massachusetts Institute of Technology, Boston, was married on June 8 to Miss Lillian Jameson, at Jamaica Plain, Mass.

Messrs. **Alfred Sang** and **G. Rafiniesque,** metallurgical engineers, of Paris, France, have transferred their offices to larger quarters at 10 Rue N.-D. de Lovette, Paris.

Mr. **Richard H. Thomas** has returned from Kyshtim, Russia, where he was engaged in improving the efficiency of the electrolytic copper refinery.

Mr. **R. H. Wolff,** well known through his long connection with the steel industry and his great activity in introducing the electric steel refining process in this country, sailed on June 15 for a stay of several months abroad.

OBITUARY.

Mr. **Seth Clinton Catlin** died at his residence in Bloomfield, N. J., on June 4. Mr. Catlin was the inventor and patentee of the "Nonesuch" electroplating machine and the "Nonesuch" carboy rocker for which Rockhill & Victor, of New York and Chicago, have the sole selling rights. Mr. Catlin was over seventy years of age and had been until a year or two ago actively associated with the electroplating industry for a period of nearly forty years.

Mr. **D. D. Dickey,** general manager of the National Carbon Company, of Cleveland, died on March 8 as the result of an operation for an internal trouble. Mr. Dickey was born at Pittsburgh, Pa., Oct. 9, 1853. In his early life he attended the public schools at Pittsburgh and later the Western University of Pennsylvania, now called the University of Pittsburgh. Mr. Dickey at the time of his death was a patriarch in the carbon manufacturing business of the United States. In 1883 he acquired an interest in the Pittsburgh Carbon Company; a few years later the plant was moved to Jeanette, Pa., and the name changed to Faraday Carbon Company. Mr. Dickey had a controlling interest in this company until the consolidation of several companies into the National Carbon Company of New Jersey in 1899, when he became a director and general manager of the consolidated companies. Mr. Dickey came to Cleveland from Pittsburgh in January, 1899, and has since that date assisted in his quiet, strong way in the advancement of many of the city's interests. He was a member of the Union, Country, Roadside and Rowfant clubs and of the Cleveland Chamber of Commerce and the Chamber of Industry. His death was a great shock to all and everyone who knew him feels a personal loss. Every employee in his company held him in the greatest respect not only as their officer but as their good friend and always ready helper.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (Continued).

551,648, Dec. 17, 1895, Louis Pelatan, of Paris, France, and Fabrizio Clerici, of Milan, Italy.

Relates to the extraction of gold and silver from ores containing the same. The ores are pulverized and mixed with a suitable alkaline cyanid solution containing a small quantity of sodium chlorid, to increase its electrical conductivity. The solution of potassium cyanid is kept in circulation either by rotary stirrers or by a suitable pump which draws the liquid off from the top of the solution and injects it at the lower part of the ore above the cathode. A mercury cathode is at the bottom of the cell which may have an amalgam plate resting on its surface. The ore is in contact with the cathode. When stirrers are used, they are connected as anodes. When the solution is circulated by means of a pump, stationary anodes are used. Agitating arms of wood attached to the rotary anodes keep the contents of the vat thoroughly stirred up, while the current is passing through the mixed ore and cyanid. The precious metals will be deposited upon the mercury and may be separated therefrom in the usual manner.

552,960, Jan. 14, 1896, Carl Hoepfner, of Giessen, Germany.

Relates to obtaining copper from copper sulfid ores. The sulfur ore is ground and leached by a solution of cupric chlorid containing sodium chlorid or calcium chlorid which reacts with the copper sulfid forming cuprous chlorid and free sulfur. The solution of cuprous chlorid is now separated from the solid residue and any other metals present precipitated. A portion of the solution of cuprous chlorid is now treated with an alkali

or an alkaline-earth in the form of a carbonate or oxid which precipitates cuprous oxid forming an alkaline or alkaline-earth chlorid. Another portion of the cuprous chlorid solution is oxidized to cupric chlorid by any suitable oxidizing agent and used as a leaching agent for fresh ore. If the ore also contains nickel, it is subjected to a preliminary treatment for the extraction of this metal which is then separated from the solvent by electrolysis. The remaining solution is now used to extract the residue from the nickel-free ore.

553,816, Jan. 28, 1896, Louis Pelatan, of Paris, France, and Fabrizio Clerici, of Milan, Italy.

Relates to the extraction of gold from its ores by a cyanid solution or by the chlorination or bromin processes. When the cyanid solution is used, a small quantity of sodium chlorid is added to increase its conductivity, and this solution then mixed with the ore in a suitable vessel, the bottom of which is covered with a mercury cathode. The anode consists of a stirring device which keeps the ore thoroughly agitated. The precious metals are dissolved and collected by a mercury cathode. When the operation is completed, the mercury is collected and the gold recovered in the usual manner.

556,092, March 10, 1896, Oscar Frölich, of Berlin, Germany, Assignor to Siemens & Halske, of same place.

Relates to the extraction of noble metals from their ores by the chlorin process. When other metals are present, the latter are also sometimes extracted, contaminating the solution. States that when a solution containing several metals is subjected to electrolysis and the voltage gradually increased, the most electronegative metal will be deposited first; the next one of the series will then be deposited, and so on. A solution containing 5 grains each of chlorid of gold, copper and iron to a pint, using a lead cathode and carbon anode and a current-density of 12 amperes to 2 square yards of cathode surface, was electrolyzed with a voltage between 1.2 and 1.4 volts. The gold separated completely with mere traces of copper and iron.

563,143, June 30, 1896, James Douglas, of New York, N. Y.

Relates to the extraction of copper particularly from solid cuprous chlorid by means of electrolysis. The cuprous chlorid is obtained by adding a chlorin salt to copper sulfate and precipitating the copper in the form of cuprous chlorid by means of sulfurous acid gas. The cuprous chlorid thus obtained is removed and placed in a vessel and positive and negative electrodes inserted in the mass which may be slightly moistened with acidulated water, if desired. Electric current converts the cuprous chlorid into copper and chlorin, which latter may be collected.

563,144, June 30, 1896, James Douglas, of New York, N. Y.

Refers to the preceding patent in which copper is recovered from cuprous chlorid. In the present patent, the cuprous chlorid and acidulated water are placed upon a cathode within a suitable vessel and an anode immersed in this solution above the cuprous chlorid. The solution is now electrolyzed. If a weak electric current is used, a reguline deposit adheres to the cathode. If a strong current is used, the copper is obtained as a spongy crystalline mass.

566,894, Sept. 1, 1896, Paul Danckwardt, of New York, N. Y., assignor to The Electro-Cyanide Gold and Silver Extracting Company, of same place.

Relates to the extraction of gold and silver from ores or compounds by the action of a solvent and an electric current. The pulverized ore, tailings, etc., are introduced into a rotary vessel, with a suitable cyanid solution. The interior wall of the vessel is connected as a cathode and is amalgamated. Within the vessel, adjacent the cylindrical wall, are a series of shelves which keep the larger particles of the ore from contact with the cathode. The shelves are electrically connected as anodes. Upon rotating the cylindrical vessel, the ore is tumbled from one shelf to another and brought into thorough contact with the cyanid solution. An electric current is continually passed and assists in extracting the gold and deposits it upon the cathode. When completed, the discharged ore and solution go to a filtering apparatus, and the solution is used over again. The gold is recovered from the amalgamated cathode.

566,986, Sept. 1, 1896, Rudolf Keck, of Denver, Colorado.

Relates to the extraction of precious metals by the cyanid process. After the ore has been treated, the gold-cyanid solution is electrolyzed in an electrolytic cell and the precious metal deposited upon the cathode. In this process, it is preferred to used a cathode of aluminum or its alloys and a lead anode. The precipitated metals may easily be removed from the aluminum cathode and smelted into bullion.

567,503, Sept. 8, 1896, Louis Pelatan, of Paris, France, and Fabrizio Clerici, of Milan, Italy.

Relates to the extraction of gold and silver from their ores by a continuous operation, and refers to patent 528,023. The pulverized ore is mixed with a cyanid solution containing some sodium chlorid and the mass put in an electrolytic cell containing a stirring device preferably connected as anode. The bottom of the cell is covered with mercury connected as cathode. The stirring device constantly agitates the ore and permits larger particles of ore to fall through and be directly amalgamated by the cathode. An electrical current not exceeding three volts is used which is below the point at which sodium chlorid is decomposed.

BOOK REVIEWS.

Chemisch-technologisches Rechnen. Von Prof. Dr. **F. Fischer.** 12 by 17 cm., 111 pages. Price 3 marks. (Retail price in New York, $1.00.) Leipzig: Otto Spamer.

Anwendung physikalisch-chemischer Theorien auf technische Processe und Fabrikationsmethoden. Von. Prof. Dr. **Robert Kremann.** 15 by 24 cm. 208 pages, 35 illustrations. Price, marks, 9.60; bound, marks, 10.95. (Retail price in New York, bound, $3.65.) Halle: Wilhelm Knapp.

These two books following on Dr. Haber's splendid "Thermodynamik technischer Gas Reaktionen" demonstrate the ability of German chemists in the important field of industrially using quantitative calculations based on physico-chemical investigations. The first work, however, is the arithmetic of the subject, the second the calcules.

Dr. Fischer of Göttingen, known for his fine work on "Kraftgas," intended his book primarily for students in technical institutions. It contains 196 problems, stated very briefly and almost all accompanied by the solutions given in the briefest possible style. This manner of presentation is very well fitted to help the student to a proper degree and yet to leave him plenty of headwork to accomplish. The use of the "rule of three" throughout strikes us as an anachronism; a man, even a student, who cannot formulate such a process as the primary value multiplied by A over B, without putting down B : A = V: X — is not very far along in mental arithmetic, and may even be regarded as clumsy in his mental processes. Anyone who studies through this little book in detail will certainly become proficient in chemical arithmetic.

Dr. Kremann of the Polytechnikum in Graz, gives us his lecture course on the application of theoretical data to industrial chemical processes. The plan and its execution are highly interesting and stimulating. Commencing with a chapter on the two laws of thermo-dynamics, he first discusses reaction velocity and catalysis, as exemplified in such processes as sulphuric acid-lead chamber reactions, oxidation and reduction processes, vitrifaction, de-vitrifaction, crystallization. The mass-action law and the influence of temperature on chemical equilibrium are illustrated by discussions of the Deacon process, contact sulphuric acid, nitric acid manufacture, causticizing alkalies by alkaline earths, Scheele's caustic soda process. Dissociation tension is considered in connection with the burning of lime, roasting of ores, blast furnace reactions. The phase rule is applied to precipitation and matting processes, iron and carbon alloys, the puddling process. Transformation

reactions are illustrated by the gypsum, Portland cement, and clay industries. More complex chemical theories are concerned in the discussion of dying, vulcanizing rubber, manufacture of soap, the ammonia-soda process.

Intended primarily for students, these two books can be of great assistance to every one handling chemical processes; the first will give him simple basic principles, the second lead into the refinements of the art of industrial chemistry. They both require hard, earnest application, and are both well worth mastering.

* * *

The Measurement of High Temperatures. By **G. K. Burgess** and **H. Le Chatelier.** Third edition, re-written and enlarged. 14 x 23 cm (5½ x 9 in.), xviii + 510 pages, 178 illustrations. Price, $4 net. New York: John Wiley & Sons.

Professor Le Chatelier, in a neat preface, protests that the book is much more the work of Mr. Burgess than of himself; we will, therefore, regard the former as having laid the foundation of the work and the latter of having built the superstructure. The book is really monumental, and the technical world may congratulate itself on having such a treatise quite as heartily as it may thank the authors for having written it. Besides the description and discussion of all forms of pyrometers (except the explosion "bomblets" of Wiborgh) there is a long chapter on recording pyrometers, which will particularly interest industrial users. Pyrometery is a meeting point where pure and applied science are co-operating with wonderful success and splendid practical results, and this book has been a powerful factor in bringing the two together.

* * *

Lehrbuch der Eisen und Stahlgiesserei. Von **B. Osann,** Professor an der Bergakademie in Clausthal. 15½ x 24 centimeters, 5 plates and 526 illustrations, 497 pages. Price, $5 in New York. Leipzig: W. Engelmann.

There was need of a complete, clear, well-illustrated text book on casting iron and steel, and Professor Osann has supplied the want. He proceeds with characteristic German system and thoroughness through thirty-five chapters, starting with the history and classification of iron and steel, discussing melting furnaces most completely, especially the making up of the charges and the chemical additions, then handles shrinkage and blow-holes in a masterly way, details the methods of testing the product, and describes minutely the operation of molding, flasks, sand, casting over a score of special forms, chill casting, malleable castings, trimmings, cleaning, and finally metallographic examination.

To give in a few words a characterization of the work, we will say that Professor Osann's book covers the subject of the iron and steel foundry in much the same style as Professor Stoughton's well-known text-book covers the whole subject of iron and steel, with the obvious corollary, however, that it goes more into working details of furnaces and plant. American practice is well represented, but the strength of the work is its minute description of best European practice. An English translation would be useful to many who cannot (but should be able to) read the German; it would give them a chance to learn how to run a foundry on better principles than most foundries in America illustrate.

* * *

Industrial Organic Chemistry. By **S. P. Sadtler,** Ph.D., LL.D., Past-President of the American Institute of Chemical Engineers. Fourth edition, revised, enlarged, and reset. 6 x 9½ in. (15 x 24 cm.). 601 pages, 122 illustrations. Price, $5 net. Philadelphia: J. B. Lippincott Company.

Since the appearance of the third edition of this book, eleven years ago, great advances have been made in the organic chemical industries, and some new ones have appeared. Dr. Sadtler has met this situation by a thorough revision. On carefully inspecting the work we can say that it is nearly everywhere up-to-date, as complete as can be expected within the space limitations of a single volume, and the information given is useful and accurate. The "Analytical Tests and Methods" and "Bibliography and Statistics," given at the end of each chapter, are a particular feature of the work, especially because Dr. Sadtler makes, in the analytical line, his own personal contribution to the subject matter of the book.

* * *

The Metallurgy of Steel.—Vol. I, Metallurgy, by **F. W. Harbord;** Vol. II, Mechanical Treatment, by **J. W. Hall.** Fourth edition, octavo, pages 551 and 440, illustrations 289 and 282. Price, $10. London: Charles Griffin & Company.

Everyone familiar with the literature of steel knows this work and its usefulness. It is undoubtedly the most comprehensive book in English on steel.

The revision has been carefully and well done. A complete set of 80 new photo-micrographs of steel sections has been inserted, plans of several new installations are given; the latest developments in basic open-hearth furnaces and their appurtenances are described. The chapter on electric smelting is not as well done as other parts of the book, too much is reported at second hand and without criticism.

Mr. Hall, in Vol. II, has added new sections on low-pressure steam turbines, gas engines and electric driving of mills, making the volume most thorough and complete. The two volumes taken together give a very comfortable feeling of satisfaction when seen on the shelves of a metallurgical library, and the profession owes a debt of gratitude to these two gentlemen for their assiduous and successful labors.

* * *

Portland Cement. By **Richard K. Meade,** M. S. Second edition, 5½ 9 in. (9 x 22½ cm.), 522 pages, 169 illustrations. Price, $4.50. Easton Pa.: Chemical Publishing Company.

The author has had long experience in the scientific control of the manufacture of cement. His book is carefully written, the information is reliable, and the presentation is free from hackneyed phrases and views. Just about one-half the book describes the manufacture, from quarrying raw material to packing the cement, while the other half is concerned with chemical analysis and physical testing. The book describes American methods and practice, up to date, in a manner which will be useful to almost any class of readers.

* * *

A Text-Book of Rand Metallurgical Practice. By **R. Stokes, J. E. Thomas, G. O. Smart, W. R. Dowling, H. A. White, E. H. Johnson, W. A. Caldecott, A. McA. Johnston,** and **C. O. Schmitt.** Vol. I. 6 by 9 inches (15 x 22½ cm.), 468 pages, 128 illustrations. Price, $6.50. London: Charles Griffin & Company; Philadelphia: J. B. Lippincott Company.

The nine authors are all technical men actively engaged in current metallurgical practice on the Rand, and each writes upon the special part of the subject in which he is best qualified. The result is a most valuable book, both practical and scientific, comprehensive and accurate. Mr. Stokes writes of the general conditions on the Rand, geology, labor and economic relations; Mr. Thomas handles sorting and breaking the ore; Mr. Smart, stamp milling; Mr. Dowling, tube milling; Mr. Thomas, treatment of sands; Mr. White, slime treatment; Mr. Johnson, precipitation, clean-up and smelting; Mr. Johnston, assaying and testing plants; Mr. Caldecott, chemistry of the cyanide process. Fifty pages of useful tables were compiled by Messrs. Caldecott and White. Mr. Schmitt will write Volume II on the design and construction of plants and the transportation of material. The writing is in particularly good style and gives a clean, snapshot picture of Rand metallurgical practice of to-day, cleverly designated by Mr. Stokes as "the rich product of twenty years concentration on the buddles of experience."

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X — New York, August, 1912. — No. 8

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.
Curtis E. Whittlesey, Treasurer. E. F. Roeber, Secretary.
239 West 39th Street, New York.
Telephone Calls, 4700 Bryant. Cable Address, Metchem, New York.

Western Office, 421 Boston Bldg., Denver, Colo.
European Office, Hastings House, Norfolk St., Strand, London, Eng.

E. F. Roeber, Ph.D., Editor.

A Pertinent Question as to Membership in the International Congress of Applied Chemistry.

The Eighth International Congress of Applied Chemistry is now only a little over a month off and the question whether to join the Congress or not becomes a burning question.

We have occasionally heard chemists ask themselves: Will it be worth while for me to join the Congress as a member? To those who will be fortunate enough to be able to attend in person, the brilliant program which has been arranged, as given elsewhere in this issue, must be convincing argument. Those members who cannot attend themselves will get at least the twenty-four volumes of the printed Proceedings—a veritable library on the present status of applied chemistry in all its phases, the cost of printing alone to the Congress being greater per member than the membership fee.

However, one point should not be overlooked. There is always a psychological moment when it becomes absolutely necessary to climb on the band wagon if one desires not to be left behind. The majority of the papers will be printed in advance and these are now in the hands of the printer. As a matter of course, the Congress had to fix the number of copies to be printed, and delivery of the printed Proceedings cannot be made to more members than the number of sets now in press. Who comes first is served first. Therefore as it is worth while to join the Congress, it is decidedly worth while to do so *now*. Mr. Wm. J. Matheson, 182 Front St., N. Y. City, is the treasurer of the Congress and the membership fee is five dollars, which is a purely nominal fee.

But, after all, the question as to worthwhileness reveals a rather narrow viewpoint. This is the first in the series of International Congresses of Applied Chemistry to be held in America. The invitation to come to America was made in the name of the "American chemists." Right at the start, the president of the Congress, Dr. Wm. H. Nichols, emphasized: "Every chemist in the United States must feel that he is part of the Congress from the very creation of the organizing committee down through all details of management to the very close of the Congress." And this principle of broadest democracy has been strictly and successfully adhered to.

The question as to worthwhileness is of decidedly secondary importance. The only pertinent question which every American chemist must ask himself is this: Can I afford not to join the Congress and thereby declare myself outside of the united democracy of American chemists?

The Value of Refined Analysis in Ore-Testing

In testing an ore to determine its amenability to a metallurgical process, it is customary to apply certain standard and well known tests. The number and nature of these tests may vary from time to time as experience and knowledge are accumulated, but the general tendency is toward standardization. An ore is subjected to certain routine treatment, and if the re-

sults are used the process in view is adopted, if not, it may be rejected on insufficient evidence.

The policy of relying on standardized methods may be carried too far. Standardization is all right if the operator is not unduly impressed by it as an expression of finality. A rule is sometimes valuable on account of the exceptions it affords, and these exceptions should be carefully noted and investigated. Ore-testing is a work which should be characterized by individuality. Rough and ready methods of analysis will not give a clue to deep-seated troubles. Such methods may serve to control a process which is running smoothly, but refined analysis is called for to determine small quantities of certain elements and ascertain their form of combination.

A case in point is cited by A. F. Crosse, of South Africa, in discussing the effect of sulphates and arsenates on cyanide solutions. It is well known, as he says, that magnesium sulphate will decompose cyanide solutions, and that the mineral kieserite, hydrated sulphate of magnesium, is not uncommon. An ordinary analysis of an ore containing this mineral in small quantities, showing percentages of silica, iron, lime, magnesia, sulphur, etc., would be of no value to the manager of a cyanide mill. It would give no direct clue to the presence of magnesium sulphate, especially if the ore was pyritic and the sulphur was assumed to exist as sulphide of iron.

Other instances are known in which small quantities of elements, even tenths and hundredths of 1 per cent, have proved detrimental to the chemical treatment of an ore, and have had to be removed or rendered innocuous. Arsenic, selenium, tellurium, fluorine and other elements are not uncommon constituents of ores. The combinations in which they occur are relatively rare, and their presence may not be indicated without resort to refined analysis. All of which leads to the belief that a complete analysis of an ore is one of the first steps to be taken in testing it for chemical treatment. With full knowledge of original conditions, the difficulties of treatment can be anticipated and usually overcome.

Tendencies in Zinc Metallurgy

Current literature and the records of the patent office show that suggested improvements in the metallurgy of zinc are almost wholly along two lines, namely, utilizing lower grade ores, and smelting with electric heat. The former appears likely to be realized before the latter, at least in this country, because the pre-requisite of igneous concentration in the first instance is more certain and easy of accomplishment than the development of cheap electric power which is required in the second case.

One of the requirements in present practice in zinc smelting is ore of comparatively high metal content. For years the standard on sulphide concentrates produced in the Rocky Mountain region has been 40 per cent metallic zinc. In the Joplin district, the standard grade is 60 per cent. Carbonate and silicate ores are marketable if they contain 35 per cent metal, and a few instances have been known in which carbonate ores containing 20 per cent zinc have been sold at Leadville.

It will be apparent to those familiar with the conditions, that the above requirements exclude the possibility of mining and treating much ore that is not up to the standard; and further, that the physical condition of some of these ores is such that mechanical concentration is out of the question. Igneous concentration suggests itself, because the production of zinc pigment already constitutes a successful industry of some magnitude. While it is true that the production of pure pigment entails certain refinements which add to the cost of the process, these need not enter into the igneous concentration of low-grade ores for the subsequent production of spelter. In the latter case, the concentrated product may be of inferior grade as a pigment, but still of higher grade than the bulk of zinc concentrate now smelted. A charge of such oxide and powdered coal would consist mainly of volatile substances, and leave little solid residue to be disposed of.

Elsewhere in this issue are recorded two interesting proposals for improvements in zinc reduction. One is embodied in an article by F. L. Clerc, of Colorado, and the other in a patent granted to C. V. Thierry, of France. The names of both of these men are known in connection with the metallurgy of zinc. It is interesting to note the similarity in the claims which each makes for the advantages to be gained by smelting zinc oxide produced by igneous concentration, as compared with ordinary roasted concentrates containing more or less of the original gangue and some metals other than zinc. Each has devised a furnace specially adapted to the reduction of this product. A novel feature of Mr. Clerc's furnace is the method of conducting heat to the charge through a bath of molten copper which, in turn, is heated by burning suitable fuel. Mr. Thierry proposes to use an electric resistance furnace to smelt the charge.

Igneous concentration as a preliminary step in treating low-grade zinc-bearing material is not a new and untried scheme. The Pape process is in successful operation in Silesia, treating zinky slag. A method of similar intent has been tried in Colorado, but without commercial success. The slag experimented with was much lower in grade than that treated in Germany. The impression prevails, however, that there is a field for the application of this method of utilizing low-grade carbonate ores and other substances containing zinc in comparatively small proportions. Certainly it presents some attractive features in the way of securing a high-grade smelting material, and in the elimination of much of the time and labor now required to dispose of retort-residue.

Finished Steel Output in 1911

A remarkable showing is made by the partial returns of finished steel production in 1911, which have just been made public by the American Iron and Steel Association. The production of wire rods, 2,450,453 gross tons, proves to have been the largest on record, whereas the output of structural shapes, 1,912,367 tons, was the smallest since 1905, with the single exception of the year 1908, when all tonnages were very small.

It is due to the fact that wire, almost the sole product of wire rods, is ubiquitous, that the output of rods exceeded the output of structural shapes in 1911 by so large a margin, 28 per cent. The year was not one of large projects. The railroads were very conservative in their expenditures, and there was not very active erection of skyscrapers and other large buildings. Normally, of course, the railroads are large consumers of structural steel, while they are not conspicuously

large consumers of wire. It has always been observed that in a "bad year" the tonnage of wire stands out conspicuously. This was the case in 1908, when the total of rolled iron and steel declined from 1907 by 40 per cent. and the wire rod output declined only 10 per cent. In 1911 production of pig iron decreased 13 per cent production of steel ingots and castings 9 per cent and the output of wire rods increased 10 per cent. These are comparisons of 1911 with 1910, but it should be observed that while in 1910 new records were made by pig iron and steel, the rod output had been greater in 1909 than in 1910, so that the rod output of 1911 exceeded the record output by only 6 per cent.

Conditions in the present year present a reversal of those of 1911. The demand for fitted structural work and for railroad cars has been exceptionally large, while, relatively speaking, the wire trade has languished. It may show a larger tonnage this year than last, but structural shapes are certain to show a very large increase.

The Condensation Problem in Electric Zinc Smelting.

In this issue we publish an able and interesting Canadian Mining Institute paper by Mr. Walter Renton Ingalls on the electric smelting of zinc ore. There is no need to say anything of Mr. Ingalls' standing as one of the foremost zinc metallurgists of the present time. On this account the stand which this authoritative and conservative representative of the old classical school of zinc metallurgy takes with reference to electric-furnace insurgency is decidedly interesting, so that his paper should prove interesting reading.

His statement in last year's *Mineral Industry* that "the electric smelting of zinc ores is not only still in the experimental stage, but is in the infancy of the experimental stage," is not repeated now by Mr. Ingalls. His paper is clear evidence of the great pains which he has taken to be fair and impartial. For this reason we will not enter into any controversy with respect to quite a number of the author's statements, with which we do not agree at all. Mr. Ingalls is "not yet by any means prepared to say that electric smelting will offer any advantage over existing methods, even if difficulties that are now in view can be overcome." We have taken repeatedly and decidedly the opposite stand and have endeavored to prove the advantages that must result from the large continuously working electric zinc furnace when all the present difficulties have been overcome.

There is no need of repeating our argument at this place now; the evolution of electric zinc smelting has gone on and is proceeding along logical lines, and nothing has happened that would induce us to modify our views. Qui vivra verra. For the present even insurgents must concede that standpatters have a right to live—*and vice versa*.

The object of this note is to discuss one single phase of electric zinc smelting on which Mr. Ingalls lays great stress, and deservedly so. This is the difficulty which almost all investigators of electric zinc smelting have more or less encountered in condensation. Instead of liquid zinc blue powder is largely produced. Mr. Ingalls limits himself to the mere statement of the fact and purposely refrains from advancing hypotheses as to the reason. It is quite true that this is quite a complicated matter, and from case to case the reasons for the formation of blue powder may differ. But it is quite possible to state concisely without any hypothesis certain conditions which must produce blue powder.

We think it was Mr. W. McA. Johnson, the electric zinc furnace pioneer, who distinguished between "physical" and "chemical" blue powder. What these catch words mean is clear. Blue powder may be produced by special purely physical conditions or by special purely chemical conditions. This is a really useful distinction.

As to "physical" blue powder, the analogy with snow is obvious. Just in the same way in which water vapor may condense into snow instead of rain, zinc vapor may condense into blue powder instead of liquid zinc under special conditions of pressure and temperature. This is simply a problem of physical chemistry and it would seem to present opportunities for more than one thesis with experiments on vapor pressure of zinc and the conditions of equilibrium between liquid and gaseous zinc or solid and gaseous zinc. But when the physical chemistry of the problem is completely understood, the chemical engineer, with a mechanical engineering instinct, will still have some interesting work to do in the design of the condenser.

With respect to the formation of "chemical" blue powder, the primary supposition is that from the vapor not merely zinc but something else is condensed. As mentioned in Mr. Ingalls' paper, Boudouard found that when a certain limit of carbon dioxide in the gas of the zinc retort is exceeded carbon dioxide acts oxidizing upon the zinc, and coating the condensing globules of zinc prevents coalescence and forms powder. Now, many impurities in the ore under treatment will act in the same way. For instance, if the ore contains silica and an arc furnace is employed, silica or silicon vapors will be formed, and in condensation each condensing globule of zinc will be coated with a fine layer of silica and the coated globules will not run together and form liquid zinc, just in the same way as it is impossible to run globules of mercury coated with flour together into a liquid mass of mercury.

This would explain why Mr. Weeks, in his Schenectady experiments had no difficulty at all in condensation, as he treated zinc dross and thus had a rather pure vapor. It would also indicate an advantage of the resistance furnace in permitting to keep the temperature low enough to prevent pernicious impurities from passing into the vapor. In connection with arc furnaces it would explain the necessity of passing the vapor through some reducing agent like a column of incandescent carbon, as used by Mr. Johnson, in order to eliminate as much as possible all impurities which might interfere later on in the condensation of the zinc.

Thus it will be seen that the formation of blue powder necessitates the maintenance of correct physical and chemical conditions, and it is clear that the difficulties of the problem are enhanced by any increase of furnace unit and condenser unit. In any case where condensation difficulties are experienced it will be of fundamental importance to establish the reasons why and especially to ascertain whether the blue powder formation is due to faulty physical or chemical conditions. Though the problem is complicated, there is no reason why it should not be solved as a matter of course and in due time.

The Iron and Steel Market.

July in the steel market furnished a surprise. While sellers were prepared for a decided falling off in business, specifications have proved practically as heavy as in June. In view of the fact that July and August are almost invariably dull months, and the further fact that many low priced contracts expired with June, a decided decrease in specifications was to be expected. There is reason now to suspect that buyers are anticipating their requirements, being moved to do so by the fact that mills are falling behind in deliveries. The average specification for steel bars now requires about six weeks to fill, and deliveries of universal mill plates are almost as far behind. Such anticipation of requirements, while perhaps necessary for buyers when mills fall behind, tends to create an unsound position, for it accentuates the conditions which the buyer wishes to protect himself against, and the movement sometimes grows like a snowball, the experience in the second half of 1909 being a good illustration. While the market is strong, there are suggestions now being made in some quarters that there is danger of a runaway market.

There are predictions that bars, plates and shapes will shortly advance a dollar a ton, following the similar advance of June 26, which was to 1.25 cents for bars and 1.30 cents for plates and shapes.

Under date of July 20 the American Steel & Wire Company advanced its products $1 a ton, making plain wire 1.45 cents, galvanized wire 1.75 cents, wire nails $1.65, painted barb wire 1.65 cents and galvanized barb wire 1.95 cents. The advance was promply followed by the independents. Buyers are well covered by old contracts, some of them made before the previous advance.

Pig Iron.

There has been a general advancing tendency in pig iron in all markets, although sales have not been heavy. Southern iron has advanced fully 50 cents, being available at $11.50, Birmingham, only for prompt shipment, while $12 is demanded for late deliveries. In the north the average advance has been about 25 cents. We quote foundry iron at $15.50 delivered Philadelphia and at $14.50 to $15 f. o. b. Chicago district furnaces. Valley prices are: Bessemer, $14.25 to $14.50; basic, malleable and No. 2 foundry, $13.50; forge, $13 to $13.25.

Steel.

Steel has become scarcer but prices have advanced only slightly. Consumers are well covered by contracts, and are only buying as their requirements exceed the deliveries they can secure on contracts. The mills are unwilling to quote for fourth quarter delivery on billets and sheet bars, and evidently expect a materially higher market. For third quarter delivery billets are quotable at $21.50 to $22 and sheet bars at $22 to $22.50 f. o. b. maker's mill, Pittsburgh or Youngstown. Rods are $25, Pittsburgh.

Finished Steel.

Effective July 1 steel pipe larger than 6-in. was advanced one point or about $2 a ton, matching the advance of June 1 on 6-in. and smaller. Iron pipe has been advanced similarly. Regular discounts, on "jobbers' carloads," sizes ¾ to 1½-in., are 80 per cent off for steel pipe and 74 per cent off for iron pipe.

Current prices, f. o. b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Light rails, 16 and 20-lb., 1.24 cents; 25, 30, 35, 40 and 45-lb., 1.19 cents.

Plates, tank quality, ¼ in. and heavier, 1.30 cents.

Shapes, 1.25 cents.

Steel bars, 1.25 cents.

Iron bars, 1.35 cents, Pittsburgh; 1.35 cents, Chicago; 1.32½ cents, Philadelphia.

Sheets, blue annealed, 10 gage, 1.45 cents; black, 28 gage, 2.00 to 2.05 cents; galvanized, 28 gage, 3.05 to 3.15 cents; painted corrugated roofing, 28-gage, per pound, 2.15 to 2.20 cents; galvanized, 3.10 to 3.20 cents.

Tin plates, $3.50 per box for 100-lb. cokes.

The Non-Ferrous Metal Market

Since our last report the market for copper and tin has shown unusual activity, followed by dullness after the national holiday. Conditions in European markets have affected the domestic market more than usual, especially in tin and copper. Lead has been arbitrarily advanced by the leading seller, and an average business has been transacted.

Copper.—Late in June copper sold at 17⅝ cents, but early in July the demoralization of the London Market caused a decline in the European price to 16½ cents, with the result that no foreign business could be transacted by sellers on this side, and the domestic market weakened. At last reports Lake copper has a nominal quotation of 17⅛ to 17⅜ cents. Electrolytic is quoted at 17 to 17.05 cents.

Tin.—The London dock strike brought about an acute situation in the New York tin market. Spot tin commanded a premium of 3 cents until July 9, when the premium was reduced. The close for July tin at last reports was 44⅜ cents, New York.

Lead.—On July 3 the price was advanced from 4.50 to 4.75 cents, New York. St. Louis advanced to 4.62½ to 4.65 cents. The market has been firm and good business is reported.

Spelter.—Consumption was excellent early in July, but later the principal buyers staid out of the market, and business was dull. Some premiums were realized on July spelter, as the supply was short, but little or no business was reported in September spelter. The last quotations are 6.95 to 7.05 cents, St. Louis, and 7.10 to 7.20 cents, New York.

Other Metals.—Consumption in aluminium continues good and the quotation is firm at 22½ to 23 cents, New York. Larger sales of antimony are reported and prices are firmer, ranging from 7.25 to 8.50 cents for various brands. Quicksilver has been quiet and there is little change in prices. New York quotations are $42.50 per flask of 75 lb. San Francisco reports quotations of $42.

The Western Metallurgical Field

Teaching Metallurgy at Missouri.

At the Missouri School of Mines and Metallurgy, assaying, metallurgy and ore dressing are taught in the same department. In designing the laboratories, the teaching staff kept constantly in mind the idea of teaching the principles of the subjects involved. Adaptability for commercial testing or for much full-scale experimenting has been considered of secondary importance. The result is believed to embody excellent testing laboratories, with some opportunity for full-scale work, but with special advantages in teaching metallurgical principles. The latter feature is believed to be absolutely essential to the successful work of graduates, and the equipment has been selected and the courses planned so that fundamental principles may be impressed on the student. Practically all the laboratory work in metallurgy is done by the student without laboratory directions before him on a printed sheet, so that he finds it necessary to post himself on the nature of the work before he undertakes it.

The assay laboratory is equipped with coal, coke and gasoline furnaces of standard design. The coal furnaces and bins are so arranged that it is easy for a student to see whether he is using fuel economically, or whether his neighbor is getting better results from less coal. The furnaces are adapted to the use of pyrometers and gas-analyzing apparatus, so that the students can make these determinations when desired. The stock room is well arranged for storing samples of ore. These are put in sacks holding about three ounces each. Original

samples weighing from 20 lb. up are carefully ground and assayed before being given to the students.

In the metallurgical laboratory there is a room for small-scale experiments. One part of the laboratory is occupied by a water-jacket furnace, 20 in. at the tuyeres and having a smelting column of 6 ft. This can be used to teach the principles of smelting. A crew of students is required to get ready the data necessary for a smelt, make the calculations, prepare the furnace, blow in, recover the products, blow out, sample and assay the products and take account of stock. By this means it is possible to reinforce the class room instruction in a way that would not be possible without the furnace. A hand-reverberatory roasting furnace and an improvised blast-roasting apparatus are provided for work of this kind. A small zinc smelting furnace is being constructed, to be used principally in emphasizing the principles of zinc smelting. A cyaniding laboratory is provided in which small-scale operations can be conducted, and the chemical principles shown.

The ore dressing laboratory contains a complete equipment for crushing, sizing and concentrating ores of all kinds. The machines in this department are full size, and are so arranged that they can be operated independently or together. In laboratory practice the student is required to work with each machine until he is familiar with the principles underlying its construction and operation. After he has become familiar with these points, he is required to use the machines in groups, and is given experiments of increasing difficulty until a complete mill scheme is carried through.

The metallography laboratory will accomodate 12 students. It is equipped with suitable miroscopes and accessories, photomicrographic camera, and other instruments needed in the microscopic study of metals. A specimen cabinet contains 1200 specimens, with a complete history of each specimen. Photographic plates also are filed and indexed.

In a bulletin recently issued from the school at Rolla, Mo., the faculty of the department of metallurgy has published a detailed statement of the work done in metallurgical instruction. Examples are given of the type of problems given the students in each branch of the work. The nature of the problem and the method of working it are designed to develop personal observation and reasoning, instead of merely telling the student what to do and what the result should be. On the whole, the article makes out a very good case for the methods used in developing young metallurgists at Missouri.

Losses by Fire.

The mine buildings of the Silver Lake mine, near Silverton, Colo., were destroyed by fire recently. The fire originated in the blacksmith shop while the employes were at dinner and spread rapidly to adjoining buildings. The boarding house was saved by dynamiting buildings between it and the fire, but the upper terminal of the long tramway which connects the mine and concentrating mill was destroyed. This resulted in stopping operations at the mill. The loss is reported to be between $30,000 and $40,000. The property is owned by the American Smelting & Refining Company, and the ore produced is smelted at the Durango smelter of that company. The fire will in no way hamper the smelter operations, as a large stock of smelting material has been accumulating at the smelter during the months following a cessation of work after the floods last spring. The company will immediately rebuild and commence operation as soon as possible.

Tonopah, Nev., was visited by a disastrous fire on July 8. The principal business section was completely destroyed, and many small buildings burned before the fire could be put out. The loss is estimated at over $300,000. Tonopah is at present a prosperous mining town. A number of companies have recently built mills there, and have adopted the latest ideas in metallurgical treatment. There is little doubt, therefore, but that the town will be rebuilt.

Revival of Interest at Marysvale, Utah.

The Bully Boy-Webster group of claims at Marysvale, Utah, includes some of the earliest locations made in that district. The mines have been worked intermittently for many years, but more recently they have been idle on account of the low grade of the ore. A new mill has been built along lines which are indicated by other successful mills on similar ore, and it is expected that the system of concentrating and cyaniding will solve the problem. A large dump will be treated first, followed by fresh ore taken from the mine in the course of development work. The ore will be screened and the larger pieces washed and hand-picked. The ore recovered from the picking belt will be crushed and added to the original fine ore. Chilean mills will be used to grind the ore to 30-mesh size, after which it will be classified and concentrated. The tailing from concentration will be cyanided by agitation, then classified into sand and slime. The sand will be discharged to the dump and the slime will be filtered on Portland filters. Zinc dust will be used for precipitation. The mill will be operated by water power, which is available practically throughout the year.

Company Reports.

The May report of the Goldfield Consolidated Mines Company was delayed in order to receive returns from ore shipped to the smelter of the International S. & R. Company, Tooele, Utah. It seems that ore carrying considerable copper and silver is being mined from the deepest workings, and is unsuitable for treatment in the mill. It is, therefore, marketed separately. The report states that the May production was 30,215 tons, containing precious metals valued at $550,656, or an average of $18.22 per ton. The mill extraction was 91.44 per cent, and the net recovery from all ore treated and shipped amounted to $16.69 per ton. Operating costs amounted to $6.60, leaving a net profit to the company of a trifle over $10 per ton. The estimated June production is 32,360 tons, being the largest monthly production in the history of the company.

The annual report of the Greene Cananea Copper Company for the calendar year 1911 has just been issued. It shows that the company treated in its mill 528,412 tons of ore produced from company mines and 113,213 tons from Cananea Duluth mines. The former had a concentration ratio of 2.4 into 1, and the latter 5.17 into 1. The operating and repair cost was $0.646 per ton, and improvements cost $0.076 per ton, giving a total cost for the year of $0.722 per ton. The average saving of copper in the concentrates was 77.69 per cent. Every pound of tailings, whether of sand or slime, is being impounded, and there is no doubt that the reclamation of clear water from the tailings pond is of more value than the cost of impounding the tailings. The concentrators are in excellent condition, the old wooden jigs having been replaced by reinforced concrete jigs. Many other small improvements have been made, but none of great magnitude.

In the reduction division the cost of smelting was $2.57 per ton. This is not quite down to the predicted mark of $2.25 per ton, but the average grade of matte has been much lower than formerly, the converting department has been congested, and the amount of by-products to be handled was greatly increased. Changes are being made in the converting department, however, by which it is still hoped to reduce the cost of smelting to $2.25 per ton of material. In the segregated costs, converting amounted to $0.6518, being a large proportion of the total cost. Blast furnace cost was $1.4055; calcining, $0.051; reverberatory, $0.3197; sampling, $0.0222; bedding, $0.0584. The cost of McDougal roasting for the year was $0.40 per dry ton.

A new reverberatory furnace was built and put in use during the year. Twelve-inch buckstays were used in place of the old 10-inch; and a 20-inch arch was built in place of the previous 12-inch arch. The cost of reverberatory smelting

amounted to $1.65 per ton of charge, as compared with $1.90 for the previous year. Without the cost of rebuilding No. 1 furnace, the cost was only $1.427 per ton of charge. Basic lining has been introduced in the converter department, but investigation has demonstrated that the barrel-type shells are not as well adapted to economical work as the Great Falls type, and two of the latter have been ordered. This will increase the capacity of the converter department, and it will be able to produce from eight to nine million pounds of copper per year. Blowing-engine capacity for the blast furnaces will be increased as the sulphur content of the newly developed ores requires more oxygen for smelting.

Copper costs for the year were as follows: Gross cost, f.o.b. Cananea, 9.568 cents per pound; freight to New York, 1.343 cents; total, 10.911 cents per pound. The value of the precious metals credited to this gross cost amounts to 1.823 cents per pound, leaving a total cost of fine copper sold of 9.088 cents per pound. The total cost of mining and treating a ton of ore, including every cost until the refined copper has been sold, was $5.257. The yield of copper per ton of ore treated was 50.01 pounds. It is probable that during the coming year the yield will not be so high.

Metallurgy as She Is Promoted.

Metallurgy is not without its humorous side. The pompous promoter who uses technical terms with reckless abandon, the ignorant tyro who flounders in a subject that is too deep for him and the crafty schemer who uses his knowledge to play on the credulity of those less well informed, all contribute to the gaiety of the profession. Occasionally these men are vicious, but more often they are sincere and exhibit a courage and assurance that is equaled only by their ignorance. In developing their processes they draw on a vivid imagination, occultism and various forms of well-known stimulants. Incidentally they may use electricity or an acid, but these are mere matters of detail and the main reliance usually is placed on something less tangible.

Some time ago one of these processes was brought to the attention of one of our large metallurgical concerns. It purported to be a process "for the disintegration of metals by vibration," whatever that may be, and promised marvelous results. No demonstration was made, but a meeting was arranged between the promoters and the company's metallurgist, at which the details of the process were unfolded. In reading the report on the process which the metallurgist made to his principals, it will be apparent that he is endowed with a strong sense of humor. The report is given below exactly as he made it, only the names being changed, of course:

"If the magnitude of the vibrations of the metals in your ores can be increased by our chemical stimulus, all of these metals will then pass into the matte and be saved. At present you solidfy; we disintegrate. These vibrations are controllable, my dear sir; that is the entire secret."

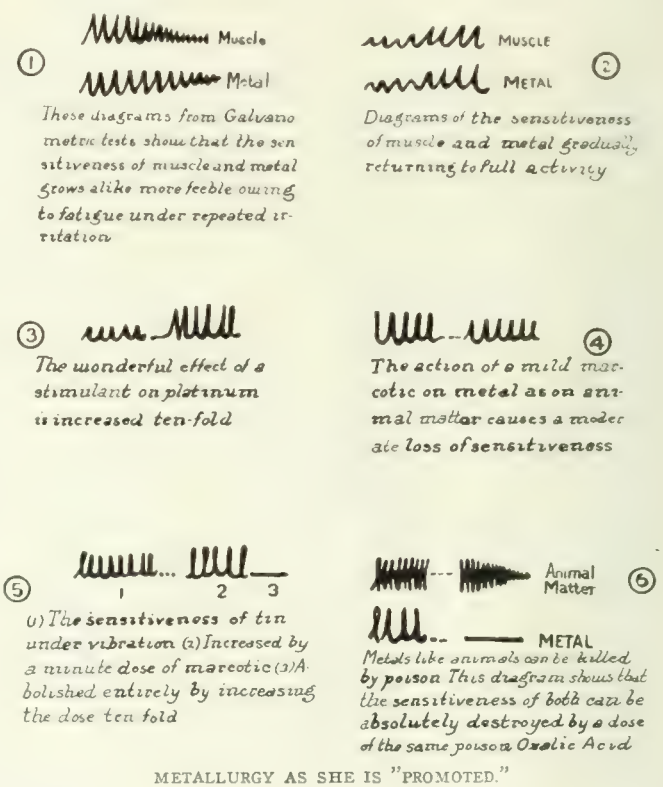
This was the dictum of Colonel Blank, Soldier of Fortune. Colonel Blank had been writing voluminous letters to Judge Breaudeigh about the recovery of platinum, iridium and other rare metals from our slag. As the colonel was very emphatic that a wet assay was needed, since his process recovers values which no fire assay would show, I judged it best to see him in person.

The colonel is a neat looking, stout man, of say, 60, with a pair of gold eye-glasses on the extreme tip of his nose. He is the man of business—"In touch with outside capital, sir." He has an assistant or accomplice named Peele, who does the actual work. Peele is a hairy, ill-kempt man, who, I judge, sleeps in his shirt. The third of the trio, the inventor, was not at the conference, he having fallen from a street car recently, probably while under the influence of the vibration.

This story goes back to the time when the inventor was a sergeant-major in India, where he met a very holy man, Prof- Jagadis Chunder Bose (not Boose, but Bose with a long o). This learned pundit has sent forth from the University of Calcutta a book entitled "Life in Metals," and to one chapter in this, called "The Response of the Living and Non-Living," your attention is particularly directed.

(At this point the waiter performs his manipulations and we place ourselves in tune with the infinite.)

The inventor sits at the feet of the aforesaid Bose and learns from him that muscle and metal are practically alike in their response to stimulants and narcotics. For example, Fig. 1 proves that muscle shows, under fatigue, a certain vibration, the amplitude of the vibration growing less and less as fatigue continues. Metals, as the diagram shows, have an almost similar action under fatigue. Fig. 2 shows that as this cause of fatigue is removed, the muscle and the metal regain their full vibrations. Passing now one step further, we learn that metals can be aroused by a stimulant and calmed by a sedative. Fig.



1
Muscle
Metal
These diagrams from Galvano metric tests show that the sensitiveness of muscle and metal grows alike more feeble owing to fatigue under repeated irritation

METAL
Metals like animals can be killed by poison This diagram shows that the sensitiveness of both can be absolutely destroyed by a dose of the same poison Oxalic Acid

METALLURGY AS SHE IS "PROMOTED."

3 shows the wonderful effect of a stimulant on platinum. Its irritability is increased ten-fold. On the other hand, Fig. 4 shows the action of a mild narcotic on metal, causing a moderate loss in sensitiveness. Coming now to the most interesting part, we learn from Fig. 5 that any metal, tin, for example, may be stupefied by a dose of poison—oxalic acid—and that on increasing the dose the metal dies, is defunct; its vital spark is extinct, and the undertaker must be called in. So Fig. 6 closes the story with a summary showing the absolute similarity of metal to muscle in its relation to stimulant and sedative.

At this point the inventor begins to perceive a practical application of this theory to modern metallurgy, and coming to America hires Mr. Peele, who was a corporal in some volunteer regiment. Colonel Blank is admitted to the secret, as the poor old inventor has no idea of business. "In fact, my dear sir, he is a mere child in the affairs of the world." Blank becomes the business manager of the concern.

(Here the colonel drops his eye-glasses off the tip of his nose into his tumbler, which proves to be empty, and the waiter comes running with the necessary chemicals.)

Now, as to the practical side of it. "Your process tears down, we build up; you solidify, we disintegrate. We have

here a table of assays made by the great Doctor Lodeux, probably the best analyst in America, showing our results. Here is No. 12, black sand from Atlin, an ore of which we treated 6 oz., and by our process reduced it to 16 dwt. 3 gr., in which Dr. Lodeux finds a total weight of metal per ton of ore of 3918 oz. 10 dwt. 15 gr. Out of this we got 376 oz. 10 dwt. 9 gr. gold, valued at $7,530, and 224 oz. 8 dwt. platinum worth $8,554; making a total recovery of 820 oz. 18 dwt., valued at $16,084 per ton, and that, mind you, from material they were throwing away.

"Sample No. 70, to which your attention is particularly directed, is a marble, an ordinary building stone. This the process reduced from 12 oz. to a button weighing 4 dwt., containing 14 oz. platinum per ton, valued at $490, and 13 oz. 10 dwt. iridium worth $536, or a total value of $742.70 per ton of marble. Yes, sir.

"Now as to your matte. You say you only recover one ton of matte from 17 tons of your ore. We took 16 oz. of your ore and by our process of disintegration made 12 oz. of matte out of it, a recovery of 75 per cent, whereas your recovery is 17 into 100—say 6. So we give you ten times the recovery you get. Now, what is it? That's for you to say."

"Yes," says Peele, "that's right. I done it myself and I added the chemicals that disinterrogate the Silica, and I thought it must be wrong when I got such a big button, but the old man said to put it back and leave it under vibration all night and the next morning the Silica was all disinterrogated and there's your values."

"It's a flux we sell you," says the colonel. "You see you kill the ore by your process; it's dead, and that's why you lose so much of the slag. We stimulate it, invigorate it—as you can see by the diagram—its vibrations are increased tenfold; it passes into the matte. You get all of it, absolutely all. *But it must be a wet assay,* fire assays are no good. Yes, thank you. Dewar's, and another split Polly."

Program of the International Congress of Applied Chemistry.

The following is a concise program of the Eighth International Congress of Applied Chemistry, to be held in this country from September 4 to 13, 1912. Further details, especially on entertainments and excursions may be found in Announcement No. 4, issued by the Secretary of the Congress, Dr. Bernhard C. Hesse, 25 Broad Street, New York City.

Meeting at Washington.

The inaugural meeting of the Congress will be held on Wednesday, September 4th, 11 a. m., at Washington, D. C., presided over by the President of the United States.

In the afternoon there will be general excursions to the Capitol from 2 to 4 p. m., a garden party on the lawn at the White House from 4:30 to 6:30 p. m., and a reception at the New National Museum from 8 to 11 p. m.

The morning of Thursday, September 5, will be devoted to visits of the Art Galleries, the Library of Congress, the Government laboratories, or a trip to Mount Vernon. In the afternoon at 4:55 and at intervals thereafter, special trains will take the members of the Congress to New York City.

Meeting at New York City.

The main work of the Congress will be done in sectional meetings, which will be held in Columbia University.

Sectional meetings will be held on Friday, September 6, from 10 a. m. to 12 a. m. and from 1 p. m. to 3 p. m., on Saturday from 10 a. m. to 12 a. m., and during the following week on Monday, Tuesday, Wednesday, and Thursday, September 9 to 12, every day from 10 a. m. to 12 m. and from 1 p. m. to 3 p. m., at Columbia University.

The Congress will be wound up officially on Friday, September 13, by a meeting of the International Commission of Congresses of Applied Chemistry at 10 a. m. and the final General Assembly of the Congress in the great hall of the College of the City of New York at 11:30 a. m.

There are twenty-four sections and sub-sections of the Congress, as follows:

Section	I:	Analytical chemistry.
"	II:	Inorganic chemistry.
"	IIIa:	Metallurgy and mining.
"	IIIb:	Explosives.
"	IIIc:	Silicate industries.
"	IV:	Organic chemistry.
"	IVa:	Coal tar colors and dye stuffs.
"	Va:	Industry and chemistry of sugar.
"	Vb:	India rubber and other plastics.
"	Vc:	Fuels and asphalt.
"	Vd:	Fats, fatty oils, and soaps.
"	Ve:	Paints, drying oils, and varnishes.
"	VIa:	Starch, cellulose, and paper.
"	VIb:	Fermentation
"	VII:	Agricultural chemistry.
"	VIIIa:	Hygiene.
"	VIIIb:	Pharmaceutical chemistry.
"	VIIIc:	Bromatology.
"	VIIId:	Physiological chemistry and pharmacology.
"	IX:	Photochemistry.
"	Xa:	Electrochemistry.
"	Xb:	Physical chemistry.
"	XIa:	Law and legislation affecting chemical industry.
"	XIb:	Political economy and conservation of natural resources.

General Lectures and Joint Sessions with the American Electrochemical Society and the American Institute of Mining Engineers.

The following general lectures will be delivered:

Gabriel Bertrand, of Paris, France: "Du role des infiniment petits chimiques en chimie biologique" on Friday, September 6, 4 p. m., in the great hall in the College of the City of New York.

Samuel Eyde, of Kristiania, Norway: "Oxidation of atmospheric nitrogen and development of resulting industries in Norway" in a joint session of sections II, VII, Xa, and Xb, on Saturday, September 7, 2 p. m., in the auditorium of the American Museum of Natural History.

Carl Duisberg, of Elberfeld, Germany: "Die neuesten Arbeiten and Probleme der Chemischen Industrie," on Monday, September 9, 4 p. m., in the great hall of the College of the City of New York.

William Henry Perkin, of Manchester, England: "The permanent fireproofing of cotton goods" on Tuesday, September 10, 4 p. m., in the great hall of the College of the City of New York.

H. A. Bernthsen, of Ludwigshafen on the Rhine, Germany: "Synthetic Ammonia," in a joint meeting of sections II, VII, Xa, and Xb, Wednesday, September 11, 10:30 a. m., at the College of the City of New York.

Giacomo Ciamician, of Bologna, Italy: "La Foto Chimica dell' Avvenire," Wednesday, September 11, 4 p. m., in the great hall, the College of the City of New York.

Ira Remsen, of Baltimore, Md.: "Priestley in America," Thursday, September 12, 4 p. m., at the College of the City of New York.

The afternoon lectures at the College of the City of New York on Friday, Monday, Tuesday, Wednesday and Thursday will be preceded by an organ recital at 3:15 and followed by an informal tea at 5 o'clock.

Joint meetings will be held by Section IIIa of the Congress with the *American Institute of Mining Engineers* and by Section Xa with the *American Electrochemical Society.*

A joint meeting of Sections IIIa and Xa of the Congress, the

American Electrochemical Society and the American Institute of Mining Engineers will be held on Saturday, September 7, at 10 a. m. and will be devoted to the reading and discussion of papers of electrometallurgical interest. Among the authors who will address this meeting are: Mr. Lawrence Addicks, Dr. Richard Amberg, Mr. F. A. J. FitzGerald, Mr. A. E. Greene, Mr. Joseph O. Handy, Dr. Paul Héroult, Mr. F. T. Snyder, and Mr. C. H. vom Baur.

Joint meetings of Sections II, Xa, and Xb of the Congress with the American Electrochemical Society will be held on Monday, September 9, in the forenoon and afternoon. The feature of the afternoon session will be an experimental lecture by Dr. E. Weintraub, of the General Electric Company, on the *element boron*, its compounds, and uses.

A joint meeting of Sections VIa and Xa with the American Electrochemical Society on the forenoon of Tuesday, September 10, will be devoted to a symposium of papers on the *electrolysis of sodium chloride* for the production of caustic soda and chlorine, and hypochlorites. Among the authors who will address this meeting are Mr. A. A. Claflin, Mr. R. E. Gegenheimer, Prof. Ph. A. Guye, Dr. R. Taussig, Dr. Wm. H. Walker, Mr. Jasper Whiting and Mr. E. Wilderman.

For the afternoon of Tuesday, September 10, another joint session of Section Xa and the American Electrochemical Society is scheduled.

On Wednesday, September 11, in the forenoon and afternoon joint sessions of Sections Ve and Xa will be held, devoted to a symposium on *corrosion and its prevention*. Papers on this subject will be presented by Mr. James Aston, Prof. Chas. F. Burgess, Dr. J. K. Clement, Mr. H. H. Hanson, Mr. J. H. Lawrie, Mr. K. Lewis, Dr. E. Liebreich, Mr. W. B. Schulte, and Mr. Maximilian Toch who will present an illustrated lecture on the condition of the battleship Maine after 13 years' submersion.

A great many more joint meetings between various other sections have been arranged, but the program of the papers has not yet been finally arranged. Further details must be reserved for our next issue.

Entertainments.

In advance of the official beginning of the Congress the following informal entertainments will be held.

A reception of the Society of Chemical Industry will be held on *Saturday*, August 31, at 8:30 p. m., at the Chemists' Club. On the same evening members of the Verein Deutscher Chemiker will gather informally on the roof garden of the Hotel Astor.

For *Sunday*, September 1, the Verein Deutscher Chemiker has arranged an automobile trip to Coney Island and in the evening a concert on the roof of the New Century Theater.

On *Monday*, September 2, 10 a. m., the Verein Deutscher Chemiker will hold a business and professional meeting at Havemeyer Hall, Columbia University, where Dr. F. Raschig will speak on the scientific and technical importance of tarphenols and Dr. F. W. Frerichs on 32 years in the United States as a chemist and manufacturer. For the evening the Verein has arranged a Kommers and for the ladies a theater party.

On the same evening the Chemists' Club will give a reception at its Club House to members of the Congress speaking the Latin tongues.

On *Tuesday*, September 3, the Society of Chemical Industry will hold its business and annual meeting at the Chemists' Club. An address of welcome by the Mayor of the City of New York and the address of the retiring president, Dr. Rudolph Messel, are scheduled for this occasion.

Wednesday and Thursday are the Washington days, as noted above.

On the evening of *Thursday*, September 5, the American Institute of Chemical Engineers will hold a banquet at the Chemists' Club.

The program of entertainments during the New York days of the Congress is as follows:

Friday, September 6, 8 p. m.: Kommers to Section VIIIb by the Apotheker Verein, of New York City, 9 p. m.: Reception to Japanese delegates by Dr. and Mrs. Takamine.

Saturday, September 7, 8:30 p. m.: Reception at the Metropolitan Museum of Art in Central Park, given by the American Chemical Society to the members of the Congress.

Sunday, September 8, 10 a. m.: Boat excursion up the Hudson to Newburgh.

Monday, September 9, 7 p. m.: Garden party at Bronx Park.

Tuesday, September 10, 8:30 p. m.: Reception by the Chemists' Club to all members of the Congress at the Club House.

Wednesday, September 11, 8 p. m.; Entertainment at the Hippodrome.

Thursday, September 11, 7 p. m.: Grand banquet at the Waldorf Astoria.

Friday, September 13, 3 p. m.: Baseball game, New York vs. St. Louis at Polo Grounds. 7 p. m.: Subscription dinner of Society of Chemical industry at the Waldorf-Astoria.

For *Saturday*, September 14, visits to the Consolidated Gas Company and the Nichols Copper Company have been arranged for the forenoon, and a visit to the Corn Products Company, the Standard Oil Company, and the Bush Terminal Company for the afternoon.

On *Monday* morning, September 16, excursion trains will carry those members who participate in the two arranged trips out of New York City. The "short trip" (10 days) includes Philadelphia, Pittsburgh, Niagara Falls, Detroit, Chicago, Cleveland, and Boston. The "long trip" (37 days) includes Philadelphia, Pittsburgh, Niagara Falls, Detroit, Chicago, Omaha, Denver, Salt Lake City, San Francisco, Los Angeles, Grand Canyon, El Paso, Fort Worth, Sulphur, La., New Orleans, Birmingham, Atlanta, Ducktown, Tenn., Asheville, N. C., Charlotte, Great Falls, S. C., Danville, Va., and Washington, D. C.

For the *entertainment of ladies* during the Congress a very elaborate program has been arranged. For details see announcement IV, issued by the Secretary.

The membership fee is $5. *Nobody who intends to join the Congress should delay doing so any longer, because delivery of the printed Proceedings of the Congress (which will comprise several volumes and will indeed form in itself a veritable library on the present status of applied chemistry worth a great deal more than* $5.) *can be guaranteed only to those members of the Congress who join before the issue already contracted for is exhausted.* (All the papers which were received by July 1 and accepted are now in the hands of the printer.) The membership fee of $5 is to be sent to Mr. *W. J. Matheson*, Treasurer, International Congress of Applied Chemistry, 182 Front Street, New York City.

Joint Resolution for Patent Office Investigation.

Representative Bulkley, of Ohio, on July 15th introduced in the House of Representatives a joint resolution requesting the President to order an investigation of the Patent Office, "to investigate fully and carefully the administration of the Patent Office with a view of determining whether or not the present methods, personnel, equipment and building of said office are adequate for the performance of its functions, taking into consideration the present character and volume of business, and also such increase in complexity or volume as may reasonably be expected in the future, and to ascertain and recommend specifically to Congress not later than Dec. 10, 1912, what changes in law, what increases in appropriations and what additional building accommodations may be necessary to enable the Patent Office to discharge its functions in a thoroughly efficient and economical manner, and to what extent any expenditures which may be recommended can be met by increases of Patent Office fees."

A Microscopic Study of California Electric Furnace Pig Iron

By D. A. Lyon and F. C. Langenberg.

A sample of pig iron was recently received from the Noble Electric Steel Company, which was made in an electric furnace at their plant at Heroult, Shasta County, Cal. The ore used in the production of this iron shows the following analysis:

Fe	69.9	per cent.
Fe_3O_4	89.4	per cent.
Fe_2O_3	7.3	per cent.
MnO	0.18	per cent.
MgO	0.30	per cent.
SiO	2.40	per cent.
P	0.011	per cent.
S	0.009	per cent.

From a hand examination of the sample, and as judged by its fracture, the iron as compared to Pittsburgh iron would be graded as No. 3 foundry iron, that is, a close-grained iron, less open-grained than a No. 2 iron, and still less than a No. 1 iron. A photograph of the fracture of this iron, actual size, is shown in Fig. 1. Fig. 2 shows the same fracture as slightly over two diameters.

FIG. 1.—FRACTURE, ACTUAL SIZE.

A microscopical examination was made of a section of this sample, as shown in Figs. 3 and 4. In Fig. 3 is shown the sample unetched at 100 diameters. In the photo-micrograph the black areas represent the graphitic carbon and the white background the ferrite and combined carbon, if any of the latter be present. In Fig. 4 is shown the same area as is shown in Fig. 3, after etching with 10 per cent nitric acid and alcohol for about one and a half minutes. The junction lines of the ferrite grains are distinctly revealed, the small additional dark areas which appear representing pearlite areas. From an examination of these two specimens, etched and unetched, we are able to predict the constitution and physical properties that may be expected of such an iron. For example: In the first place we note that the carbon is practically all in the graphitic form, there being present not over 0.05 per cent of combined carbon. We also note the absence of the phosphide eutectic, which indicates that the iron is practically free from phosphorus. Also, by reason of the carbon being present almost entirely in the graphitic form, we are led to believe that the manganese and sulphur content of the iron are very low and the silicon content comparatively high. That this is true is shown by the following chemical analysis of the iron which was subsequently made:

Si	3.64	per cent.
S	0.00	per cent.
P	0.02	per cent.
Combined carbon	0.00	per cent.
Total carbon	3.58	per cent
Mn	0.00	per cent.

The properties of such an iron, that is, one practically free from sulphur, phosphorus and manganese, have not, so far as we are aware, been studied due to the fact that pig iron of such purity is rarely produced. We are therefore only able to judge of the physical properties of such iron by noting the influence of the elements we find present upon iron *per se*,

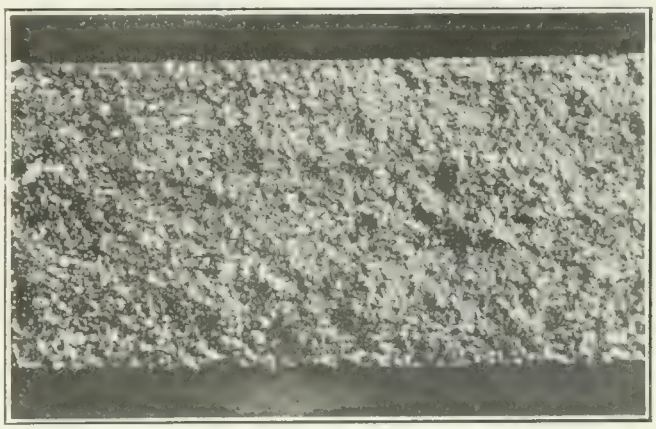

FIG. 2.—FRACTURE X2.

for, as has been shown by Howe, although one element may exert a very decided influence of itself upon the physical properties of iron, yet when in combination with others its effect is entirely different. In this case we have practically no other element present except iron, carbon, and silicon, and hence have only one element to consider, namely, silicon.

In order to study the influence of this element upon iron, Turner,* in 1885, prepared an iron by heating wrought iron and charcoal in closed crucibles. This was then remelted with a silicon pig, containing about 10 per cent silicon, in proportions necessary to yield any desired composition. However, the phosphorus content was in some cases as high as 0.32 per cent, and the manganese present in the most extreme cases was 1.95 per cent. Sulphur varied from 0.05 to 0.03 per cent. Therefore the irons compounded by Turner were in no instance as free from impurities as the iron under consideration, and hence we are unable to state by analogy what the principal properties of the latter should be.

The influence of silicon on the physical properties of cast iron has also been studied by W. J. Keep† and many others. Keep found that a small addition of silicon to white iron eliminates blowholes and produces soundness, while a further addition of that element gives the greatest crushing strength. He also observed that silicon in excess of that required to give the greatest crushing strength diminishes brittleness and yields the greatest transverse and tensile strength. This is, of course, due to the fact that silicon of itself has a tendency to cause whatever carbon may be present in the iron to assume the graphitic form. As might naturally be inferred from the manner in which the graphite is distributed throughout the iron, the strength of the matrix is necessarily less than would be the case if the graphite particles were not interspersed throughout the same.

Turner in his investigations of the influence of silicon upon the properties of cast iron arrived at conclusions similar to those of Keep. Turner obtained maximum hardness with an iron containing less than 0.8 per cent of silicon, maximum

*Journal Chem. Soc., 1885, p. 577.
†Am. Inst. Min'g Engs., 1888

crushing strength with about 0.8 per cent, and greatest tensile strength with about 1.8 per cent. He also found that an iron possesses the softest and best working qualities when its silicon content was about 2.5 per cent. But it is to be remembered

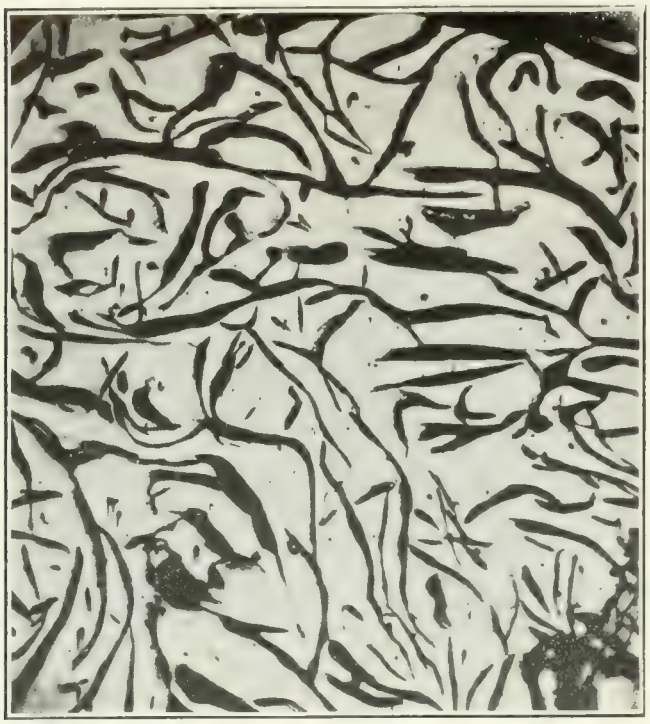

FIG. 3.—MICROPHOTOGRAPH OF ELECTRIC PIG IRON.

that he performed his tests on pure iron containing appreciable amounts of manganese and phosphorus.

From the start it has been the aim of the Noble Electric Steel Company to produce an iron which would best meet the

FIG. 4.—MICROPHOTOGRAPH OF ELECTRIC PIG IRON.

requirements of the Pacific Coast foundries. In order to understand what these requirements are we may state that scrap cast iron is largely employed for making all grades of castings, and that the sulphur, phosphorus and combined carbon content of the same is very often so high as to impart very undesirable qualities to the finished product. For this reason the Pacific Coast foundrymen have been in need of an iron high in graphitic carbon and silicon and low in other impurities.

From the analysis given above it may be seen that the pig iron made in the electric furnace in California is of that nature. It is, therefore, apparent that if a foundryman using this iron understands the effects of phosphorus, manganese, sulphur, and especially silicon, upon the physical properties of iron he may by an intelligent mixing of this electric furnace pig iron with scrap cast iron, based upon actual analyses of the latter, obtain an iron in which the predominating physical property shall be the one most desired or a combination of physical properties best suited to meet the requirements.

Due to the fact that this electric furnace pig iron is practically free from phosphorus, sulphur, and manganese, while the irons used by Turner and Keep in their investigations contained appreciable quantities of other substances, the writers are of the opinion that a study of the former along lines similar to those pursued by Turner and Keep and Paglianti* will result in furnishing additional data on this subject. They are planning to conduct such an investigation in the very near future and hope to be able to supplement the data which has already been obtained on this subject by Turner, Keep and others.

Harvard Metallurgical Laboratory.

On the Simultaneous Electrolytic Deposition of Copper and Zinc from Various Solutions Not Containing Cyanide

By M. de Kay Thompson.

The use of potassium baths for electroplating with gold, silver, zinc and other metals was discovered simultaneously and independently by Elkington and Ruolz in 1841.[1] Brass plating was first carried out by means of a cyanide bath by Ruolz in 1842,[2] though cyanide baths were not introduced into practice at first on account of their high cost.[3] At present brass plating is done only from a bath of potassium zinc and potassium copper cyanide, with a small excess of potassium cyanide. The cyanide brass bath is not entirely satisfactory, as it is slow and discoloration in spots is likely to appear after the surface has been polished and lacquered.[4]

Of the numerous different brass plating baths or brass plating methods that have been published or patented since the discovery by Ruolz of the use of cyanides for this purpose, there seem to have been only two in which cyanides were absent. The first was invented by Brunel, Bisson and Gaugain[5] in 1848 and has the following composition: 500 parts of potassium carbonate, 20 parts of copper chloride, 250 parts of ammonium nitrate and 40 parts of zinc sulphate. The volume in which these salts are dissolved is not given. In order to test this bath the above figures were divided by ten and these numbers of grams were dissolved (except for a small residue) in 450 cubic centimeters of water and electrolyzed with brass anodes and a platinum cathode. The temperature was 25° C. and the current density in the different experiments varied from 0.55 to 2 amperes per square decimeter. This bath proved to be of no value, for the deposits were in all cases copper, as was evident from their appearance.

The second method of brass plating without cyanides, referred to above, consists in using a sulphate solution of copper

and zinc with rotating cathode and anodes of copper and zinc on opposite sides of the cathode.[5] A high electromotive force from one dynamo was applied between the zinc and cathode and a low electromotive force from another dynamo between the copper and the cathode. The return wire from the cathode was common to both dynamos. By this arrangement it is said brass could be deposited on the cathode. It is rather difficult to see how brass could be obtained in this way, however, for in sulphate solutions of equal ionic concentration the potentials of zinc and copper are over a volt apart, and this cannot be very much reduced by making the zinc concentrated and the copper dilute. If the current density is increased greatly with the idea of reaching the potential difference between solution and cathode at which zinc would be deposited copper is certain to come down in a spongy form. Whether the current starts from a copper or a zinc anode only affects the composition of the bath and has nothing to do with determining which metal is deposited on the cathode at any given instant. A similar method to that of Jacobs was patented in 1858 by S. J. Goode for controlling the composition of cyanide baths,[6] though separate dynamos were not used. The current through the anodes was regulated by changing the depth to which they were immersed or their distance from the cathode.

It was thought that it would be an interesting subject for investigation to see whether some other than the usual cyanide bath could not be found from which brass could be plated and which would not have the disadvantages of the cyanide bath. This is the subject of the following paper.

In order to get a good electrolytic deposit of a metal the bath must not be too dilute with respect to the metal, but in order to have two metals whose electrolytic solution pressures are widely different deposit simultaneously, it is necessary that the ionic concentration of the less electropositive metal should be reduced to such a degree that the two potentials of the two metals in the solution should be nearly equal, that is:

$$\frac{RT}{n_1F}\log\frac{P_1}{p_1}=\frac{RT}{n_2F}\log\frac{P_2}{p_2}$$

where the subscripts refer to the two metals and the letters have the usual significance. It is not necessary that exact equality should exist, for the potentials at which the two metals deposit are reduced if they form an alloy at the instant of deposition, and also the concentration change taking place near the anode increase the potential difference between the cathode and the solution when the current is passing.[7] The only way in which low ionic concentration can be obtained with a comparatively large amount of the metal in solution is to have the metal in the form of a complex salt. If the ionic concentrations of both metals were equally reduced in any given complex not much relative change would be produced in the potentials of the two metals. Copper, however, has a much greater tendency to form complexes than zinc, and its potential is changed much more than that of zinc in the case of the cyanide solution[7] and probably in other cases also.

In attempting to find a bath from which copper and zinc can be deposited simultaneously the obvious thing to do was to try all the possible complex salts of copper. In order to measure out easily any desired amount of copper or zinc sulphate for making the complex salt solutions, a solution of copper sulphate containing one gram atom of copper per liter and another containing two gram atoms of zinc per liter were made up. The cathode used in the following experiments was polished platinum. The following is an account of the experiments with various complex salts.

1. The additions of glycerine, of sugar and of tartaric acid to the solution of a copper salt prevent some of the ionic reactions of copper, which indicates the formation of complex salts.[8] A bath was made up containing 0.25 gram atom of copper, 0.25 gram atom of zinc and 250 cubic centimeters of glycerine per liter. This was electrolyzed at room temperature with 2.6 and 1.6 ampere per square decimeter. The appearance of all of the deposits obtained showed them to be copper.

2. Sugar.—The effect of cane sugar was tested by electrolyzing a solution containing 0.5 gram atom of copper, 0.5 gram atom of zinc and 50 grams of sugar per liter. The current density was 3.3 amperes per square decimeter. This being very high, precipitated copper in a spongy state, but there was no evidence of zinc, as shown by the color.

3. Tartaric Acid.—A solution containing 0.5 gram atom of copper, 0.5 gram atom of zinc and 0.5 formula weight of tartaric acid was electrolyzed with 0.33 ampere per square decimeter. Only copper was deposited.

4. Glycocoll.—The addition of glycocoll to the solution of a copper salt produces a deep blue color and a very complex salt of the formula $Cu(NH_2CH_2COO)H_2O$, which is only partially precipitated by hydrogen sulphide. This seemed therefore to be promising, but on electrolyzing a solution containing 0.5 gram atom of copper, 0.5 gram atom of zinc and 100 grams of glycocoll per liter only copper was obtained. The current density was 3.85 amperes per square decimeter. At 60° C. the deposit was also copper, but of a lighter color. In cyanide baths the more free potassium cyanide is present the more the ionic concentrations of copper and zinc are reduced. It was not found, however, that 50 per cent more glycocoll added to the above bath had the effect of causing zinc to be deposited with the copper. This result is probably due to the formation of a very complex zinc salt, as explained above.

5. Sodium Potassium Tartarate.—A solution of copper was made according to Brown and Mathers[9] containing in 1000 grams of water 60 grams of copper sulphate (0.24 gram atom of copper), 50 grams of sodium hydrate and 159 grams of sodium potassium tartrate. On dipping metallic zinc into this solution it slowly becomes colored with a dark iridescent layer. A zinc solution was made from zinc sulphate and sodium hydrate containing 0.24 gram atom of zinc and 140 grams of sodium hydrate in 1000 grams of water. Equal volumes of these solutions were mixed and the resulting bath electrolyzed with a current density of 0.3 ampere per square decimeter. The deposit was smooth, adhered well and had a rich bronze color. The deposit was analyzed qualitatively and was found to contain some zinc. The same solution was electrolyzed with 0.6 ampere per square decimeter. The deposit was of a paler color and also contained zinc.

A bath was made from 150 cubic centimeters of the zincate solution and 50 cubic centimeters of the copper tartrate solution. On electrolyzing this with a current density of 0.3 ampere per square decimeter the deposit was similar to that obtained with the same current density in the solution made from equal volumes of the zinc and copper solutions, except that it was streaked in places with a granular deposit. This deposit also contained zinc. A great reduction in the total amount of copper in solution does not improve the deposit in this case nor in any other studied in this connection. Very little hydrogen was liberated on electrolyzing these solutions.

6. Thiosulphate.—On adding a solution of sodium thiosulphate to a copper salt the color changes to bright green and then to yellow, finally becoming colorless, with a large excess of the thiosulphate.[10] On electrolyzing a solution containing 0.4 gram atom of copper, 0.4 gram atom of zinc and 280 grams of sodium thiosulphate per liter, with a current density on the platinum cathode of 1.94 amperes per square decimeter, with brass anodes, a flaky bronze colored deposit was formed which did not adhere well to the cathode. This deposit was washed well with water and dissolved in nitric acid, except a small residue, which seemed to be sulphur. The amount of copper contained was determined electrolytically. The zinc was de-

[10] Abegg, l. c., p. 557.

termined by precipitating with diammonium hydrogen phosphate as described in Talbot's "Quantitative Analysis." The results of a single analysis were the following:

Copper	50.5 per cent
Zinc	41.0 per cent
Deficit	8.5 per cent
	100.0

The deficit of 8.5 per cent is probably due to the residue which did not dissolve in nitric acid. The residue is probably also the cause of the bronze color. On allowing this solution to stand over night a muddy precipitate formed. It would therefore not be of any practical importance even though a good deposit could be obtained from it.

7. Phosphorous Acid.—The addition of phosphorous acid to a copper salt produces a complex copper phosphite anion.[11] A solution containing per liter 0.5 gram atom of copper, 0.5 gram atom of zinc and 50 cubic centimeters of phosphorous acid of 1.2 specific gravity was electrolyzed with a cathode current density of 1.33 amperes per square decimeter. A deposit of copper was obtained. On adding 10 cubic centimeters more of the acid to 100 cubic centimeters of this bath the deposit was the same.

8. Ammonia.—The deep blue color produced by adding ammonia to the solution of a copper salt is due to a complex copper ion, and it has been stated that the ammoniacal solution of copper and zinc is one of a number of others from which zinc and copper can be deposited simultaneously.[12] It was found that only copper is deposited from a solution containing 0.225 gram atom of copper, 0.225 gram atom of zinc and 660 cubic centimeters of strong ammonia per liter. This amount of ammonia precipitated and then dissolved the two metals.

9. Thioglycollate.—Salts of thioglycollic acid, $CH_2SHCOOH$, form complex salts with copper when added to a copper salt solution.[13] The potassium salt of thioglycollic acid was prepared by the method of Claesson,[14] which consists in adding one mol of monochloracetic acid to a solution of two mols of potassium sulfhydrate. The potassium chloride was filtered off and the filtrate treated with several times its volume of strong alcohol, which dissolves most of the potassium thioglycollate. After boiling off the alcohol the residue of white potassium thioglycollate was dissolved in water and added to 5 cubic centimeters of the copper solution, producing a bluish black precipitate which slowly turned white. This is the salt $(HOCOCH_2S)_2Cu_2$. This was filtered and dissolved in strong hydrochloric acid. The final solution contained 0.046 gram atom of copper, 0.36 gram atom of zinc, and was clear and colorless. The zinc sulfate was added to the copper glycollate without producing a precipitate. Electrolyzed with 0.07 ampere per square decimeter, only copper was deposited. On electrolyzing with a higher current density the solution became muddy.

10. Oxalate.—Copper oxalate forms a complex when dissolved in an excess of ammonium oxalate, in which the copper is in the anion.[15] A bath was made up containing in one liter 5 grams of oxalic acid, 55 grams of ammonium oxalate, and 15 grams of copper sulphate, as a similar solution, slightly more dilute, was found a good starting point for bronze plating.[16] When a zinc rod was dipped into this solution it took several minutes for it to become covered with a layer of copper, and when finally covered the copper was bright and adhered firmly. A solution of zinc was made from 12 cubic centimeters of the stock zinc sulfate solution and 40 grams of ammonium oxalate in one liter, corresponding to 0.024 gram atom of zinc per liter. A bath was made by mixing 150 cubic centimeters of the zinc solution with 50 cubic centimeters of the copper, corresponding to 0.015 gram atom of copper, 0.021 gram atom of zinc, 1.25 gram of oxalic acid, and 43.8 grams of ammonium oxalate per liter. With 0.17 ampere per square decimeter the deposit was spongy and apparently only copper. With 0.51 ampere per square decimeter the deposit was spongy and dark. It was washed and analyzed qualitatively for zinc; none was found present. With 1 ampere per square decimeter the deposit looked like brass in places and was found to contain zinc.

A solution was then made by mixing 25 cubic centimeters of the above copper oxalate solution with 175 cubic centimeters of the zinc oxalate solution and was electrolyzed with a cathode current density of 0.33 ampere per square decimeter. This gave a dark deposit. With 0.15 ampere per square decimeter the deposit was dark and easily wiped off.

Another solution made by mixing equal portions of the copper oxalate and the zinc oxalate solutions, thus containing in one liter 0.03 gram atom of copper, 0.024 gram atom of zinc, 2.5 grams of oxalic acid and 47 grams of ammonium oxalate. On electrolyzing with 0.28 ampere per square decimeter a deposit was obtained which first looked like smooth copper, but which later became granular. On increasing the current to 0.56 ampere per square decimeter, the deposit had a light brown color, and was found to contain zinc. The deposit had a similar appearance with a current density of 0.84. Hydrogen was liberated in all the electrolyses in oxalate solutions.

With this solution a rather curious observation was made. On repeating the electrolysis in the last mentioned bath with a current density of 0.56, the light brown deposit was not obtained, but the deposit seemed to be granular copper. On changing the platinum cathode for another, the light deposit was again produced. It is therefore evident that the cathode itself is of some consequence in determining the nature of the deposit. This experiment was repeated several times with the same result.

11. Pyrophosphate.—The nearest approach to success was with the solution made by dissolving zinc and copper pyrophosphate in an excess of sodium pyrophosphate.[17] Good deposits of zinc or of copper could be obtained from solutions containing only zinc or copper pyrophosphate. A solution was then made containing 0.054 gram atom of zinc, 0.054 gram atom of copper, and 108 grams of $Na_4P_2O_7 . 10 H_2O$ per liter. This sodium pyrophosphate includes that used to precipitate the metals and to redissolve them. On electrolyzing this solution with brass anodes and a platinum cathode with a cathode current density of 0.83 amp per square decimeter a brassy looking deposit was obtained. It was tested qualitatively for zinc, which was found present. There is a large polarization at the anode apparently caused by the resistance of a salt produced by the action of the current on the anodes, which does not dissolve readily at room temperature. If the solution is heated to 60 deg. C. this salt does not appear on the anodes. The deposit on the cathode is also good when obtained from a hot solution, but both in the hot and the cold solutions the deposit remains smooth and of a brassy appearance only for a short while. When the electrolysis is prolonged, the deposit becomes discolored, or granular. The solution around the cathode also becomes quite alkaline, as was noticed by the slippery feeling of the cathode on removal from the solution. If the cathode is rotated in order to stir up the solution in its neighborhood only copper is deposited by the current, which shows that the action of the current is partly responsible for producing the proper concentrations of copper and zinc ions near the cathode for depositing both metals together. It seemed that the alkalinity of the solution around the cathode caused the copper to form an oxide, thus spoiling the deposit. Various proportions of copper and zinc were tried without observing any improvement. The deposit is very much changed by a small change in the current density. The cathode frequently

[11] Abegg, l. c., p. 546.

[12] Abegg, l. c., p. 559.

[16] Curry, *Jour. Phys. Chem.* 10, 515-20 (1906).

[17] Abegg, l. c., p. 546.

had an entirely different appearance in the center and on the edges, doubtless due to a slightly different current density at these points. In no case did the deposit continue to have a smooth surface when the electrolysis was prolonged. If the current density was low, only copper came down.

If a zinc rod is dipped into a solution of copper pyrophosphate, copper is deposited only very slowly, adhering firmly.

A deposit was obtained with a rotating platinum cathode frequently of a very light color like zinc, but on touching with a drop of nitric acid it turned copper colored immediately. It would seem therefore that this color is due to some oxide or hydrate of copper.

As the alkalinity of the solution around the cathode seemed to be the cause of the change in the appearance of the deposit, an attempt was also made to prevent the solution becoming alkaline by holding the pyrophosphate of zinc and copper in solution with pyrophosphoric acid. Free pyrophosphoric acid hydrolyzes slowly, changing to phosphoric acid, but there was a possibility that it would not do so when combined with these salts.

Pure copper pyrophosphate was made by adding an excess of copper solution to a hot solution containing 11.2 grams of $Na_4P_2O_7$, 10 H_2O, which forms 0.025 of a formula weight of copper pyrophosphate. This was washed with decantation with hot water until the wash water gave no test for sulphates. It was then filtered and transferred to an Erlenmeyer flask while moist. Then a fresh standardized solution of pyrophosphoric acid was run in from a burette until the solution became clear. A solution of zinc pyrophosphate in pyrophosphoric acid was prepared in the same way. The commercial pyrophosphoric acid was standardized against a solution of sodium carbonate with methyl orange as an indicator, taking into account that when the end point is reached only two hydrogen ions have been neutralized.[18] It was found that one formula weight of pyrophosphoric acid would dissolve 0.5 of a formula weight of zinc pyrophosphate, the final volume being 3.7 liters for the above amounts of acid and salt. In the case of copper 1.35 formula weight of the acid was required for 0.5 formula weight of copper pyrophosphate. The final volume here was 2.96 liters. With a rather high current density zinc could be deposited from the zinc pyrophosphate solution with the simultaneous evolution of hydrogen. Copper was easily deposited from its solution without evolving hydrogen. A solution containing both copper and zinc pyrophosphates was made by mixing these solutions, so that there was 0.15 gram atom of zinc and 0.15 gram atom of copper per liter. On electrolyzing this with brass anodes and varying current densities, the highest being 1 amp per square decimeter, only copper and hydrogen were deposited. The acid solution is therefore not as complex as when the salts are held in solution by sodium pyrophosphate.

On standing over night some of the zinc and copper pyrophosphate precipitates, showing that the combination with these salts does not prevent the hydrolysis of pyrophosphoric acid.

Summary and Conclusions.

Eleven complex copper salts were made by the following agents and were electrolyzed after mixing with zinc sulphate solution: glycerine, cane sugar, tartaric acid, glycocoll, sodium potassium tartrate and sodium hydrate, thiosulphate, phosphorous acid, ammonia, thioglycollate, oxalate and sodium pyrophosphate. The only solution which gave a smooth, bright deposit when electrolyzed for an hour or more was the alkaline sodium potassium tartrate solution. This deposit, however, had a bronze color.

The solutions from which appreciable amounts of zinc were deposited with copper were the alkaline potassium sodium tartrate, the oxalate and the pyrophosphate.

It was not found in any case that diminishing the total amount of copper in the solution improved the deposits. It seems that the complexity of the copper salt must be relied on to reduce the concentration of the ions sufficiently, while there must be enough copper present in the unionized state to furnish ions as rapidly as they are used up.

Massachusetts Institute of Technology.

An Efficient Electric Furnace for High Temperatures.

By D. F. Calhane and E. E. Bard.

In October, 1910, a description of a small electric furnace was given in this journal. As much interest was shown in the furnace from various quarters, it was decided to make it convenient for general use. In the past year and a half or so a great deal of work and investigation has been expended in producing the furnace that will be described in this article.

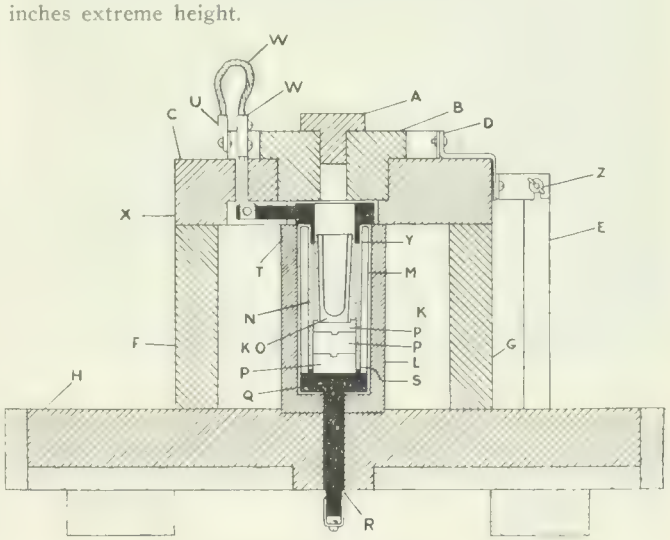
In the first place it was necessary to build the furnace in a way that would permit of easy assembling and dissembling.

Secondly, the use of refractories that would stand the exceedingly high temperature desired, in presence of incandescent carbon.

Thirdly, an electrical design that would give even distribution of current in the carbon core and sufficient resistance in the heating element to permit of using the furnace on the 110-volt circuit without transformers.

In what follows it will be shown how far these requirements have been met in the present form of the furnace.

The photograph gives a good idea of the general appearance of the furnace. It is 2 ft. long, 11½ in. wide and 33 inches extreme height.



SECTION OF FURNACE AS FINALLY COMPLETED SHOWING NEW TOP RING IN POSITION

In pursuance of the idea to make the furnace in such a form as to allow of quick and easy assembling and dissembling of the parts, it has been built upon a base *H* of cement composition, contained in a wooden frame *I* that rests upon wooden blocks *J*, allowing ready access to the electrode stem *R*. After considerable experimentation to find a composition that would have both good heat insulating qualities and a certain degree of strength necessary, a mixture of sand, Portland cement and magnesia-asbestos was decided upon. *E G* to fill the base mold *I*—7.45 kg. sand, 3.75 kg. cement and 1.25 kg. magnesia-asbestos were used These were mixed dry and then 6.0 kg. of water were used to convert the mass to a thick paste. This was placed in the mold *I* and allowed to set. Provision was made for a hole through the mass to permit of the insertion of the electrode stem *R*.

Upon this base stand four cement sides; the two longer ones shown in vertical section at *F* and *G*. Two end pieces not there shown. These sides are cast in simple wooden boxes, painted in order to prevent warping. The inner dimensions of side boxes are 12 in. x 6⅞ in. x 1⅝ in.—giving a volume of

134 cu. in. each, or 268 cu. in. for the two long sides. The inside of the moulds is greased with vaseline to permit of the removal of the casts. The mixture for these two sides is sand 4 kg., cement 1.6 kg., magnesia-asbestos .6 kg., water 3 kg. The moulds are put together with screws to allow of easy dissembling of the sides and removal of the casts.

The end pieces are cast in wooden moulds whose inside measurements are 7½ in. x 6⅞ in. x 1⅝ in., giving for the two a volume of 168 cu. in., requiring sand 2½ kg., cement .8 kg., asbestos-magnesia 35 kg. and water 2 kg.

The four sides stand upon the base and are held firmly together by two iron straps and binding screws, forming a rectangular space, the center of which is occupied by the fire-clay muffle *L*. This is made from two No. 40 furnace muffles manufactured by the Buffalo Dental Co., of Buffalo. The space *K*— *K* outside the muffle and within the walls is filled with shredded asbestos-magnesia for heat insulation.

The top *C* is also of cement mixture with three holes for the top electrode connections, and a large central hole for the cover *b*. This is cast in a wooden mold designed to give the proper contour to the cast. To fill the volume of 290 cu. in. a mixture of 4.5 kg. sand, 2 kg. cement, .75 kg. asbestos-magnesia and 3.3 kg. water are used.

ELECTRIC FURNACE

In the central hole of the top, fits the cover *b*, that has a different composition owing to the higher heat it is to stand. The mixture used is sand 200 gr., cement 300 gr., asbestos-magnesia 300 gr., water 850 gr. and fire-clay 200 gr.

In the central hole of the cover is a cement plug *a* cast from a mixture of 40 gr. sand, 30 gr. cement, 20 gr. old fire-clay, 10 gr. new fire-clay, 40 gr. asbestos-magnesia and 100 gr. of water. All the sand used in these mixes passes 20 mesh screen. These castings as well as the top of the base, when completely dry, are given a heavy coat of water white for a finish.

Between the top *C* and the sides is placed an asbestos cloth gasket to help exclude air. Around the outside at the juncture of top with sides at *x* is fitted an asbestos cloth gasket sewed into one piece. This is bound air tight by four iron straps with tightening screws and rods, provided with thumb nuts. The photograph shows this arrangement. It is necessary to exclude air that will burn the carbon if allowed to enter.

By this arrangement it may be seen that the first requirement to make the furnace in a shape readily assembled and dissembled, has been met. Only seven cement parts have to be handled and these are put together and taken down in a very few minutes. Any one can make the moulds and cast these pieces with very little trouble.

Coming to the second requirement, the use of refractories that would stand the excessively high temperatures desired in presence of glowing carbon, the most difficult part of the problem was met. A great deal of experimentation has been done in the past twenty months and finally with the help of the Norton Company a line of alundum refractories has been developed that gives good satisfaction. The conditions are severe and put the alundum to very extreme tests. The alundum question is the backbone of the whole thing, and its wonderful properties make the furnace possible.

By reference to the cross-section figure it may be seen that the refractory portions consist of the crucible *O* that sets on three blocks *P, P, P*. The crucible is of pressed alundum 3¼ in. long, 1⅜ in. wide at top and 1⅛ in. wide at the bottom. It is 2¾ in. deep and will hold about 100 grams of molten steel of specific gravity 7.9. The three blocks *P, P, P*, are of tamped alundum of a special composition, to resist the excessive temperature at this part of the furnace. They are 1½ in. wide and ½ in. and ¾ in. thick. They are made in three sections to prevent cracking from unequal expansion.

Between the walls of the muffle *L* and the carbon core *N* is a tube of alundum *M* in two pieces 2 in. and 3⅜ in. long, respectively. This arrangement, in two pieces, is to avoid cracking from uneven stresses. The walls are 5/16 in. thick and bore is 1⅞ in. Another crucible of alundum is also used for certain work that is 5¼ in. long and 1¼ in. internal diameter. This sets on a block ¾ in. high.

These alundum parts stand excessive heat in contact with glowing carbon. The alundum parts formed of material compacted under hydraulic pressure give the ideal substance that is practically unaffected by incandescent carbon at 1900° C. It has taken months of investigation to determine the best composition and size of the various alundum parts now used in the furnace.

The third proposition, the electrical design, has been a difficult one. This for two reasons: In the first place it has been exceedingly hard to obtain even current distribution in the carbon core. Any inequality in this respect results in uneven heating of the alundum that causes cracking and at the higher ranges of temperature in burning out of the alundum by carbide formation. Again, it has been difficult to design the parts for current introduction and distribution, so as to make them simple, rugged and effective in operation. It has also been necessary to design the electrical part so as to get voltage drop enough across the furnace to work it direct on the 110-volt lighting circuit without transformer and only a simple rheostat to regulate the current. This has been obtained by a long, thin core of carbon, whose wattage density has had to be nicely adjusted so as not to exceed the endurance of the alundum parts at any point. After a great deal of experimentation and many changes in the electrical design success in this direction has been attained

Referring again to the figure, p. 461. The current enters by *R*, the lead screwed into the electrode *Q* that rests on the bottom of the muffle. On the upper face of this is cut a circular lip *S*. In the inner space fit the blocks *P, P, P*, and down over the outer edge of the lip sets the alundum tube *M*. By this arrangement the current is evenly distributed all around from the upper face of the lip and through the carbon core *N* to the under side of the lip of the upper electrode *Y*. The means of exit from the upper electrode to the circuit is readily seen by an inspection of the drawing and general view of the furnace

The voltage drop across the furnace can be varied within a range of 20 per cent by method of compacting carbon core *N* and the pressure exerted by the lip of the upper electrode on the carbon. This should be enough to give good contact, but undue pressure avoided. As an average of 10 heats, 80 volts across the furnace at 12½ amp. gave a kilowatt consumption of energy at full heat, melting point of platinum.

A block of fire-clay with a hole in the center is placed upon the crucible to conserve the heat. The furnace should not be

held at platinum temperature more than twenty minutes or half an hour, as the alundum does not endure so well. Alundum softens between 2000° C. and 2100° C. It is best to run the heat up to the m. p. of platinum as quickly as advisable and then pour the melt at once. The temperature of molten platinum is close to 1775° C. and the hottest parts of the furnace, especially the two upper alundum blocks are very near 2000° C. when the crucible holds melted platinum.

As a typical instance of the working of the furnace the data from a platinum heat are appended:

Time.	Amperes.	Volts.	Watts.	Temperature, Room Temp. at start.
3.21	8.5	60	510	
3.26	8.5	45	382	
3.38	10	45	450	dull red.
3.52	12	47	564	bright red.
4.02	16.5	53	874	
4.11	19	58	1102	white hot.
4.35	15.5	66	1022	
4.38	15	70	1050	platinum melts.

Twenty grams of platinum were melted in the above heat in an hour and 17 minutes, starting with the furnace at room temperature. Starting with the furnace warm from a previous heat, the same result as above was secured in one hour. With successive heats to melting point of platinum the crucible of pressed alundum endures very well. As many as twelve successive heats to platinum m.p. have not caused any marked effect on the material of the crucible.

Alundum tube *M* sustains the extreme temperatures very well, and will endure a number of successive heats to m.p. platinum without any appreciable deterioration. Its composition is of tamped alundum with low binder.

The two top blocks, *P, P, P,* have to endure extreme temperatures and will be made in the future of hydraulically pressed alundum, done in a steel mould. This material, as mentioned in the case of the crucible, is the ideal refractory.

The design here presented is the form most convenient for melting small amounts of very high fusing metals that can be done without carbon contamination and with good electrical efficiency. Other uses require slight modifications to fit the exigencies of the case.

The adaptation of this furnace to various uses is being studied in this laboratory and a larger size along the same lines, of 6 to 7 K.W. capacity, is being developed to give continuous operation. Patents are pending on the design here presented.

In conclusion, I wish to express my obligations to the Norton Co. for their kindness in developing the alundum parts; Also to Mr. P. A. Boeck of the same company for valuable assistance with the alundum question; also to Mr. Bard for his valuable suggesions that have led to marked improvements in the furnace design.

Electrochemical Laboratory,
Worcester Polytechnic Institute.

Progress in Fuel Briquetting.—Although the United States is still far behind European countries, particularly Germany, in fuel briquetting, considerable progress has been made in the two last years. In 1909 the production of fuel briquets in the United States was 139,661 tons; in 1911 the production amounted to 212,443 tons. The main factor operating against the more rapid development of this industry is the low cost of raw fuel in the Middle West. The average price for fuel in the northern Middle States in 1911 was between $1.10 and $1.75 per ton. The cost of manufacturing briquets, exclusive of raw material, is about $1 per ton. Culm banks contain briquettable coal, and by-products from coke ovens can be used as binders.

The Arizona Copper Co. produced 1575 tons of copper in March, 1912.

The Elmore plant at Sulitelma, Norway, produced 1225 tons of copper concentrate in March, 1912.

A Zinc Retort with a Copper Bottom

By F. L. Clerc.

The proposal to reduce and volatilize zinc from the surface of molten copper is so radical a departure from the lines along which zinc metallurgy has been developed that it is likely to impress unfavorably those most skilled in present practice.

It is the settled conviction of most zinc smelters that the metal must be reduced and distilled in a closed vessel of fire-clay; that this vessel must be of small dimensions, and that a very considerable amount of high-temperature heat must be transmitted through its walls. With our present knowledge I believe that this conviction is in the main based on a solid foundation of facts. I wish, therefore, to show how closely the conditions within a copper-bottomed retort can be made to agree with the conditions in a fire-clay retort heated from the outside. It is admitted that the retort must be small, in at least one of its dimensions, in order that the heat can reach the charge to be reduced. In present practice the actual distillation is an intermittent operation, which is interrupted to charge and empty the retort. The period of firing may be divided into two very distinct stages, according to the work accomplished in each of them. In the "heating-up" stage the charge is dried; this must be done thoroughly in order to free the charge from volatile substances which would oxidize the distilled zinc if both were given off at the same time. How then can these two distinct stages be effected over a copper bath? How can the products of each of them be kept separate? And how can a closed vessel, heated from the outside, be formed with molten copper?

The answer to these sample questions must be somewhat categorical. The drying of the charge and the expulsion of troublesome volatile matter is done outside of the retort. The charge is ready for reduction when it enters the retort. The closed vessel for reduction and distillation is, of course, not wholly of copper. The bottom only is copper; the top, the sides and the ends are built of firebrick. The closed chamber, or retort, so formed, is heated from outside, as are all retorts, and therefore some of its dimensions are limited to the distance external heat can be made to pass into it. This composite retort is heated only through the bottom. For this reason its height is strictly limited. Its other dimensions are controlled by other considerations. Compared with cylindrical retorts, supported only at the ends and surrounded by flames, this may be thought an uneconomical manner of heating, but it has certain advantages. The length of cylindrical retorts is limited by the strength of the material of which they are composed.

In Silesian practice the retorts are made higher and longer, but at the expense of some heating surface, for they are supported along the bottom. There are other objections to these larger retorts, which are generally called muffles, and their use is restricted to localities which afford rather unusual conditions.

A copper-bottomed retort, with mechanical feed of a prepared charge, can be extended in length indefinitely.

As has been said, the heat comes through the bottom of the retort, but the source of heat is not below it. The copper extends beyond the retort, and this exterior projection receives the heat.

This is a familiar device to be seen in most chemical laboratories where a metal plate is used for heating. The desired temperature is obtained by moving toward or away from the hotter end of the plate. The plate is generally short, since the range of desired temperature is not great. The range of temperature desired for zinc reduction is even more restricted; consequently the limit of width of such a retort is soon reached. We now face the question, Can sufficient heat be passed through the bottom to affect reduction and volatilization of the zinc? In considering this question attention must

be given to both the temperature and the amount of heat required.

Heat Conductivity of Molten Copper.

The temperature of melted copper is well above the reduction point of zinc oxide by carbon. If, therefore, we keep the bottom molten the temperature will be sufficiently high. To get at the amount of heat which can be sent through the bottom we must know something about the conductivity of copper. It is generally known that this conductivity is considerably greater than that of any other of the common metals, and that all of the metals conduct heat much better than any earthy material. Measurements of the conductivity of solid copper, up to about 1000 deg. C., indicate that it diminishes rather slowly with rising temperature. This is what should be expected from what we know of the structure of commercial metals, all of which consist of an indefinite mixture of certain definite chemical compounds, with a ground-mass of so-called solid solutions. The solid solutions are unsegregated mixtures of two or more of the chemical compounds, which are more completely miscible at higher temperatures when all of them are fluid.

The flow of heat through solids is influenced by unhomogeneous structure, and its rate is likely to change at each separating surface or juncture. As a commercial metal approaches its temperature of fusion unknown changes occur in the arrangement of its constituents, and these changes must affect the heat conductivity. It is not safe to figure the conductivity of a molten metal by extrapolation from the formula of its conductivity as it approaches its fusion point. From heat phenomena of cooling metals certain temperatures can be noted at which definite changes in structure are known to take place. Before this segregation occurs the molten metal is more homogeneous. It is generally admitted that heat conduction in a molten metal is by metallic contact, where no force exists to produce convection currents. There can be little doubt that molten copper maintains its superior rank as a heat conductor, compared with other common metals when they are in the fluid state.

The freezing of melted copper in the ingot mold illustrates this.

Tests of the heat conductivity of clay materials show great variations. In general, it is probable that this conductivity is considerably greater at higher temperatures. But retorts are composed of artificial mixtures, of different clays in varying proportions, and there is a great range in the intimacy of the admixtures. It is, therefore, not safe to generalize on tests of isolated samples. It is difficult to measure accurately either the actual temperature within a zinc retort or the average temperature throughout a large heating chamber which contains several hundred retorts, and deductions made from such measurements are likely to lead to very erroneous conclusions. We can get a fairly adequate idea of the relative conductivity of copper and fire-clay by comparing the conductivity of copper at ordinary temperature with the conductivity of fire-clay corrected for high temperatures if we keep in mind that this ratio is subject to correction when the conductivity of molten copper is better known.

The conductivity of copper at ordinary temperatures is given as 0.92 cal., which means that this amount of heat will pass through a section 1 sq. cm. a distance of 1 cm. in one second for each degree of drop in temperature. The average conductivity of a specimen of burnt fire-clay, measured in the same way, between 0 deg. and 1300 deg., was found to be 0.0031 cal. Copper has, therefore, 300 times the conductivity of hot fire-clay under the above conditions.

Preheating the Charge in a Feeding Device.

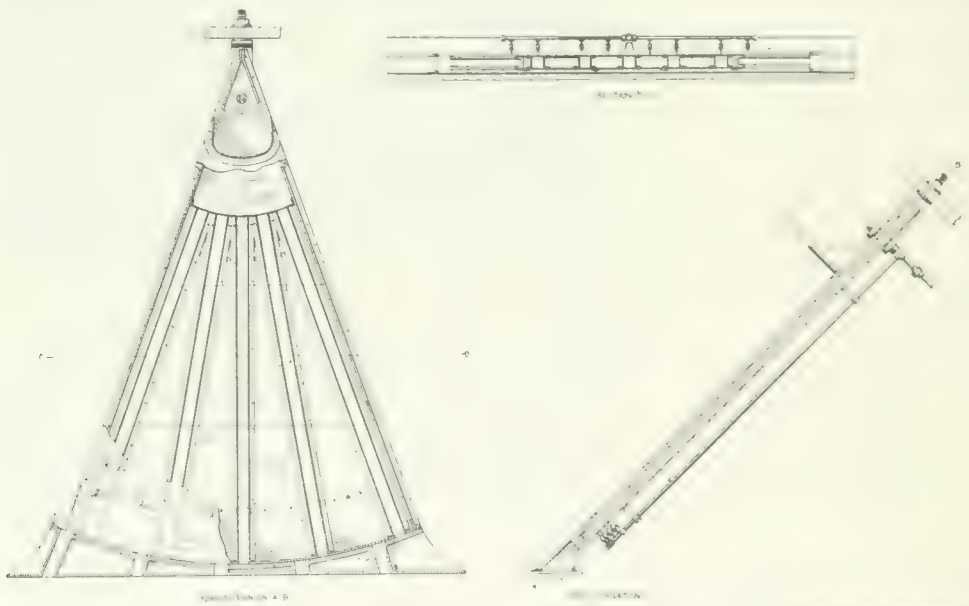
Reference has been made to a preparatory treatment of the charge which should replace the drying and "heating-up" stage after it is in the retort.

It is not necessary to say much about the cost or possibility of briquetting the charge. When briquetting is successful in the treatment of much less valuable material, it offers no serious obstacle if anything is to be gained by its application.

A device is here shown (Figs. 1, 2 and 3) for heating the briquets by burning around them some of the carbon monoxide which passes out of the condensers. This heating is done in the mechanical feeder. No special merit is claimed for the arrangement shown, which can be varied indefinitely. It was designed to feed rather friable briquets and heat them to about 500 deg. C. It provides for a simultaneous feed through five hoppers, and has at least the advantage that it can be swung in its own plane and be raised out of the way of any work which must be done in repairs to the top of the furnace.

The gas, of high calorific power, is admitted into four sheet-iron compartments between the five spouts. Entrance of air and exit of products for each compartment is through holes in the sheathing. A common hood and a pipe through the roof of the furnace building carry off the burnt gas. By this preparatory treatment of the charge it is probable that ten hours of the work of an ordinary furnace can be dispensed with, and its capacity increased 12/7 times.

A compressed briquet of sublimed zinc oxide and carbon for reduction, measuring 4½ by 2 in., will weigh about 4 lb., and five will weigh 20 lb. Consequently the feeder will oscillate 100 times to deliver a ton of charge into the retort.



PROJECTION ON LINE A B OF FIG. 2.

FIG. 2.—SIDE ELEVATION OF FEEDING DEVICE.

FIG. 3.—SECTION OF FEEDING DEVICE, TAKEN ON LINE C D OF FIG. 1.

Construction of Furnace.

A general idea of the arrangement of the copper-bottomed retorts, and of how they are heated, can be gained from the

accompanying axiometric elevation shown in Fig. 4, and cross-sectional view, Fig. 5. I will here consider only two pairs of connected retorts having a heating chamber in common. The cut shows four pairs so connected. The heating chamber is centrally located between the retorts of each pair. Four such retorts, each with a bottom area of 15 by 74 in., would present a heating surface equal to four large cylindrical retorts, and would be contained in a block 15 by 8 ft. The bottom section of the furnace, which holds the pool of molten copper forming the bottom of the isolated retorts and the center well common to all of them, should be carefully built. It should have a casing of steel plates, should be strongly braced, and should have the best available heat insulation. This part of the furnace structure is almost indestructible. Above this level the superstructure of four retorts is raised to the height of about 7 in.

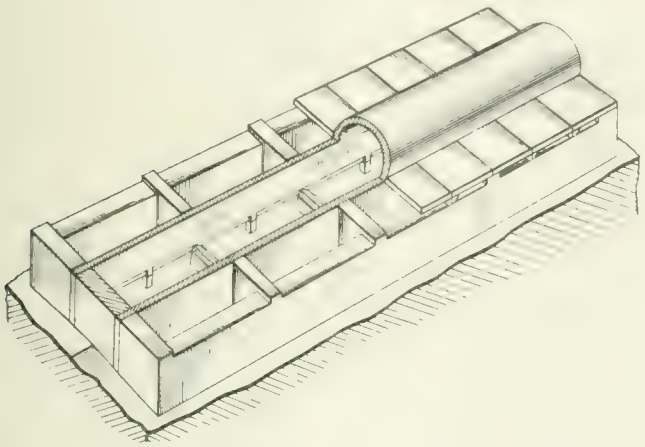


FIG. 4.—AXIOMETRIC ELEVATION OF COPPER-BOTTOMED ZINC FURNACE.

The outside walls, 15 ft. in length, are met at their middle points by a cross wall, which separates the first pair of retorts from the other pair. This transverse division wall extends entirely across the furnace block; but within the combustion chamber it is built up only to the top of the molten copper. The longitudinal division walls, which constitute partitions isolating each retort and separating it from the adjacent heating chamber, have the same height as the outside walls. They terminate below, just under the surface of the copper. They are supported midway in their length, at intervals of about 3 ft., by slender pillars of fire-brick resting on the bottom of the furnace. If the lower edge of these walls touches the copper when it is just melted, the expansion of the metal by heat will insure an effective seal. The buoyancy of fire-brick immersed in copper is considerable, and it will help support these flat lintels.

The outside walls will be cut down about 2 in. to form the slot through which the products enter the condenser. The top of the retorts will be formed of suitable plates spanning the 15-in. width of the retorts. These plates are tightly luted and are easily replaced. Through openings in these plates, at proper intervals, the charge is fed. The function of the full center-arch over the combustion chamber is to confine the heat and reflect it onto the copper to be heated. It has a span of 30 in. and supports little more than its own weight, which requires only a light section, but it should be of very refractory material. It could be moulded in two or three solid lengths to cover the full length of the furnace. This arch is covered with light insulating material, and should be encased in a jacket of steel plates. The slots through which the briquets are dropped can be built into this casing. With regenerative firing the hot gases should be brought from detached stoves, through moulded clay pipes jacketed with insulated coverings, and should pass out of the combustion chamber through similar pipes to the recuperators.

The flameless combustion of gas,* introduced by Prof. W. A. Bone, which consists in burning it within the pores of a very refractory diaphragm, and as it issues from them, would be a most effective method of heating the copper in the external well by direct radiation. In that case the arch with its insulating cover could be dispensed with, for the gas, under light pressure, keeps the top of the diaphragm cool and carries the heat downward to its lower face. The radiating surface can be brought close to the surface to be heated, and the top of the furnace will be left clear except for the feeding device.

Condensers.

The condensers are constructed separate from the furnace and are easily detached from it. They are supported and moved on wheels or rollers. Tracks should be laid parallel to the axis of the furnace and at right angles to it, so that the condensers can be moved expeditiously in either direction when it is necessary to replace one of them. When in position, they are secured in place and a good connection with the retort is effected by a sand joint.

The box of the condenser should consist of a sectional jacket of cast or rolled plates, some of them easily removable, so that access can be had to the interior. The lining should be of refractory insulating material, moulded, rammed and burned in place, as is usual with the lining of converters and ladles for hot metal. The gas escaping from the condensers can be utilized to some extent to effect this burning with gas-burning jets.

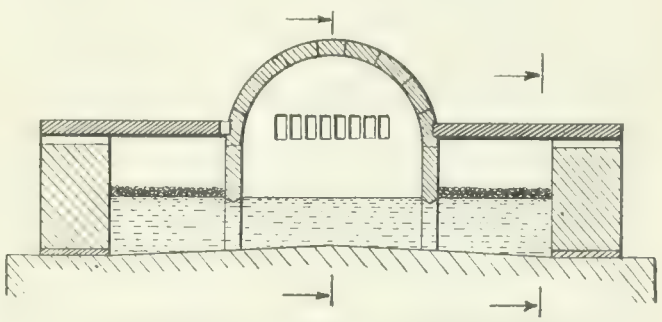

FIG. 5.—CROSS SECTIONAL VIEW OF COPPER-BOTTOMED ZINC FURNACE.

It would be easy to deduce empirical dimensions for the condensers based on condensers now in use. Considerable variation will be found in these dimensions. The aim should be to make the condensers as large as practicable; that is, as large as it is possible to keep them properly heated, without being exposed to the danger of air being drawn in by changes of temperature within them. It is well to maintain a pool of melted zinc in the bottom of each condenser to equalize its temperature. The metal may be drawn off whenever the condenser is likely to become overheated, instead of emptying the condenser several times a day, as is done in Belgian furnaces, or once a day, as is the practice in Silesian works.

From the top of the last compartment of the condenser an adjustable iron pipe, fitting loosely into a socket, should lead to pipes connected with all the retorts for the purpose of conducting the gases to a common washer, in which the solid fumes are removed. The issuing gas is nearly pure carbon monoxide, without admixture with nitrogen.

With the dimensions here employed it will require forty-five briquets in a single layer to cover the bottom of each retort, making a charge of 180 lb. A second layer on top would add an equal amount without danger of crowding the disintegrated briquets over into the condenser. It is desirable to keep the retort well filled in order to minimize the cooling effect of feeding. Assuming then that a charge of 300 lb. is maintained in the retort, we can calculate how much its temperature is lowered every time 20 lb. of charge heated to 500 deg. C. is

*This Journal, Dec., 1911, p. 628; July, 1912, p. 402.

added to it. This charge is fed 100 times for each ton of charge reduced by the retort in twenty-four hours.

Contact of Charge with Heating Surface.

In both the Belgian and Silesian retorts the several particles of the charge remain in almost the same relative positions with respect to each other into which they were thrown in charging. Although there is some contraction in the charge as the zinc is worked off, this contraction is found to be objectionable, and as there is no way to replenish the charge while distillation is going on, it is customary to obviate contraction by mixing with the charge a large excess of coke or other inert material. The result is that the interior particles of charge do not get close to the walls of the retort. It is not probable that an intermittent feed of charge at a temperature of 500 deg. C. will cause greater fluctuations in the temperature within the retort than is inherent in any method of heating them. The hottest region in a copper-bottomed retort is at the surface of the copper. Here the zinc will be reduced and distilled. The prepared zinc oxide yields no considerable residue, and the ash of the reducing coal can be brought down to a minimum.

The lower briquets, by their weight, press closely against the copper. As they are consumed their places are taken by briquets fed from above in a way that avoids increasing the distance through which heat must be conducted to reach the particles of zinc oxide which are reduced. This average distance is evidently the length of an arc of the circle through the center of the sections through which the heat is conducted. This distance, 47.12 in., is eight times the average distance heat must be conducted to reach all the particles in a cylindrical retort 8 in. in diameter.

Reducing Capacity of Copper-Bottomed Retort.

We can now arrive at some approximation to the reducing capacity of a copper-bottomed retort by comparison with the Belgian retort, treating an equally rich charge.

Four copper-bottomed retorts having the same heating surface, working $\frac{12}{7}$ times as long, and having 300 times the conductivity of a fire-clay retort, but obliged to conduct heat eight times as far through their bottoms, should be equal to $4 \times \frac{12}{7} \times \frac{300}{8} = 257$ ordinary retorts. The comparison would be even more favorable if we should consider the conditions under which the retorts are heated in the two systems. It is with great difficulty that a uniformly high temperature can be maintained throughout a large chamber containing several hundred retorts; it is less difficult to maintain an even temperature within a specially designed combustion chamber of moderate dimensions. The effect of a higher temperature outside of the retorts is very marked. The excess of exterior over interior temperature in the retort is the potential which causes the heat to pass through its walls. The amount of heat which passes through them is directly proportional to this difference.

In the case of a copper-bottomed retort, the two endothermic reactions which occur close to the surface of the copper, namely, the reduction of zinc oxide by carbon monoxide and the reduction of carbon dioxide by carbon, will prevent its interior temperature from rising much above the fusion point of copper. Taking this to be 1080 deg. C., it can readily be seen that a temperature of 1280 deg. in the combustion chamber will produce twice the heat flow which is possible with a temperature of 1180 deg. in the combustion chamber.

The temperature which can be obtained in the combustion chamber is limited only by the resistance of its walls to heat; for, as I shall show, the consumption of fuel in heating ordinary zinc retorts is so great that a saving of fuel can be effected, even though the method adopted to heat the smaller chamber is not the best which can be devised. For example, in a recent publication Prof. Eng. Prost,* of Liege, gives a table of the performance of twelve typical modern zinc furnaces, which he credits to W. Borchers (*Métallurgie*, 1908, 522). From this I take as follows: The average fuel consumption of five Belgian furnaces per ton of zinc produced was 3.55 tons; for three Silesian and Belgo-Silesian furnaces it was 6.31 tons; for three Rhenish furnaces, 2.568 tons, and for one furnace using natural gas it was 2770 M^3.

Any saving in these amounts, when the costs and quality of the fuel are duly considered, may be regarded as satisfactory. The first object to be attained is to heat the copper bath effectively; when this is done, a more economical method of heating should be sought for.

Absorption of Zinc and Contamination of the Copper Bath.

Two other matters should be considered briefly: the absorption of zinc by the copper bath and the deterioration of the copper by contamination. Something can be learned on the first subject from the experience of brass founders. They are careful to immerse solid zinc in molten copper. The resulting brass remains fluid at a lower temperature, and since its specific heat is less, it holds less heat at this temperature. The cold zinc and its fusion absorb heat from the copper. On the other hand, the formation of the alloy is an exothermic reaction, of which the heat liberated is approximately known. If the loss of heat by radiation during the operation of compounding brass exceeds the sum of the heat given out by this reaction, and that no longer held by the specific heat requirements of the brass, the temperature of the brass will be lower than that of the copper to start with; otherwise the brass will be hotter than the copper. What would a brass founder answer to the proposal to make brass by pouring melted zinc on top of a ladle of hot copper, or, by passing a stream of mixed zinc gas and carbon monoxide over its surface? What would any one think of the proposal to form an alloy at a temperature at which this alloy is decomposed by heat? But it may be admitted that no chemical reactions are complete; that is, in the complexity of intermolecular action opposing reactions may take place simultaneously.

If, then, it is admitted that some absorption of zinc can occur, the ratio of the weight of zinc absorbed to the weight of zinc which escapes absorption is directly proportional to the relative velocity with which it passes away from the surface of the copper in opposite directions, this being the only place at which zinc and copper are in contact. Above the copper the zinc has the velocity due to its own expansion in passing from a solid to a gaseous state and due to the expansion of an equal volume of carbon monoxide simultaneously produced. This velocity must amount to many meters per second, and is very great compared with any velocity of diffusion that can be assumed to be possible through the body of the copper.

The danger of contamination of the bath by impurities contained in the sublimed zinc oxide is slight, both because of the small amount of deleterious matter it contains and because the impurities which it does contain are highly comminuted. The separate particles of these impurities, scattered through very light flakes of oxide of zinc, have no chance to come together; they will be liberated by the volatilization of the zinc in isolated particles, which are readily carried away as fume. The reducing coal is the greatest source of contamination, and its quality is a matter of prime importance. Any impurity which can be volatilized or carried away by the gases, before the region of greatest heat is reached, will have little chance to come in contact with the copper.

Conclusion.

In conclusion, it is not out of place to call attention to the fact that recent industrial progress has been due largely to two

*Cours de Métallurgie des Metaux autres que le Fer, Paris and Liege, Ch. Beranger, 1912.

underlying influences, the strength acquired by co-operation, and the efficiency attained by specialization. In the domain of hand labor, co-operation involves the concurrence of numerous individual wills acting for a common object. Under these circumstances specialization of function stands for individual skill. When machinery supplements labor, having no will of its own, it must be directed by intelligence. Corresponding to a concurrence of wills there must be a consistent system or policy evolved in order to reach the desired end. Special tools are elaborated which are highly efficient in special work, and intelligent direction of them is to be found in the mechanical development of metallurgy, which concerns the shaping and use of metals. Modern progress in these directions is due largely to the extent to which co-operation and specialization have become effective. Analytical methods of chemical laboratories have been successfully introduced in the development of metallurgy on its chemical side, which may be distinguished as manufacturing chemistry. Between mechanical and more strictly chemical metallurgy there remains a vast field of metallurgical industries which have felt these modern influences and adopted these modern methods to a greater or less extent. I believe it will be found that those special forms of metallurgy which have shown the greatest progress are those in which co-operation and specialization have been carried furthest. A special tool does a special work well; a special process should do one thing well. Metallurgy begins in separating a metal from its associates in nature. In the laboratory the elements and compounds are separated into groups. Isolation is reached by gradual stages. Desired compounds can then be formed. In the metallurgy of iron, copper, gold, silver and aluminium the distinct stages are clearly defined and they are perfected separately. I think a notable advance in zinc metallurgy will result from a proper recognition of the advantage of preparing its raw material before it is submitted to the complicated and expensive operation of reducing and distilling the metal it contains. Cost of a product does not depend on the number of operations required to produce it. It does depend on the simplicity of these operations and the ease with which they can be controlled and accomplished.

Co-operation when machinery is employed, and when numerous processes are required for the separation of metals associated together in nature, can only be secured under intelligent direction. From the fact that several metals are found together it results that a company organized to extract one metal must handle several others.

Zinc usually is found with lead or copper and with gold and silver. In present practice one of the metals in the ore is sacrificed more or less to obtain the others. Zinc is troublesome to work with other metals, and the immediate object is to get rid of it. When most of it is driven off, the residue from this treatment, whether it be a slag or a matte, can be worked for the extraction of the other metals which it contains. It is well known to metallurgists that the zinc driven off carries with it in the furnace gases notable amounts of more valuable metals.

I think it is safe to believe that practically all of the gold and silver contained in sublimed zinc oxide prepared for spelter production will be caught and held by the copper in a copper-bottomed retort or by the condensed zinc metal. This belief is based on the known affinities of these metals. The collection of an amount of the precious metals, too small to enter into the valuation formula, perhaps even too small to be detected by commercial analyses, may amount in the aggregate to enough to pay for the renewal of the copper bottom and the cost of refining the copper. It would appear that zinc smelting should be carried on as one department of a larger industry by which all of the valuable constituents of the ore treated would be utilized, so that by-products would be equivalent to material at intermediate stages of the system of production.

Estes Park, Col.

Metallography and Metallurgy at the Bureau of Standards.

By George K. Burgess, Sc. D.

Among the functions of the Bureau of Standards is the determination of physical constants and the properties of materials when such data are of great importance to scientific and manufacturing interests. Although there are innumerable physical constants and properties of materials that are not yet known with the accuracy oftentimes needed in the sciences and arts, a selection is most naturally made from among those problems for which on the one hand the need for their solution is presented in some concrete form, and on the other hand from among those problems which in themselves are evidently fundamental and form a basis for many applications.

A glance through a standard treatise such as Professor J. W. Richards' "Metallurgical Calculations" will convince anyone of our deplorable lack of sufficiently exact knowledge of many of the constants and fundamental properties of materials necessary to a proper carrying out of many of even the more usual operations in metals alone, to say nothing of the other metallurgical products. For example, at the temperatures at which they are usually worked, for most metals we do not know either their specific heat, heat of fusion, thermal or electrical conductivity, porosity to gases, thermal expansion, mechanical properties, of which there are so many, or their radiation properties, nor for any one metal do we know all of these well enough even for a rough calculation of the efficiency of a projected new operation.

The Bureau of Standards receives almost daily requests for more exact information in this field, but cannot pretend, with its present limited staff and equipment, to keep abreast even of the most urgent demands. As has been pointed out by others, the United States lags behind Europe in an aggressive attack from the scientific side, which forms the basis for all rational development, of the problems underlying the metal industries and on which their ultimate economy depends.

By studying just such fundamental problems of interest either directly or indirectly to the metallurgist, the Bureau of Standards hopes to be able in some measure to be as useful to the scientific and industrial world in general and to the metal industries of America in particular, as are the corresponding foreign national physical and testing laboratories such as those of England, France and Germany.

To cite some of the metallographic work of but one of these, the English, we may mention the comprehensive study of the iron-carbon system and of the heat treatment of high-speed steels, and more recently the mechanical properties of steel at high temperatures and a very elaborate study of aluminium alloys, some of which find application in aeronautical and naval construction.

In the field of metallography and physical metallurgy there are, of course, individuals in this and other countries who are working independently and producing admirable results; nevertheless many urgent problems require complicated and costly equipment, and others are so elaborate that the association of a group of persons becomes imperative for a complete solution within a reasonable time of all the phases involved; and such cases fall naturally to the lot of the laboratory which has facilities for attacking simultaneously the various aspects of the problem such as physical, chemical, metallographical, and mechanical, and on a scale, when necessary, of sufficient magnitude involving large units to work with, that an individual would in most cases not care to consider.

The testing and research laboratories of some of the larger manufacturers also produce, oftentimes, results of the greatest scientific interest and practical importance, but usually they are mainly interested in attaining some definite technical goal, so that in their general work, when available, requires supplementing and generalizing to make it most useful. This is particu-

larly true for investigations of the metals and their alloys; the temptation for a commercial laboratory to discontinue an investigation when a given material having the sought-for properties is attained is too great to be resisted. For example, an electrical firm seeking a high resistance, high melting-point alloy of small temperature coefficient, will probably drop the problem when a suitable alloy is found, regardless of other equally valuable (to someone else perhaps) properties that may have shown signs of developing during the research.

For all those reasons it is clear that a national physical and materials laboratory has a very definite rôle assigned to it in its relation to the progress of metallurgical science on the one hand and to the metallurgical industries on the other.

The question may be raised as to the respective provinces of the Bureau of Mines and the Bureau of Standards. The former occupies the domain between the Geological Survey and the Bureau of Standards, and in the words of the report of the House Committee on Mines and Mining:*

"Nothing in these provisions (i.e. the bill H.R.17260 amending the Act establishing the Bureau of Mines) would authorize or permit the Bureau of Mines to extend its investigations beyond 'mining' operations so as to duplicate the geologic and topographic work of the Geological Survey; nor will anything herein authorize the Bureau of Mines to extend its work to cover the investigation of finished manufactured products, which come properly within the scope of other branches of the Government service."

Briefly, then, the Geological Survey deals with materials in the ground, the Bureau of Mines with getting them out of the ground and refinement from the ores, and the Bureau of Standards with the properties of the manufactured material. Another well recognized phase of the work of the Bureau of Standards is, of course, the investigation of testing methods and the certification of measuring instruments of all sorts.

The Bureau has for some time been engaged on problems of interest to the metallurgist. One of the most important is the preparation and analysis of standard samples of irons, steels, alloys, and ores which are distributed broadcast to works chemists and others interested, for a small fee, and serve as a basis for obtaining uniform analytical results in all localities by checking both the metallurgical chemist and his methods. Incidentally new and better methods of analysis have been devised and described for some of these materials.

Samples of standard substances, such as naphthalene, sucrose, and benzoic acid are similarly distributed for the standardization of combustion or fuel calorimeters. The preliminary study and preparation of these calorimetric combustion standards have entailed very elaborate investigations which are still in progress and in the course of which new methods and apparatus have been devised. A study of the calorimetric and thermal properties of various gases is also under way.

A very troublesome problem of the greatest practical importance, which is being investigated with thoroughness and on a large scale, is the resistance of steels to electrolytic and corrosive action. Some extremely interesting data have been obtained which will be published shortly.

The mechanical properties of the metals, especially of steels suitable for structures, have received considerable attention, although this work has been but recently organized, and with the completion of the new machines now being installed at Washington and Pittsburgh, the Bureau will be equipped for testing of large members, as well as for the usual test sizes.

A comparative experimental study of the methods of determining hardness has been made, a modification of the Brinnell test suggested, and several investigations on the correlation of the physical and mechanical properties of steels are under way, having as a partial object the simplification of the test.

Some of the thermal properties of the metals have been studied with particular care; for example, a considerable number of melting points have been determined with exactness for use in defining the temperature scale to 3000° C. An investigation of the reproducibility of some of these standard temperatures by means of metals from various sources has also been made, and a new method devised for the determination of the melting points of microscopic samples. A study of the methods of obtaining cooling curves has been published.

Sir Robert Hadfield has placed at our disposal several hundred samples of steel for the determination of melting and transition points, hardness, etc. These steels, covering a very complete range of compositions, are of particular interest as many of their mechanical, magnetic, and electrical properties have already been studied elsewhere.

A thermal analysis has been made of a series of standard steels for Prof. H. M. Howe in conjunction with his thermo-microscopical study of grain size. The results of this investigation have confirmed our previous opinion of the desirability, in view of the existing confusion on many points, of attacking anew the iron-carbon series of alloys from the thermal standpoint, using only pure components, i.e. eliminating all impurities, and studying one by one all the factors that enter into the location of the transition points on heating as well as on cooling, such as methods of measuring the phenomena, rate of temperature change, atmosphere, impurities, size of sample, etc., etc. Starting with pure iron, some interesting and unexpected results have been obtained which will be published shortly.

It is planned to attack in a similar way other series of alloys of practical and scientific importance, and to determine for these alloys such of their mechanical and physical properties as may be of interest as well as their constitution, microstructure and heat treatment. For some time past the Bureau has been equipped for the examination and heat treatment of small samples including the taking of heating and cooling curves in vacuo, in air or other gas. The equipment is being extended to permit the handling of larger test pieces.

Of considerable practical importance in the working of hot metals, is the ability to determine their temperatures correctly with optical and radiation pyrometers. Such corrections have been published by the Bureau for pure copper and copper-oxide, the experiments for iron-oxide have just been made as well as some preliminary work done on liquid steel, aluminium and oxides. Nickel, special steels and other substances of practical importance are to be studied, the emissivity for each substance throughout the visible spectrum being also determined.

It is hoped shortly to be able to take up some of the high-temperature electro-metallurgical problems, particularly those of interest in furnace design and operation such as electrical and heat conductivity and temperature coefficients of metals, electrodes, furnace materials, and charges, carrying the measurements to the actual working temperatures. As to the non-metallic materials of interest to the metallurgist, a paper is in press on the melting points of fire-clays covering representative U. S. samples. A study has also been made of the load-carrying capacity of such bricks at high temperatures, and the determination of the refractory qualities of such material forms a part of the routine work of the Bureau.

Another field of usefulness of the Bureau is aid furnished in the drawing up of specifications in connection with the technical societies interested and after experimental study. In the metallurgical field there is room for a great deal of work here. Again, there is the question of nomenclature, for example, of bronzes and brasses, which has been raised before the Institute of Metals, and with new alloys appearing almost every day, some rational system of naming becomes imperative.

In conclusion, it may be said that it is the policy of the Bureau of Standards not to concern itself with those problems that are best treated in private laboratories nor is there any desire to encroach on the field of the consulting engineer or ordinary testing laboratory.

Washington, D. C.

* House of Representatives, 62nd Congress, Report No. [illegible]

The Extraction of Vanadium from Carnotite and Vanadiferous Sandstone Concentrates

By Siegfried Fischer.

Within the last decade numerous attempts have been made to extract vanadium from carnotite by a process that would be commercially feasible. These efforts have been based on two principles: first, dissolving all the metal constituents of the ore by means of acids and then separating uranium from vanadium by precipitating the latter; and, secondly, changing the insoluble vanadium into the soluble form by means of caustic alkali, salt and heat, and then leaching and precipitating the extracted metal.

I believe that, up to the present time, only the second of these two principles is of commercial importance. Patents have been granted on the acid treatment, but none of the processes has been successfully adopted in practice. While their theory is very plausible, they encounter various difficulties in practice, some of which will be discussed later.

Extraction by Acids.

The acid treatment is susceptible to several modifications. One method consists in making a direct extraction of uranium and vanadium from carnotite by means of a solution of sulphurous acid. Later the solution is boiled, whereupon the uranium is precipitated as basic sulphite, and subsequently calcined to uranium oxide. The vanadium remains in solution and is precipitated by means of caustic lime.

By another method the ore is ground and treated with dilute sulphuric acid, which will dissolve the uranium, vanadium, copper and iron contained in the ore. The solution containing these metals is reduced with sulphur dioxide, producing ferrous and vanadous compounds. A calculated quantity of pulverized limestone is then added until the metals would just begin to separate, calcium sulphate being formed. The solution is again filtered, and the precipitation of the metals completed by boiling with pulverized limestone. The precipitate is a mixture of basic sulphates and carbonates of uranium, vanadium, copper and iron. If it is desired further to refine this product it may then be treated with sulphurous acid solution as indicated in the first method mentioned above.

In practice, however, a process of this type will encounter many difficulties. When we consider that nearly all precipitated metal vanadates are gelatinous, and that they will hold varying amounts of other metals as impurities, the washing of such a precipitate becomes a problem in itself. In case the vanadium is precipitated as calcium vanadate, the amount of calcium sulphate formed will handicap the production of a clean precipitate of vanadate. This will necessitate further steps for the elimination of this substance, and more time will be required to produce a clean precipitate, all of which will increase the cost of production. Cost is an important item in these chemical processes, especially in view of the fact that the largest producer of vanadium encounters none of these difficulties in treating its ore.

Extraction by Alkalies.

The second class of processes for extracting vanadium from raw ore may be typified by the method patented by Mr. W. F. Bleecker.[1] In my opinion, Bleecker's process is, at present, the only one which promises commercial success. Briefly, it is as follows: The ore is mixed with caustic alkali and salt, and subjected to a roast at a temperature not above that of low red heat. If heated above this point the vanadium becomes insoluble again. The roasted product is then leached with water, the alkaline vanadate passing into the solution. After filtering, the vanadium is precipitated by the addition of a salt of copper, lead or iron, and the desired metal vanadate obtained. This product can be converted without difficulty into the corresponding vanadium alloy.

[1]Patent, No. 1,015,469, issued Jan. 23, 1912, to W. F. Bleecker, Canonsburg, Pa.

I have successfully applied this process to six different lots of vanadium ore. Different ores of carnotite, such as those contained in sandstone or clay, were mixed with equally good results. The extractions were high; and from two of the samples the residues showed only a trace of vanadium after leaching with hot water.

After considerable work for the last two years the author has come to the conclusion that the only successful means of extraction of vanadium is by means of the caustic alkalies, namely, sodium and potassium hydroxide. Many chemicals have been tried, both in the wet and dry way, but none of them gave satisfactory results on the *crude ore*. Tests were made with all of the mineral acids, as well as with some of the simpler organic acids, but without material success. The acids would attack the uranium as well as the vanadium and this means of extraction had to be abandoned. Potassium cyanide and cyanamide were tried, but without success. In the dry way, fusions were made with phosphates, fixed alkalies, and mixtures of these chemicals with carbon in an effort to render one element soluble; but while some experiments gave extractions as high as 65 per cent, none of the methods seemed wholly satisfactory.

It was never possible for me, with pure alkali alone, to obtain satisfactory results on the *crude ore*, using the wet method, even on boiling. On using commercially prohibitive quantities of alkali nearly complete extractions were obtained. The reason for the excessive consumption of caustic alkali probably was due to the reaction between that chemical and the silica in the ore. This led me to consider the concentration of carnotite and similar ores in the hope of eliminating the troublesome silica and securing a more suitable mineral product for treatment.[2]

Advantages in Treating Concentrates.

On applying the caustic treatment to concentrates improved results were immediately apparent. Much smaller amounts of the chemical were necessary in order to obtain good results, than had been the case in treating crude ore. The highest amount of caustic used was in the ratio of one ton of alkali to five tons of concentrate; and as the ratio of concentration was 1:3, the consumption of caustic alkali per ton of original ore amounted to only 135 lb. With this treatment I obtained an extraction of 93.44% vanadium.

Naturally the consumption of alkali must be referred to crude ore, and not to concentrate, in order to compare the process with those which work on crude ore. The following tests will show the importance of concentration. An ore carrying 3% vanadium was treated with caustic soda in the ratio of 100 parts crude ore to 20 parts alkali. After leaching, the residue still gave a strong reaction for vanadium. One hundred grams of concentrate from the same ore, carrying 8.97% vanadium, was treated in a similar manner with 20 grams of caustic soda. The residue after leaching gave only a slight reaction for vanadium. The concentration ratio was 3:1. In order to obtain 100 gm. concentrate, I was obliged to use 300 gm. crude ore. Basing the alkali consumption on crude ore treated, it is not excessive.

The foregoing tests showed, also, the important role which silica plays in the alkali treatment. If the liquor obtained from the crude ore extraction is acidified, a dense precipitate will be observed, which is readily identified as silica. A similar test on the extraction liquor from the treatment of concentrates will show scarcely any cloudiness. Even if a small amount of silica should be present, it would not be a menace to the further steps of the process. As it is apparent that this method of attack is not commercially applicable to crude ores, and is successful in treating concentrates from which the bulk of the silicious material has been removed, I have applied for a patent on the extraction of vanadium from the concen-

trates of carnotite and vanadiferous sandstone by means of caustic alkali.

Details of the Process.

The process comprises three distinct steps:

1. The conversion of insoluble vanadium into the soluble form.
2. Leaching and separating vanadium from uranium.
3. Precipitating and drying the vanadium compound.

The dried product is then ready for reduction to ferro-vanadium, and the uranium residue is in marketable shape.

The procedure is as follows, reference being made to the accompanying diagrammatic flow-sheet. The necessary

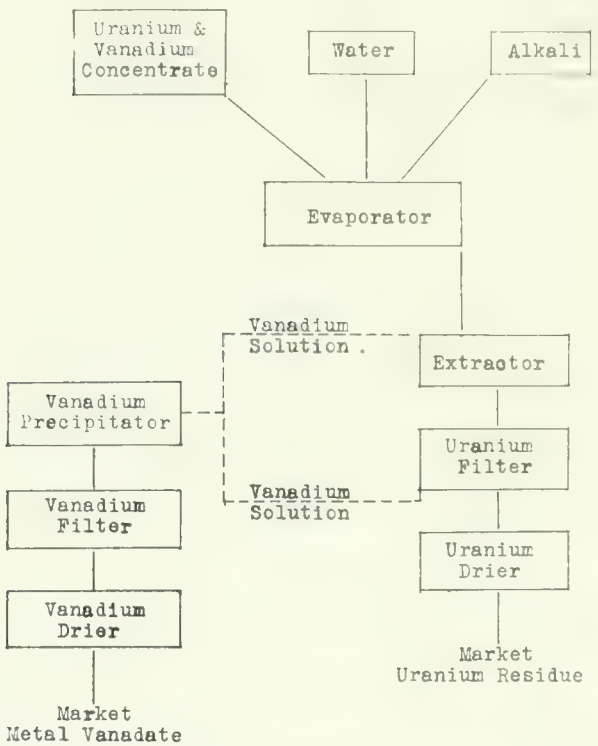

FIG. 1.—DIAGRAM SHOWING TREATMENT OF CARNOTITE CONCENTRATE.

amount of alkali is dissolved in water in the evaporator, and concentrate is then added in proper proportion. The whole is mixed to a pasty consistency in order to insure intimate contact of the alkali and mineral, and then evaporated to dryness, finishing at a temperature ranging between 200 and 300 deg. C. In some cases it may be necessary to repeat this step by the addition of water and subsequent evaporation. Tests will indicate whether the attack of the alkali has been complete. The dry mass is now ready for extraction with water, and is transferred to the leaching tank, or extractor.

The leaching tank is steam-jacketed, and is provided with a stirrer to thoroughly disintegrate the mass and produce a slight friction or abrasion of the solids. The vanadium passes into solution, and the latter is pumped to the vanadium precipitation tank. Here the solution is neutralized with sulphuric acid, after which iron vanadate is precipitated by the addition of ferrous sulphate. The mixture is filtered, and the precipitate dried and reduced to ferro-vanadium in the electric furnace or by the Goldschmidt process.

The residue from the original leaching step is filtered and washed, the liquor passing to the vanadium precipitator after it has reached a suitable degree of concentration by repeated use as wash liquor. The uranium residue is dried and marketed, being in excellent condition for further treatment on account of the previous removal of the silica by concentration.

The process permits the use of a minimum amount of chemicals, requires but little labor, is easily manipulated, and can handle large amounts of concentrates. It is practically continuous, that is, successive lots of ore can be kept continually moving through the various steps of the process.

The completion of the reactions can be tested by taking samples from various tanks, thereby controlling the process. Tests can be made to determine the efficiency of the alkali reaction, the precipitation of the vanadium and the washing of the various precipitates and residues. Ordinarily intelligent labor can be taught to make these tests, so that technically skilled labor will not be required. It would be a good scheme to have a testing equipment for the concentration and extraction of ores in 50 or 100 lb. lots. This would give the best preliminary information regarding the dies to be treated.

To obtain the highest efficiency, various conditions must be taken into consideration. The concentrates treated must be of uniform character. This can be accomplished by mixing various ores before concentration so that the proper ratio of concentration can be maintained. By careful analysis of the different ores, any difficulty in this respect may be avoided.

Another factor which must be considered is the loss of vanadium by washing. While the amounts which may be lost from time to time may seem slight, they will amount to considerable in the course of a year's operations. The author has given quite some time to the study of this point and may publish the results of his experiments in a later paper.

Comparison of Results.

Utah and Colorado carnotites have been treated by this process, both in the crude condition and as concentrates. The following figures will show the advantage to be gained by treating concentrates instead of crude ore.

Utah Crude Ore: Assay, 3% vanadium; treatment, 100 parts ore and 20 parts caustic alkali. Extraction liquor contained large amount of silica. *Extraction*, 65.3%.

Utah Concentrate: Assay, 8.97% vanadium; treatment, 100 parts concentrate and 20 parts alkali. Extraction liquor showed no turbidity on acidifying, and the precipitated iron vanadate contained no aluminum. *Extraction*, 94.66%.

Colorado Crude Ore: Assay, 5.59% vanadium; same treatment as above for Utah crude ore. Extraction liquor contained much silica. *Extraction*, 67.03%.

Colorado Concentrate: Assay, 16.34% vanadium; same treatment as for Utah concentrate. No turbidity in extraction liquor on addition of acid, and no alumininum in the iron vanadate. *Extraction*, 92.98%.

In all, about 20 different ores were tried, and none of them gave less than 87% extraction when treated as concentrates. Smaller amounts of alkali were tried in some instances, with satisfactory results. The process never required more than 1 part of alkali to 5 parts of concentrate. Many samples were tested for copper alone, and while some of them showed the presence of this element in the crude ore, it was scarcely noticeable in the concentrate, and the resulting iron vanadate showed no trace of it.

The important part of the process evidently is the first step —converting the insoluble vanadium into the soluble form. The water added at this point is not a leaching agent, but a means of carrying the alkali and bringing it in contact with every particle of carnotite. It is essential that the alkali should be uniformly distributed throughout the mass. As the solution becomes more concentrated, the action of the alkali is more intense, and I have found that in some cases it was unnecessary to perform the final drying operation at a high temperature. The alkali in this finely disseminated form evidently has a better opportunity to act than if it were mixed dry with the ore. The latter method would cause lumps to form, and give less efficient reaction between the ingredients. It was found by experiment that if the mass was kept moist and at a temperature of 100 deg. C., the change from insoluble to soluble form of vanadium was nearly complete. Whether this mode of treatment would be more economical than the

evaporation and calcining, remains to be seen. A factor which naturally comes into consideration is time.

We may now consider the merits of this process. It is apparent that by the original concentration of the ore a large quantity of undesirable material is removed, thus increasing the probability of getting a pure final product. Also, the possibility of obtaining the uranium residue in a concentrated form is an advantage. The use of but one chemical in making the extraction is advantageous. Taking the cost of alkali at $52 per ton and the maximum quantity required per ton of ore at 135 lb., the cost of this ingredient would be about $3.50 per ton of ore.

The cost of producing a pound of iron vanadate by this process is hard to give, as it was possible for me to handle charges of only 10 lb. at a time; but I believe that the cost will be lower than that of any other chemical process. An important matter at the present time is to create new uses for both vanadium and uranium. As long as the market for these metals remains limited it will be difficult to interest capital in this field.

Golden, Colo.

New Mining Laboratory of the University of Illinois.

The Department of Mining Engineering at the University of Illinois is just completing a new mining laboratory 100 ft. long by 42 ft. wide, divided into two equal sections, one for the treatment of ores and one for the washing of coal. The crusher room contains a Jeffrey coal roll, a pulverizer, an Allis-Chalmers gyratory crusher and a Colorado Iron Works 12 x 12 roll for ore. This end of the building also includes sample crushers and screens and two steel sampling floors, one for ore and one for coal.

The crushed material is elevated in a 15 x 20 continuous Peck carrier equipped to dump automatically along the upper run into any one of a row of steel bins, each holding five tons of coal. Beneath these bins is an Avery automatic traveling scale through which the material is delivered to any one of the screens or the washing or concentrating appliances. On the coal side there is a Holmes Brothers shaking screen and a Webster revolving screen, each fitted to separate four sizes and each about 13 feet long. On the ore side is a vibrating screen. Beneath each of these screens is a set of bins from which the screened material is taken by wheelbarrows to a dormant scale and then delivered to the lower run of the Peck carrier which elevates it to the upper tier of bins. Through the automatic traveling scale the coal is delivered to a three-compartment American concentrator jig or to a Stewart jig. A Luhrig jig and a Jeffrey-Robinson cone washer will be added later. The washed coal is delivered into a 1300-gal. settling tank from which it is elevated by a Webster bucket elevator to an overhead bin and from thence carried by the Peck carrier delivered to a bin outside the building, from which it is carted away to the boiler plant. The coal side of the laboratory has a capacity of 5 ton per hour.

On the ore side the material may also be crushed in a stamp battery. The fine screened ore is mixed with water and delivered by a Traylor centrifugal sand pump to three-compartment classifier, the products from which go to a 6-ft. Williams & Chalmers vanner, an 11-ft. Traylor concentrating table and a buddle. These three machines deliver to four Callow tanks beneath which are drying tables.

In the adjoining room is a completely equipped chemical laboratory and assay room for carrying on such tests as are required in the concentration of ores and the washing of coal. The equipment also includes an assortment of hand jigs, Munro classifiers, a spiral separator, a small Jeffrey-Robinson tub and a small laboratory concentrating plant made by the General Engineering Company. The machinery is being erected by the Burr Company, of Champaign, Ill.

The Mining Department is also equipping a new blasting and explosives laboratory, a rock drilling and coal-cutting laboratory and is building a new rescue station for giving training with oxygen helmets and other rescue appliances.

The offices, drafting rooms, library and recitation rooms of the Mining Department are located in the new engineering building, which will be ready for occupancy Sept. 15. In this building there is also a completely equipped laboratory for the study of mine gases and safety lamps.

Beginning with the collegiate year the Mining Department of the University of Illinois will thus have a very complete equipment for teaching all branches of mining engineering.

Drying Air for Blast Furnaces.

Mr. **Bruce Walter,** dry-blast engineer of the Carnegie Steel Company, of Pittsburgh, Pa., presented an interesting paper on this subject at the meeting of the Engineers' Society of Western Pennsylvania, held on April 16, 1912. The full paper is published in the May issue of the *Proceedings* of the society.*

The author remarks that up until very recently all of the dry-blast plants which have been built have followed very closely the original installation, made in 1904, at the Isabella furnaces of the Carnegie Steel Company.

In this **original dry-blast installation** a chamber is employed containing coils of pipe through which a cold calcium chloride solution is circulated, passing from top to bottom of the coils, the air passing upward through the spaces between the pipes. As the air rises the heat which it contains is transferred to the brine, and as its temperature is lowered its capacity for carrying moisture is reduced and the precipitated water is deposited on the pipes in the form of snow or frost. Two vertical sections of one of these chambers are shown in Fig. 1.

It will be seen that the pipe coils are in four separate compartments, any one of which can be thrown out of service without interference with the operation of the other three. This arrangement enables the operator to remove the frost without material interference with the efficiency of the plant as a whole. The defrosting must be done about every four days; that is, one compartment each day, and is accomplished by means of water sprays located at the top of the compartment. While the frost is being washed off, the air is shut out of the compartment and the brine is removed from the coil. The operation requires two or three hours.

There is no question as to the effectiveness of this method of drying air, as the moisture can be reduced to any desired point, depending on the temperature of the brine used and the amount of pipe surface to which the air is exposed, but there are certain disadvantages which are inherent in such installations and which are avoided in the latest designed plants. The most important disadvantage is the expensive construction required. The building itself is of steel framework construction well braced, and is sufficiently strong to withstand a sharply pulsating pressure; the walls are of first-class brickwork and the entire building is lined with a good insulating material which will withstand moisture and which also makes the building practically airtight. Much space is provided to give access to all parts of the chamber and the percentage of effective area is about 55 per cent of the ground space occupied.

Among the minor disadvantages in this original method are:

First—The freezing of the greater part of the moisture, a considerable saving in power being effected by precipitation without freezing.

* In connection with the subject of methods for drying air see the detailed description of the dry-blast plant of the Illinois Steel Co., South Works in our Vol. VI, p. 513 (Dec., 1908), and the Iron and Steel Institute paper by F. A. Daubine and F. A. Roy on the desiccation of air by calcium chloride in our Vol. IX, p. 343 (July, 1911).

Second—The necessity, in order to avoid excessive expenditure for pipe surface, of maintaining the temperature of the brine 15 deg. lower than the temperature of air desired, thus increasing the cost of operating the refrigerating machinery.

Third—The expense of defrosting and the slight irregularities in the drying action due to this cause.

The foregoing disadvantages seem to be sufficient warrant for the dry-blast engineer to investigate the problem with the idea of decreasing the cost both of installation and operation and to secure, if possible, a more uniformly dry air.

Proposed New Method of Drying Air: One of the proposed methods of improving the operation of drying the air is shown in Fig. 2. This refrigerating chamber or drying tower consists of a cylindrical steel shell about 100 ft. high and 20 ft. in diameter, enclosing a smaller inner shell, the annular space between the shells being utilized for the purpose of removing the heat from the air. The air enters the tower at a pressure of about 2 ounces per square inch through pipe *A*, passes upward through pipes *B* and the hooded pipes *C*, where it comes into contact with mechanically cooled water dripping over the screens *D*.

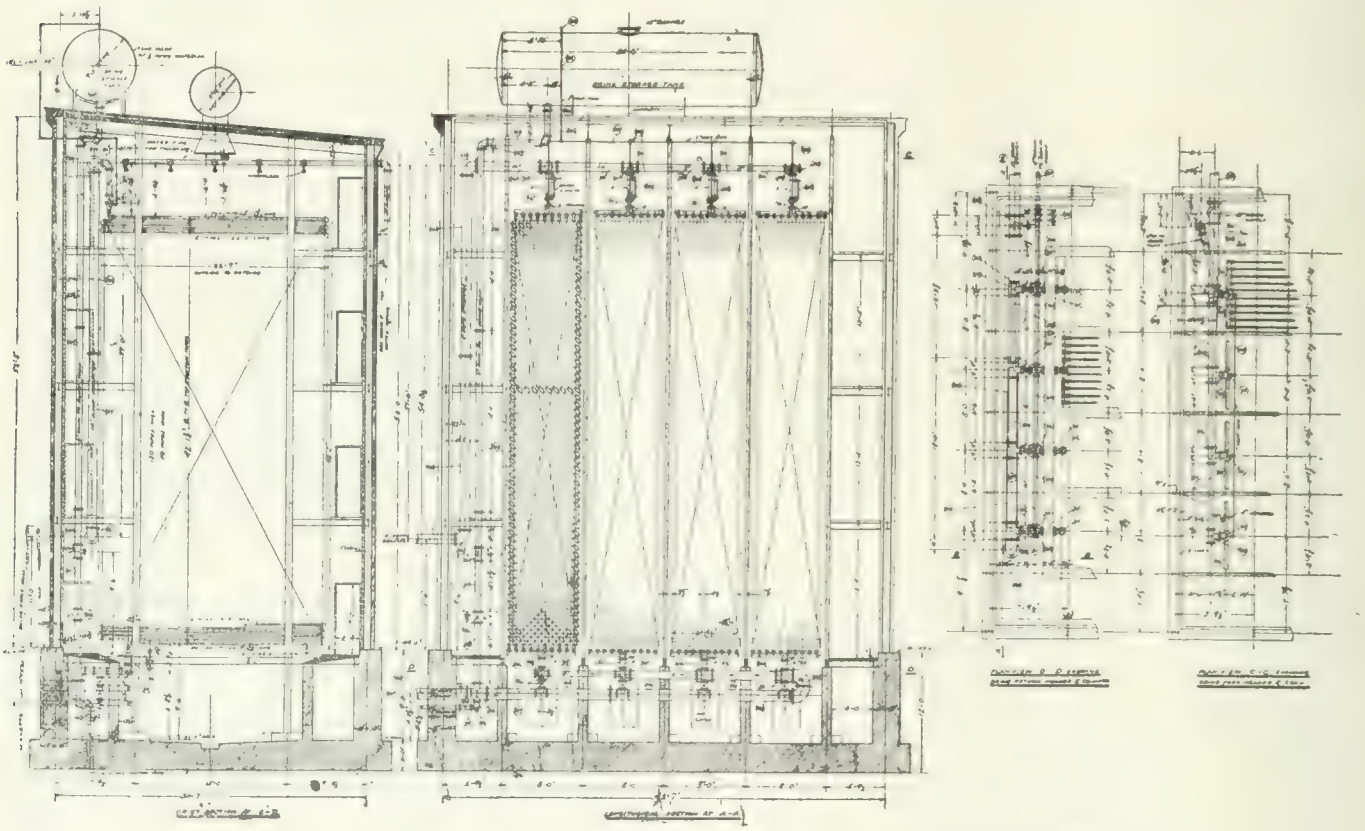

FIG. 1.—CROSS-SECTION OF AIR DRYING CHAMBER FOR COOLING AIR BY CONTACT WITH BRINE COILS.

The construction of these screens with the water distributing troughs *E* is shown in detail in section 7. The screens occupy the entire annular space and are arranged in radial sections, as shown in section 4. The water is pumped into the tower through pipe *F* and to tank *G*, from which it flows by gravity through regulating valve *H* to annular trough *I*, and thence by pipes *J* to pan *K*. From pan *K* it overflows to distributing troughs *E* through pipes *L*, which are so adjusted as to give an equal distribution of water over the entire annular space. After the water has passed over the screens it is collected in pan *M*, from which it flows through pipes *N* into filter *O*, where the dirt which is collected from the air is removed. The water passes from the filter through pipe *P* to the water coolers, where the heat is removed by means of refrigeration, after which it is again pumped to tank *G*.

When it is desired to clean the filter bed the valves in pipe *N* are closed, the water is taken to the coolers through pipe *O* and the filter bed is washed through pipe *P*, the overflow water passing out through trough *R* and pipe *S* to the sewer. As the air passes upward it is compelled to pass through the wetted screens many times and when it reaches the top of the grillwork it will be almost as cold as the entering water. In the design shown, if the entering water is 34 deg. Fahr. and the entering air 90 deg. Fahr., the temperature of the air will be reduced to 39 deg. and the temperature of the water will be raised to about 50 deg. The moisture content of the air will be 2.75 gr. per cubic foot after the air passes the eliminators *T*, which are intended to remove any entrained or unvaporized water.

In a similar manner the air passes through a second stage of cooling, passing through pipes C^1 and screens D^1, where it comes into contact with a non-freezing liquid, usually a solution of chloride of calcium, commonly called brine. The brine may be cooled to any desired temperature and is introduced into the system through tank G^1, from whence it is distributed over the grillwork, which is an exact duplicate of the first or water stage of cooling, with the exception that no filter is provided for the brine, as the air has been thoroughly washed before reaching the second stage. If it is desired to have a final moisture content in the air of 1/5 gr. per cubic foot, its temperature will be 24 deg., and the initial temperature of the brine must be 19 deg. The air then passes through pipe *U* to the blowing engines. The structure is entered through air lock *X*, and openings having a removable cover are provided in the inner shell at all points where it is desired to have access to the working parts of the tower. A general arrangement of a blast furnace equipped with dry blast, Fig. 3, shows the tower described in its relation to the refrigerating machinery, the blowing engines, the stoves, and the furnaces.

Calculation of Heat to be Removed: In order to properly design an air-drying plant of any type it is first necessary to know the quantity of heat to be removed from the air. In order to show in a concrete manner how this may be done

Mr. Walter assumes a case of a furnace requiring 40,000 cu. ft. of air per minute, the initial temperature of which is 90 deg. Fahr. and the moisture content of which is 8 gr. per cubic

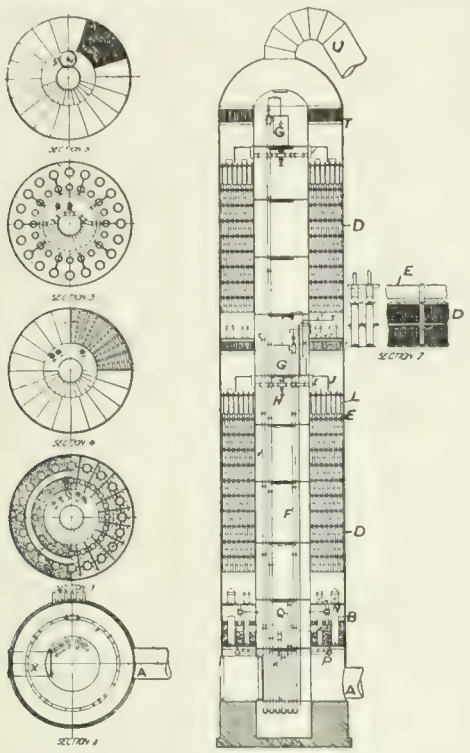

FIG. 2.—AIR DRYING TOWER FOR DRYING AIR BY THE TWO-STAGE, DIRECT CONTACT METHOD.

foot. It is desired to dry the air to such a degree that it will contain only 1.5 gr. of moisture per cubic foot, and as this corresponds to a saturated condition of air at the temperature of 24 deg. it is necessary to reduce the temperature from 90 deg. to this point. In the process described above this is done in two stages, the first, or water stage, reducing the temperature to 39 deg. with a moisture content of 2.75 gr. per cubic foot, and the second, or brine stage, in which the reduction is completed.

The heat to be removed in the first stage is determined as follows: 40,000 cu. ft. of air at 90 deg., containing 8 gr. of moisture, weighs 2867.4 lb., of which 45.7 lb. is water vapor and 2821.7 lb. is dry air. The heat to be removed from the dry air is, therefore,

$$2821.7 \times 0.2375 \times (90 - 39) = 34,178 \text{ B.t.u.}$$

The quanity of water vapor condensed and the heat rejected in the process is as follows:

The volume of dry air in the mixture at 39 deg. is

$$2821.7 \div 0.079843 = 35,340 \text{ cu. ft.}$$

In a saturated condition the volume is increased 0.8 per cent, or $35,340 \times 1.008 = 35,623$ cu. ft., which is the volume to be considered in the determination of the water vapor remaining in the air at this temperature. As saturated air at 39 deg. contains 2.75 gr. of moisture per cubic foot, the quanity of water vapor remaining is

$$35,623 \times 2.75 \div 7000 = 14 \text{ lb.}$$

As the original quantity was 45.7 lb., the quantity condensed by the reduction of temperature is 31.7 lb. There is no condensation until the temperature of 70 deg. is reached, as the air is not in a saturated condition above this point; each degree of reduction after passing the 70 deg. mark produced a condensation of water vapor, but the quantity condensed becomes less as the temperature is lowered; thus from 70 to 69 deg. the quantity of water vapor is reduced 0.25 gr. per cubic foot, and from 40 to 39 deg. the reduction is 0.1 gr. One-half of the 31.7 lb. is condensed when a temperature of 59 deg. is reached, and it is assumed that the latent heat of condensation for this temperature, which is 1058.4 B.t.u., is practically correct for determination of the work of condensation of all the water vapor precipitated, and the heat to be removed is

$$31.7 \times 1058.4 = 33,551 \text{ B.t.u.}$$

The remainder of the work of heat removal consists of cooling the water vapor to the condensation point, cooling the water vapor not condensed, and cooling the condensed water to the temperature of the cooling water leaving the refrigerating chamber. As the mean temperature of condensation is 59 deg., we may consider that all the water vapor is cooled from 90 to 59 deg., and the heat to be removed, its specific heat being 0.475, is

$$45.7 \times 0.475 \times (90 - 59) = 673 \text{ B.t.u.}$$

The water vapor not condensed is cooled from 59 to 39 deg. and the heat to be removed is

$$14 \times 0.475 \times (59 - 39) = 133 \text{ B.t.u.}$$

Assuming that the water leaves the refrigerating chamber at 50 deg., the condensed water vapor must be cooled from 59 to 50 deg., and the heat to be removed is

$$31.7 \times 9 = 285 \text{ B.t.u.}$$

The total heat to be removed in the first stage is, therefore, 68,820 B.t.u. Assuming that the initial temperature of the cooling water is 34 deg. and its final temperature 50 deg., there must be circulated $68,820 \div (50 - 34) = 4301.25$ lb. of water, equal to 516 gal. per min. To this must be added the heat absorbed from the atmosphere, which in any well-insulated plant will not be more than 1 per cent. This makes the total heat to be removed by the refrigerating plant 69,508 B.t.u. per min. And the water to be circulated 521 gal. per min.

In the second stage the brine enters at a temperature of 19 deg. and leaves at 29 deg. The air enters at 39 deg. and leaves at 24 deg. The heat to be removed is as follows:

Heat to be removed from dry air is

$$2821.7 \times 0.2375 \times (39 - 24) = 10,052 \text{ B.t.u.}$$

Volume of dry air at 24 deg. is

$$2821.7 \div 0.0823 = 34,286 \text{ cu. ft.}$$

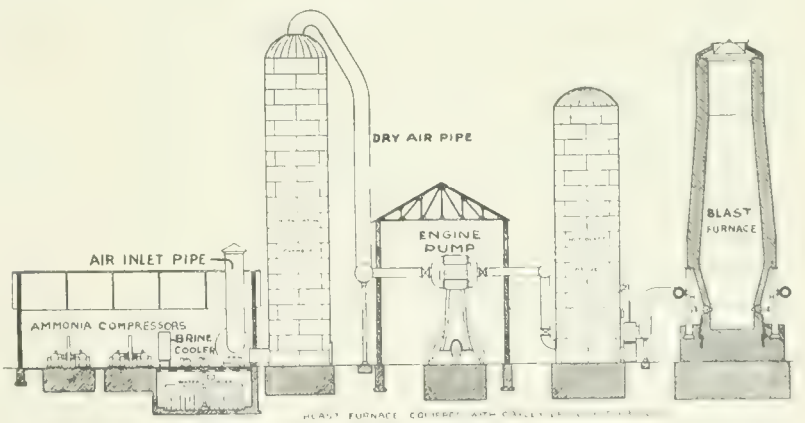

FIG. 3.—DIAGRAMMATIC SKETCH OF BLAST FURNACE EQUIPPED WITH GAYLEY DRY BLAST PLANT.

Volume when saturated is

$$24,286 \times 1.0043 = 34,433 \text{ cu. ft.}$$

Quantity of water vapor remaining in mixture is

$$34,433 \times 1.5 \div 7000 = 7.3785 \text{ lb.}$$

The water vapor condensed is

$$14 - 7.3785 = 6.6215 \text{ lb.}$$

Heat to be removed for condensing water vapor is

$$6.6215 \times 1073.4 = 7108 \text{ B.t.u.}$$

in which 1073.4 is the latent heat at 32 deg., which is the mean temperature of condensation.

Heat to be removed from water vapor before condensation is

$$6.6215 \times 0.475 \times (39 - 32) = 22 \text{ B.t.u.}$$

Heat to be removed from water vapor not condensed is

$$7.3785 \times 0.475 \times (30 - 24) = 53 \text{ B.t.u}$$

Heat to be removed from condensed water vapor is

$$6.6215 \times (32 - 29) = 20 \text{ B.t.u.}$$

The total heat to be removed in the second stage is, therefore, 17,255 B.t.u. Adding 1 per cent for heat leakage through the insulation, the quantity becomes 17,428 B.t.u. Assuming that the brine weighs 10 lb. per gallon and has a specific heat of 0.7, the quantity to be circulated, when heated by the air from 19 to 29 deg., is

$$17{,}428 \div [10 \times 0.7 \times (29 - 19)] = 294 \text{ gal. per min.}$$

New Method for Concentrating Brine: It is obvious that some means must be provided for removing the accumulation of water from the brine used in the second stage of cooling. The quantity of water added is 6.6215 lb. per min., and it is desirable to evaporate this with as little disturbance to the regular action of the plant as possible. An automatic device is shown in Fig. 4.

A sample of brine is continuously taken from the system by means of several funnels *V*, Fig. 2, Section 1, into tank *W*, and overflows into pan M^1. This constant level tank is tank *A* in Fig. 4.

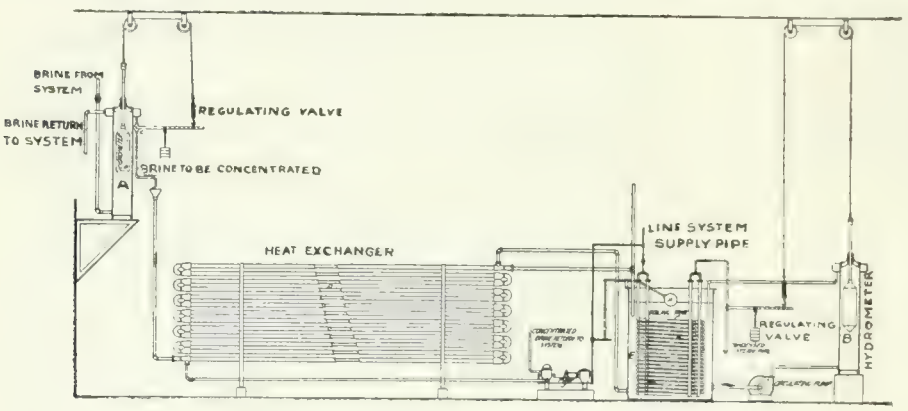

FIG. 4.—AUTOMATIC BRINE CONCENTRATOR.

A hydrometer *B* floats in the tank and operates valve *C*, which is adjusted to open when the brine falls below a desired specific gravity. This brine, which is drawn off at a temperature of 29 deg., flows through a heat exchanger *D* to boiler tank *E*, where the volume of brine is reduced one-third by boiling. The heat is furnished by a live steam coil *F* and is regulated by the density of the brine. A pump circulates a small portion of the liquid through the constant level tank *G*, where the hydrometer *H* acts upon the exhaust from the steam coil, supplying more or less heat as the density of the brine decreases or increases. The pump *J* returns the brine through the heat exchanger to the brine coolers. This pump is governed by float *K* in the boiling tank.

If it is desired to have the brine in the system at 1.2 specific gravity it is necessary to draw off by means of this apparatus about 3 gal. per minute and boil it down to 2 gal. By installing an efficient heat exchanger the heat returned to the system is reduced to a negligible quantity. Any convenient source of heat which will give a temperature of 250 deg. can be used for boiling the brine, and in many cases gas will be found less expensive than live steam.

Refrigerating Machinery: Having determined the heat to be removed from the air in each stage, it is necessary to install the proper refrigerating machinery to remove these same quantities of heat from the water and brine. A specification can be drawn up from the foregoing figures giving the quantities of water and brine, the temperature range through which they are to be cooled, the steam pressure available, and the temperature of the water supply for the ammonia condenser. Having this information, any builder of refrigerating machinery can quote a price for an installation guaranteed to do the required duty.

Power Required to Operate the Plant: The power required to operate the plant varies with atmospheric conditions, and Table No. 1 shows the maximum and average requirements. The saving of power in the blowing engines is due to the reduction of volume in the air blown, and is based on average temperature and humidity conditions in the blowing engine room. The blast pressure is assumed to be 15 lb. per square inch.

TABLE No. 1.

Power required to operate a two-stage Gayley dry-blast plant having a capacity of 40,000 cu. ft. of air per min. at a temperature of 90 deg. Fahr. with a moisture content of 8 grains per cu. ft.

	Maximum	Average
Ammonia compressors, first stage	433 i.h.p.	152 i.h.p.
Ammonia compressors, second stage	137 i.h.p.	96 i.h.p.
Total	570 i.h.p.	248 i.h.p.
Steam for brine concentrator, lb. per hour	544	409
Motor driven fan	60 e.h.p.	60 e.h.p.
Motor driven water pump	19 e.h.p.	14 e.h.p.
Motor driven brine pump	11 e.h.p.	11 e.h.p.
	90 e.h.p.	85 e.h.p.
Average saving of power in blowing engines		270 i.h.p.

Cost of Operation: The cost of operating the plant described will vary to some extent with local conditions. In the Pittsburgh district, at the present rate of wages, the cost will amount to $6,800 per year, which is equivalent to 4¼ cents per ton of iron produced for a furnace making 160,000 tons per year. This estimate includes labor, power, water, repairs, oil, waste, packing, ammonia, and chloride of calcium. A plant of double the size of the above can be operated at $11,000 per year, making the cost per ton of iron 3½ cents.

Detailed Cost of Installation: The cost of installation is estimated as follows:

Building	$9,400
Refrigerating chamber	23,300
Refrigerating machinery	34,300
Pumps and motors	1,400
Fan and motor	3,500
Brine concentrator	800
Piping and covering	3,400
Electric wiring for power and light	1,000
Steam condenser	1,300
Engineering and incidentals	7,700
Total	$84,800

This estimate does not include steam and water pipe lines to the plant, or air piping from the plant to the blowing engines, as these items depend very largely upon local conditions. Under moderately favorable conditions these items should not cost more than $8,000, making the total cost of installation $92,800. A plant having a capacity of 80,000 cu ft. of air per minute requires the expenditure of $170,000. These figures are 25 per cent below the lowest installation costs of plants in which the air cooling is done by the brine coil system.

This expenditure is compared by Mr. Walter with the savings attained in blast furnace operations, as follows: It is conservatively estimated by those who have operated dry-blast furnaces that a saving in fuel of 12.5 per cent is effected, and, at the same time, the production of iron is increased 10 per cent. This means that if a furnace uses 2400 lb. of coke to make 1 ton of iron and has a production of 400 tons per day,

the fuel saved by dry blast is 300 lb. per ton and the production is increased 40 tons, all of which is accomplished without increased labor cost. The furnace operation can be varied to suit the market conditions so that, if it is desired, a larger increase in production can be made while saving a smaller percentage of fuel, or a larger saving of fuel can be effected with a corresponding decrease in production. Another important advantage is that the furnace receives a uniform weight of air with a uniform moisture content, and, therefore, works with greater regularity, producing a more uniform product than one blown with natural air. The necessity of carrying reserve heat in the hot blast stoves is also eliminated, as the irregularities which necessitate this precaution do not occur. By reducing the fuel the limestone required is decreased. Regularity in working means a reduction of flue dust carried off by the gases. The actual profit in dollars and cents from the installation of a dry-blast plant is a separate problem for each blast furnace. A fair figure for the Pittsburgh district is a net saving of 50 cents per ton of iron, which, for a furnace making 160,000 tons per year, is $80,000 annually.

* * *

Mr. Walter's paper elicited quite an extended discussion.

Mr. **W. H. Carrier,** of the Carrier Air Conditioning Company, pointed out that the latest and best data on water vapor are to be found in Marks and Davis' steam tables and in W. H. Carrier's paper on rational psychrometric formulæ in the December, 1911, issue of the *Proceedings* of the American Society of Mechanical Engineers. In the latter paper a simple method is described for obtaining the refrigerating requirements in cooling and dehumidifying air. The cardinal principle of this method is that for a given temperature of evaporation; that is, for a given wet bulb temperature, a pound of air contains a fixed and definite amount of heat, regardless of the dry bulb temperature or of the moisture contents. This means that the wet bulb temperature is the rational and convenient measure of the total heat contents of the air, both latent and sensible.

For example, an ordinary recording thermometer with the bulb covered with a wetted wick, over which a current of air is circulated, could be made to record B.t.u. contents per pound of air by graduating the record in terms of B.t.u. instead of in degrees temperature. Consequently in dehumidifying the maximum refrigerating load will occur at the maximum wet bulb temperature, relation of dry bulb temperature to moisture contents being immaterial.

The condition which Mr. Walter assumes is 40,000 cu. ft. at 90 deg. and containing 8 gr. of moisture. This is equivalent to saying that the wet bulb temperature is 76.2 deg. This, however, to Mr. Carrier's knowledge does not represent the extreme conditions. He has personally observed in Buffalo wet bulb temperatures as high as 78 deg., and thinks possibly they may be found in Pittsburgh as high as 79 or 80 deg., which would considerably increase the refrigerating requirements.

Mr. Carrier also thought that the calculations could be much simplified by basing them on pounds of air instead of cubic feet of air. The calculation may be made as follows: We will make the assumption of Mr. Walter, which is 2821.7 lb. of dry air, containing 45.7 lb. of moisture at a temperature of 90 deg. This will then give us $45.7 \div 2821.7 = 0.00162$ lb. of dry air, or $0.00162 \times 7000 = 113.4$ gr. of moisture per pound of dry air.

The volume of 1 lb. of dry air plus 113.4 gr. moisture, we find from the chart, is 14.22 cu. ft. This will give us $28\,217 \times 14.22 = 40{,}120$ cu. ft., instead of 40,000 cu. ft., given by Mr. Walter.

From the writer's psychrometric chart we find air at 90 deg. and containing 113.4 gr. per pound of dry air has a temperature of evaporation, or true wet bulb temperature, of 76.2 deg. Taking a point on the total heat curve corresponding to this temperature, we find that 1 lb. of air contains 38.85 B.t.u. Assuming this cooled to a saturation temperature of 39 deg., we find the corresponding heat content to be 14.9 B.t.u. per pound of dry air, requiring a removal of 23.95 B.t.u. per pound of dry air. We will, therefore, have a total refrigeration requirement per minute of

$$2821.7 \times 23.95 = 67{,}670 \text{ B.t.u.}$$

This, however, does not include the heat of the liquid, which has to be cooled from a wet bulb temperature of 76.2 deg. to 39 deg., the final water temperature. As there are 45.7 lb. of water in the air, 1700 B.t.u. will be required for cooling this, giving us a total refrigerating requirement of 69,310 B.t.u. per minute, or approximately 350 tons refrigeration. Allowing for the rise of the water temperature to 50 deg., there will be a saving of 355 B.t.u., reducing the total requirement to 69,015 B.t.u. per minute.

In the second stage, as before, we have a saturation temperature of 39 deg. at which the air contains 14.9 B.t.u. per lb. of dry air. This is then cooled to a saturation temperature of 24 deg., at which, according to the psychrometric chart, it contains 8.55 B.t.u. per pound of dry air, making a removal of 5.35 B.t.u. per pound of dry air. The total B.t.u. removed per minute is then $2821.7 \times 5.35 = 15{,}095$ B.t.u. The refrigeration required in reducing the heat of the liquid is for 13.7 lb. through a range of 15 deg., or 200 B.t.u. per minute. This gives a total of 15,295 B.t.u.

Mr. Carrier finally mentioned that a dehumidifying plant embodying many of the principles contained in Mr. Walter's proposed new method of drying air was installed under the writer's supervision by the Carrier Air Conditioning Company and successfully operated in 1908. This plant is in operation to-day, its capacity having been doubled by the purchase of an additional unit, the exact duplicate of the first.

In the second stage the essential principle involved is the direct contact of the brine with the air to be dried. The practicability of this process was demonstrated by Mr. Carrier in Mr. Walter's presence in June, 1909, using an experimental apparatus having a capacity of 10,000 cu. ft. per minute in which the air was cooled as low as 20 deg. with an inappreciable entrainment of calcium chloride as determined by careful chemical analysis. The chief difference between Mr. Carrier's process and Mr. Walter's process appears to be in the fact that Mr. Carrier introduces the refrigerating liquid directly into the air in the form of a finely divided spray, which is afterwards eliminated, while Mr. Walter distributes his brine over screens.

To Mr. Carrier's mind the latter process has several mechanical objections, the chief of these being the difficulty of distributing water uniformly over the screens and secondly the rapid corrosion of the screens which must necessarily take place in an atmosphere quite noticeably charged with sulphur dioxide or traces of sulphuric acid as in the Pittsburg district.

Mr. Carrier has found in these plants that the recirculated water becomes highly acid in a short time and will corrode practically everything but monel metal and cast iron. The pumping equipment and water piping must, therefore, be carefully considered with reference to its acid-resisting construction. Mr. Carrier would recommend extra heavy piping, monel metal nozzle and eliminators. He also recommends so far as possible the elimination of all easily corrosible parts, such as screens, etc., unless they are constructed of monel metal or other acid-resisting material.

Mr. **Louis Block,** of New York City, was the next speaker. He mentioned the fact that if air is blown over or through a calcium chloride solution, particles of calcium chloride are carried along with the air and are deposited upon the surfaces with which the air afterwards comes in contact. In a certain fur storage plant the air was blown over a cooled calcium solution and the method of cooling had to be abandoned because the chloride was distributed to a considerable extent over the fur garments hanging in the cooling room. The question arises, will the calcium chloride injuriously affect the inner surfaces of the blowing cylinders? Will it affect the product of the blast furnace?

Mr. Block further thought that if regularity of blast-furnace operation is the all-important consideration, it will be sufficient to remove the moisture out of the air down to 2.75 (39° F.) or 2.50 gr.—which is a perfectly simple proposition—and not to attempt to remove another 1.25 gr. of moisture down to 1.5 gr. (240° F). This second step is cumbersome and expensive and Mr. Block gives figures to show that this second step probably costs more than it saves, and introduces the liability of irregularity in blast-furnace operation.

Mr. **J. B. Ladd,** of Philadelphia, asked on what calculations or actual results the author's statement was based that the saving in blowing engine power is practically equal to the power required for operating the refrigerating plant, so that the power for refrigeration is obtained at no expense.

Mr. **S. M. Marshall,** of the Cambria Steel Company, of Johnstown, Pa., pointed out that there are three methods of refrigeration which are being considered more or less to-day; one cooling the air before the blowing engine, one after the blowing engine, and the dense air system by which the air itself is compressed under the ordinary blast pressure, cooled at this higher pressure, and later re-expended to reduce the temperature and moisture. He asked Mr. Walter as to the merits of his system as compared with the other two. Further the percentage of saving due to the use of dry blast depends on the initial coke consumption of the furnace and upon the stove heats. How do these two factors affect the percentage of saving? Moreover, dry blast and thin lining in blast furnaces produce apparently large savings in the fuel economy when used independently. Are there any data on the probable effect of using the two simultaneously?

Prof. **S. L. Goodale,** of the University of Pittsburgh, emphasized that a saving of 20 per cent of fuel alone in such a big fuel-consumer as a blast furnace, is itself a very important item. The statement of Mr. Walter that one pound of coke is required to break up one pound of water vapor, he considers to be slightly inaccurate. In the reaction for breaking up the moisture we may say that 12 parts of carbon are needed, actually, to break up 18 parts of water vapor; and there is an absorption of heat in that reaction which must be made up by the combustion of an additional 12 parts of carbon. So that if 24 parts of carbon were consumed to 18 parts of water vapor broken up the heat produced would be practically balanced by the heat absorbed; and in addition a little carbon must be burned to heat the products of this reaction to the temperature of the furnace hearth. So that it seems that about 1½ pounds of coke is a more close approximation to the amount that is actually used by the furnace in breaking up one pound of water vapor.

As to the two-stage condensation, Prof. Goodale said that most of the work is done with the cheaper energy. That is, it is more expensive to remove a certain amount of water vapor at a very low temperature than to remove the same quantity at a temperature nearer the ordinary; and as Mr. Walter proposes to do most of the condensing at a temperature economically obtainable, compared to freezing and undercooling, a considerable economy of operation should result. At the opposite extreme of temperature, in other operations, vast quantities of heat are thrown away by metallurgical plants in waste furnace gases because heat is not usable by the particular furnace unless supplied at a high temperature. In some cases heat of this kind is recovered for steam raising; but Prof. Goodale believes that there is still a field from which good technical work can be made to yield large returns by utilizing the heat for purposes for which moderate temperatures only are rquired. This is just another problem in multi-stage operation for economy.

In regard to the amount of power used, it would seem as if there were a sufficient amount of furnace gas available around blast furnaces that could be used, and there should not be needed any great additional expense for the power used in the refrigerating plant.

There is another method of drying blast which has been introduced at one place abroad, and that is direct drying by contact with dry calcium chloride. Prof. Goodale asked if it would be possible perhaps to substitute that method of drying in place of the proposed second stage. In that way would be secured the advantage of the uniform moderate temperature of the blast, and possibly a lower cost for the final drying of the air.

Mr. **E. D. Leland,** superintendent of the compressing stations of the Philadelphia Company at Pittsburg, inquired concerning another plan of drying air proposed as cheap and efficient. The idea is to spray glycerine into the air cylinder of a blast engine, in order that the glycerine might absorb the moisture and thus give dry air for the furnace. A separating receiver was to be introduced between the engine and the furnace, and the glycerine thus recovered was to be used again. Several years ago the device was patented, and an experimental plant erected at Bradford, Pa., from which very satisfactory results were claimed.

In Mr. Walter's sketch, after the second refrigeration, the air goes directly from the top of the tank to the blast engine. Now, after cooling, the excess of moisture would doubtless be present in the air in the form of fog, and this fog might continue on through with the air current into the furnace. This action is probably what did occur in the case mentioned where chloride of calcium spray was carried over to the injury of some furs. It requires time to precipitate a light fog, and Mr. Leland thought that by passing the air through a large tank or drum, after its final cooling, the temporary checking of the air current would give time for moisture precipitation and thus add materially to the efficiency of the new apparatus.

Mr. **J. J. Lilie,** of the Carrier Air Conditioning Company, of New York City, asked as to the kind of insulation employed by Mr. Walter. He also gave figures on some power requirements not considered by Mr. Walter. These are the frictions of the air going through the cooling chamber and the work lost by the falling of the water and the falling of the brine, the water and brine being pumped to tanks and allowed to flow down. These losses he found to amount to 2.3 per cent.

Mr. Lilie then replied to the criticism which had been raised that there was liability of entrainment and carrying over of a certain amount of calcium chloride. In installations using a direct spray, which may be found in other industrial work, if a proper velocity is kept through the eliminating plates and they are properly constructed, there is no entrainment passing the eliminating plates such as Mr. Walter proposes to use and a chamber such as Mr. Leland had mentioned is not necessary. Mr. Lilie had recently seen the records of some very accurate tests worked out by people "who were in no way interested in the plant which showed as little as 0.07 of a grain of moisture as the maximum amount carried over in a test extending over a period of several days. This was the maximum reading they found in taking the temperature of the dew point and the temperatures after they had been heated up, that is, taking a sample from the bustle pipe."

Mr. Lilie finally pointed out that Mr. Walter's system, as it is, would not deliver to the furnace a constant weight of air, on account of the variations of the barometric pressure. A variation in barometric pressure affects the amount of air delivered to the furnace because the weight is inversely in proportion to the pressure, and if we have in one day a variation in barometric pressure of 1½ in. it makes a variation in the amount of air delivered to the furnace of over 5 per cent. Hence, by maintaining a constant speed of our engine and delivering to the blowing engine air at a constant temperature, we are not necessarily delivering a constant weight of air. If it is of importance to deliver a constant weight of air we ought to take the barometer into account as well as the temperature.

In his final reply the author, Mr. **Bruce Walter,** first answered Mr. Ladd's question as to the power saved in the

blowing engines, which is simply a matter of volume of air blown.

A fair estimate of the power required to compress air in a blowing engine to 15 lb. gauge pressure, is 60 i.h.p. per 1000 cu. ft. of air per minute so compresesd. Assuming that the air is taken from the engine room and that the average temperature is 85 deg. and the average moisture content is 4.8 gr. per cubic foot, then the power required to compress 1000 cu. ft. of this mixture is 60 i.h.p. and the weight of dry air in mixture is 71.96 lb. The power required to compress one pound of dry air under these conditions is 0.8338 i.h.p.

When the air is dried before compression to 1.5 gr. water vapor per cubic foot, it is assumed that a rise of five degrees in temperature occurs between the drying tower and the blowing engines, so that a condition of 29 deg. and 1.5 gr. exists at the inlet valves and the weight of dry air in 1000 cu. ft. of this mixture is 81.13 lb.

The power required to blow one pound is

$$60 \div 81.13 = 0.7395 \text{ i.h.p.}$$

The power saved on the delivery of one pound of dry air is, therefore, 0.0943 i.h.p., equal to 11.3 per cent of the power required to blow one pound under the natural air condition.

In reply to Mr. Marshall, Mr. Walter said he was not prepared to discuss in detail the system of refrigeration after compression. He offered, however, the criticism that we lose something in regularity in quantity of oxygen delivered to the furnace by refrigerating after compression unless some effort is made to regulate the speed of the blowing engines to meet the temperature and moisture conditions in the blowing engine room.

We also lose from 80 to 100 deg. of heat by drying after compression. In drying before compression we get the benefit of the heat of comparison added to the initial temperature of the air entering the blowing engines, but in the after-compression method, all the heat of compression is removed and the temperature is further lowered to 40 or 50 deg. This lost heat must be supplied by the hot blast stoves and, therefore, the gas consumed in furnishing it should be charged against the plant as power consumed.

As to the dense air drying, Mr. Walter referred to some tests made some years ago where the cost was found to be excessive. It is nothing but an air refrigerating machine and air refrigeration is much more costly than ammonia refrigeration for the B.t.u. removed.

Mr. Walter's insulation figures are based on covering the tower with two inches of cork lagging from the bottom of the filter to the water distributing pan and three inches of the same material from this point to the air outlet. The exact calculations show a loss of 504 B.t.u. per minute, which is less than 0.6 per cent of 86,075 B.t.u., the whole work to be done on the air.

In regard to the barometric pressure that is a matter over which we have no control, and Mr. Walter thinks that our efforts at regularity in temperature and moisture are commendable even if we do have some irregularity of barometric pressure. In other words, we should not stop at efforts to deliver a regular quantity of oxygen to the furnace because of the barometric changes.

By introducing the air to the blowing engines at a constant temperature and moisture content, we eliminate the greatest variable and prevent a combustion of an abnormally low barometer with a high temperature.

In reply to Prof. Goodale Mr. Walter said that if it requires one and a half pounds of coke to break up one pound of water, the saving of fuel due to the elimination of moisture is a larger percentage of the total saving than he had assumed in the paper and the saving due to regularity is proportionally reduced. This being true, Mr. Block's calculation will, therefore, have to be revised and will then show a considerable saving in fuel for the second stage.

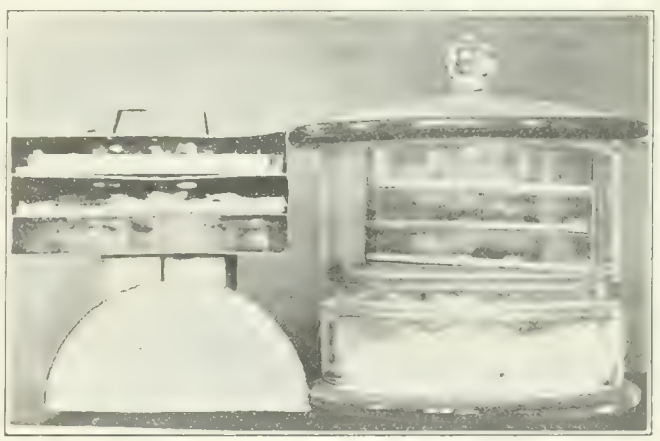
In regard to Prof. Goodale's suggestion of using calcium chloride in a crystallized form for removing the moisture in the second state, Mr. Walter said that this method of drying the blast was tried at a furnace in France. The towers were provided to be used in a regenerative manner, so that while the air was being dried in the first tower, in the second the calcium chloride was being dried by heat from waste gases, and in the third the calcium chloride was being cooled to be ready to dry air again. But it was found impossible to keep the calcium chloride from fusing into a solid mass which was not broken by the method used in drying it and consequently had to be broken up by hand. While the air was very dry when the calcium chloride was fresh, the moisture rose rapidly and the tower had to be changed very frequently.

In reply to Mr. Carrier, Mr. Walter thought that he overestimates the difficulties to be encountered due to the corrosion of the screens and surfaces exposed to the air and the circulating water. While this water in time may become acid, it can easily be changed and a new charge of purified water put into the system. In fact this will be done automatically to a large extent when the water wasted from washing the filter is replaced by new water. If this is found to be insufficient an occasional introduction of lime will be found efficient in preventing the corrosive action of the acid.

Metallography Sample Holder.

By Stephen L. Goodale

The accompanying photograph shows a holding device planned by the writer for use in the Metallography laboratory of the University of Pittsburgh. Its utility lies in storing a considerable number of polished small samples of iron and steel in a desiccator in such a way that any sample is easily



METALLOGRAPHY SAMPLE HOLDER.

accessible without disturbing the arrangement of the rest. None of the preservative coatings that we have tried are satisfactory, as the view through the microscope is invariably somewhat blurred by the thin film of varnish.

This holder is made of ordinary tin in two parts, each of a half circle plan and several inches high, the two together just filling an eight inch desiccator. The shelves are made of perforated tin, and on each shelf is placed a perforated loose pan of the same shape and size as the shelf itself, and with its edges slightly turned up. A soft paper or cloth cover is used over the tin pan in order not to mar the fine polish of the samples.

For any special series of samples, as for instance a set to show varying heat treatment on any steel, we use a piece of quarter or half-inch wood cut to the size of the pan. Depressions are cut in the wood with a twist drill and numbered, so that it looks like a miniature biscuit pan when finished, each sample in the series having its own place.

It is well to use the porcelain rest in the desiccator under

this holder, as the sloping glass walls of the desiccator do not hold one half of it securely if the other is taken out for examination. In that case the half left in the desiccator may slip down and mix up the samples and also rub their polished surfaces.

We have found it advisable to have a large number of prepared samples ready for our students to examine, with the record of just what each one is and its heat treatment. Each student is given a sufficient number of pieces to polish and etch so that he becomes thoroughly familiar with those operations, without having to devote so much time to the purely mechanical part of the work as to be objectionable. Besides this each man is required to repolish and re-etch a number of the prepared samples, and study the different effects of varying the etching, etc., on one sample.

The photograph shows one half of the holder in place in the desiccator, the other half outside, with a wood tray on top shelf, a pan with samples on middle shelf, and an empty pan standing below. *University of Pittsburgh.*

Determination of Very High Temperatures

By G. A. Shook.

Radiation Laws of Planck and Wien.

In the earlier papers of this series, published in the April, June and July issues of this journal, the methods of calibrating pyrometers on the basis of Wien's law were taken up. Within the limits of experimental error, Wien's law will hold for all temperatures from 600 deg. to 3000 deg., and, of course, this includes all of the temperatures ordinarily met with.

It can be shown in several independent ways, however, that for large values of temperature and wave-length, in the visible spectrum, Planck's law represents more nearly the relation between the temperature T and the luminous intensity J for a particular wave-length λ.

It is now necessary to make a comparison of these two laws in order to determine what error will be committed by the use of Wien's law for temperatures of the magnitude of 6000 or 7000 deg. C., the probable temperature of the sun.

Planck's law may be written in the form

$$J(e^{C_2/(\lambda T)} - 1) = C_1\lambda^{-5} \qquad (1)$$

Wien's law may also be written

$$J = C_1\lambda^{-5}e^{-C_2/(\lambda T)} \qquad (2)$$

Obviously if we can neglect the -1 in Planck's formula, equation (1), it will reduce to Wien's formula. This can only be done when $e^{C_2/(\lambda T)}$ is large compared to unity.

Suppose we take λ as 0.6μ (red light); since $C_2 = 14{,}500$, if T is not too large, the quantity $e^{C_2/(\lambda T)}$ will be large in comparison to 1. We may calculate its value as follows:

Let

$$e^{C_2/(\lambda T)} = x$$

Taking the logarithm of both sides of this equation

$$C_2/(\lambda T) = \log x$$

or

$$\frac{\log_{10} e\, C_2}{\lambda T} = \log_{10} x = \frac{K}{T}$$

where $\log_{10} x$ means the *common logarithm of* x. $\log_{10} e = 0.4343$

Therefore,

$$\frac{0.4343 \times 14{,}500}{0.6} = K = 10{,}500.$$

Taking T as 1000 deg. (absolute Centigrade)

$$\frac{10{,}500}{1000} = 10.5 = \log x,$$

whence $x = 31{,}630{,}000{,}000$.

Taking a somewhat larger value of T, say $T = 3000$ deg., about the temperature of the carbon arc

$$\frac{10{,}500}{3000} = 3.5 = \log x$$

and

$$x = 3163$$

For $T = 6000$ deg., the temperature of the sun

$$\frac{10{,}500}{6000} = 1.75$$

whence

$$x = 56.24.$$

Therefore,

$$e^{C_2/(\lambda T)} = 31{,}630{,}000{,}000 \text{ for } T = 1000$$
$$= 3163 \text{ for } T = 3000$$
$$= 56.24 \text{ for } T = 6000$$

Hence it is evident, as far as J is concerned, that for large values of T, the 1 in equation (1) cannot be neglected; *i. e.*, Wien's law is only an approximation to Planck's law for these high temperatures.

The effect of this error on the measurement of temperature will now be considered. Equation (1), Planck's law, may be written:

$$(e^{C_2/(\lambda T)} - 1)J = C_1\lambda^{-5} \text{ or}$$
$$Je^{C_2/(\lambda T)} - J = C_1\lambda^{-5} = J.$$

Replace $C_1\lambda^{-5}$ by K' and take the logarithm of both sides of this last equation.

Hence

$$\log [e^{C_2/(\lambda T)} \cdot J] = \log (K' + J)$$

The logarithm of a product is the sum of the logarithms of each quantity and $\log e = 1$, therefore

$$\log J + \frac{C_2}{\lambda T} = \log (K' + J) \text{ or}$$
$$\frac{C_2}{\lambda T} = \log \left(\frac{K' + J}{J} \right)$$

Whence

$$T = \frac{C_2}{\lambda \log (1 + K'/J)}$$

and

$$t = \frac{\log_{10} eC_2\lambda}{\log (1 + K'/J)} - 273$$

Let

$$K_1 = \log_{10} eC_2\lambda$$

therefore

$$t = \frac{K_1}{\log (1 + K'/J)} - 273 \qquad (3)$$

Equation (2), Wien's formula, can also be written

$$J = C_1\lambda^{-5}e^{-C_2/(\lambda T)}$$

Taking the log of both sides of this equation,

$$\log J = \log_{10} C_1\lambda^{-5} - C_2/(\lambda T) \text{ or}$$
$$\log J = K_2 - K_3 T$$

where

$$K_3 = \frac{C_2 \log e}{\lambda}$$

and

$$K_2 = \log_{10} C_1\lambda^{-5} = \log_{10} K'$$

Wien's law now becomes

$$t = \frac{K_2}{K_3 - \log J} - 273 \qquad (4)$$

The application of equation (4) was taken up fully in my article in the July issue. The expression "log" will henceforth be taken to mean the "common log." To compare equation (4) with equation (3) we may rearrange (4) as follows:

$$t = \frac{K_2}{K_3 - \log K' + \log J} - 273$$

or

$$t = \frac{K_2}{\log (K'/J)} - 273 \qquad (5)$$

A comparison of equations (3) and (5) will show at once that when the 1 in Planck's formula, equation (3), is neglected the latter reduces to Wien's formula, equation (5).

Suppose we are using a Wanner pyrometer for determining high temperatures. To simplify the calculations we will assume convenient but plausible values of the various quantities in the above equations. In order to determine K' assume that $\varphi = 45$ deg. when $T = 1300$ deg., then $J = \tan^2 45 = 1$, *i. e.*,

at this particular angle the temperature of the standard source must equal the temperature of the body under consideration.

Substituting these values in equation (3)

$$1300 = 10{,}500 \div \log (K' + 1)$$

and

$$\log (K' + 1) = 10{,}500 \div 1300 = 8.1$$

therefore

$$K' + 1 = 126{,}000{,}000 = 126 \times 10^6.$$

Since the 1 can be neglected

$$K' = 126 \times 10^6$$

and

$$\log K' = 8.1 = K_1.$$

Finally

$$T = \frac{10{,}500}{\log [1 + (126 \times 10^6 / J)]} \qquad (6)$$

Again, as before, if we neglect the 1, equation (6) reduces to

$$T = \frac{10{,}500}{8.1 - \log J}$$

the familiar equation used in previous work.

Now when J is large, the 1 cannot be neglected, as will be shown. Let $J = 5 \times 10^6$, a rather large value, then

$$T = \frac{10{,}500}{\log (25.2 + 1)}$$

But $\log (26.2) = 1.41830$

and $\log (25.2) = 1.40140$

Consequently these two values will give temperatures as follows:

$T_P = 10{,}500 \div 1.41830 = 7400$ (Planck's formula)

and

$T_W = 10{,}500 \div 1.40140 = 7500$ (Wien's formula).

The use of Wien's equation will, therefore, introduce an error of about 1.3 per cent at 7400 deg.

Taking J as 4×10^4 there results

$$T = \frac{10{,}500}{\log [1 + (126 \times 10^6) \div (4 \times 10^4)]}$$

In this case $\log (1 + 3150) = 3.49845$

and $\log (3150) = 3.49831$.

This difference will obviously not introduce any difference in the fourth place of the number representing the temperature.

$$T_P = \frac{10{,}500}{3.49845} = 3000$$

$$T_W = \frac{10{,}500}{3.49831} = 3000$$

Hence it is evident that for temperatures below 3000 deg. Wien's law is sufficiently accurate for all purposes.

If we consider a value of J even still larger than the above, say 100×10^6, the expression for the temperature becomes

$$T = \frac{10{,}500}{\log [1 + (126 \times 10^6) \div (100 \times 10^6)]}$$

Here $\log (2.26) = 0.35411$

and $\log (1.26) = 0.10037$.

Whence

$$T_P = 10{,}500 \div 0.35411 = 30{,}000$$

and

$$T_W = 10{,}500 \div 0.10037 = 100{,}000.$$

Now there are stars which have temperatures as high as 30,000 deg. and evidently erroneous results would obtain if their temperatures were estimated by the aid of Wien's law. However, for such extreme temperatures even Planck's equation may be only a gross approximation.

Experimental Methods of Determining High Temperatures.

In the previous discussions on the application of radiation laws to the determination of temperatures the methods considered were not complicated by the introduction of the usual devices utilized for the estimation of very high temperatures.

Most of the pyrometers now in use will not indicate temperatures accurately beyond 2000 deg. unless the incident energy is diminished by means of some sort of an absorption device, such as absorption mirrors, absorption glasses, sectored disks, polarizing prisms, etc.

The ratio of the intensity of the light incident on such a diminishing device to the intensity of the light transmitted is called the *absorption factor.*

The intensity of the incident light is always obtained, therefore, by multiplying the transmitted intensity by the absorption factor. This use of the term *absorption factor,* in the case of transparent bodies, is somewhat different from that considered in the case of radiating bodies.

Let J' = the luminous intensity of the incident radiation and J the value as indicated by the pyrometer when an absorbing device is used, then

$$J' = JR,$$

where R is the *absorption factor.*

If, furthermore, this transmitted light passes through another diminishing device, whose absorption factor is R_1, then the intensity of the incident light must be expressed by the formula

$$J' = JRR_1$$

and in general

$$J' = JRR_1R_2 \ldots \ldots$$

or if the absorption factors are equal, then

$$J' = JR^n.$$

Suppose, for example, that the absorption factor of a piece of smoked glass is 20, if two such glasses are used to cut down the intensity of a luminous source, then the intensity of the incident light is 400 times as great as the intensity of the transmitted light.

Equation (4) may now be written

$$t = \frac{K_2}{K_1 - \log JR} - 273$$

or

$$t = \frac{K_2}{K_1 - \log J - \log R} - 273 \qquad (7)$$

Equation (7) may be applied directly to any pyrometer of the Wanner or Le Chatelier type for the determination of high temperatures when the absorption factor, R, is known. In the case of pyrometers which can only be calibrated empirically, such as the Holborn, Kurlbaum, the temperature T^1 of the radiating body in question, in terms of the temperature, T, indicated by the instrument and the absorption factor, R, may be determined from the following equation:

$$K = \frac{\log R}{K_2 \left(\frac{1}{T} - \frac{1}{T'}\right)} \qquad (8)$$

Total radiation pyrometers, such as the Féry and Thwing, are seldom used for the determination of very high temperatures, but when they are, the intensity is cut down by means of a sectored disk, *i. e.,* the effective aperture is simply made smaller.

As the total energy of the spectrum is utilized in this type of pyrometer any absorption device, such as smoked glass, absorption mirrors or polarizing prisms, which is selective in its absorption could not be used.

If J' represents the total energy falling upon the pyrometer and J the quantity indicated by the pyrometer when a sector disk is used, then

$$\frac{J'}{J} = R$$

where R is the absorption factor of the disk.

From the fourth power law

$$J' = KT'^4$$

and

$$J = KT^4$$

whence

$$J'/J = R = (T'/T)^4 \qquad (9)$$

By means of equation (9) the scale of any total radiation pyrometer may be extended when the absorption factor R of the disk is known.

The ratio of the intensity of the incident radiation to the

intensity of the transmitted radiation, in the case of the sectored disk, is obviously the same for all wave-lengths.

Absorption glasses, however, are usually selective in their absorption, *i. e.*, they absorb one part of the spectrum more than another, consequently the absorption factor of an absorption glass may be different for different wave-lengths.

Now, in any case where the light used by the pyrometer is strictly monochromatic, as is the case with the Wanner or Scimatco, an absorption glass will produce just as accurate results as any other diminishing device and it is considerably more convenient.

With the Le Chatelier, H-K and the Morse pyrometers, however, the case is quite different, for here the light is rendered monochromatic by means of colored glasses and these are never strictly monochromatic. The color transmitted by these so-called "red transmission glasses" will depend considerably upon the spectral distribution of the transmitting source, which in turn varies with the temperature.

If the wave-length of such a transmission glass is determined at two different temperatures of the radiating source, a decided difference will obtain. Consequently if the absorption factor R, of an absorption glass which is strongly selective, is determined for one temperature, the same factor cannot be used for any other temperature without introducing an error. Therefore Wien's law cannot be used directly for the extrapolation of the scale of such an instrument without making corrections for the lack of monochromatism and selective absorption. It is seen from equation (8) that the determination of T′ involves R and also the wave-length λ, for the latter is included in K_2.

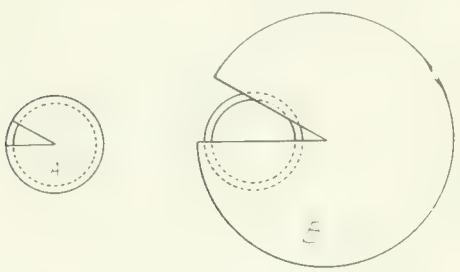


FIG. 1.—SECTOR DISKS.

Two types of sectored disks are shown in Fig. 1. A is a simple diaphragm provided with a sectored opening of definite angle, placed in front of the objective of the pyrometer. This is the sort of disk used on the Féry instrument.

B is similar to A, except that it is rotated by means of a small motor; moreover, the axis of rotation does not coincide with the axis of the instrument as in the first case. It is preferable to use the second type of disk in the case of the H-K pyrometer, since it will produce no distortion of the image which is essential in this type of instrument. Since the Féry instrument, when once focused on an object, functions independently, this fact is not so important, hence it is sufficiently accurate to use the more convenient stationary disk.

The absorption factor in either case is

$$R = \frac{360}{\phi}$$

where ϕ is the angle of the opening measured in degrees.

The absorption factor of an absorption glass, *i. e.*, of a so-called "smoked glass" is generally determined by means of a spectrophotometer. A spectrophotometer is simply a photometer which compares light intensities for a single color or wave-length. The absorption factor may also be determined by any pyrometer in which the intensity can be varied in a continuous and determinate manner as in the Wanner, Scimatco or Le Chatelier.

If a Wanner pyrometer is directed toward any constant source of illumination and a reading made without and with an absorption glass before the slit of the pyrometer, the absorption factor R may be calculated from the formula

$$R = \frac{\tan^2 \phi'}{\tan^2 \phi}$$

ϕ is the angle through which the nicol is turned in order to obtain a photometric balance, when an absorption glass is used, and ϕ' is the corresponding angle obtained for a balance without an absorption glass.

If a Le Chatelier is used R then becomes

$$R = (s/s')^2$$

where s is the reading of the iris diaphragm with a glass before the objective and s' is the corresponding reading obtained without a glass.

The method of extending the scale of a pyrometer will now be illustrated by concrete examples of particular instruments.

High Temperature Scale of Le Chatelier Pyrometer

For a particular Le Chatelier instrument the pyrometer equation becomes

$$t = \frac{9700}{4.82 - 2.80 \log (1 + n)} - 273 \qquad (10)$$

See equation (3) of my article in the July issue. This equation can be modified by means of equation (7) to include the absorption factor. For low temperatures this instrument sometimes requires one or more absorption glasses before the comparison lamp, in which case log R is negative. Suppose that we use n absorption glasses, then equation (10) may be written

$$t = \frac{9700}{4.82 - 2.80 \log (1 + n) - n \log R} - 273 \qquad (11)$$

With this pyrometer directed toward a uniformly illuminated area of a frosted-globe incandescent lamp the reading s of the iris diaphragm was found to be 17.93 when one absorption glass was placed before the objective and 4.90 without any glass.

Hence

$$\log R = 1.26 - 1.7403 + 4.9003 = 1.13$$

For $s = 20$ and $n = 0$.

$$t = \frac{9700}{4.82 - 2.80 \log 1.20} - 273 = 1033.$$

For one glass before the objective: $s = 25$, $n = 1$, $\log R = 1.13$,

$$t = \frac{9700}{4.82 + 2.80 - 1.13} - 273 = 1222.$$

For two glasses before the objective: $n = 2$,

$$t = \frac{9700}{4.82 - 2.80 \log 2 + 1.13} - 273 = 1520.$$

For one glass before the comparison lamp (n in this case is negative),

$$t = \frac{9700}{4.82 - 2.80 \log 0.74 - 1.13} - 273 = 285.$$

In a similar manner a number of values of t were calculated and Table I constructed.

TABLE I.

Temperature in degrees Centigrade.

s	No glass	One glass (+)	One glass (—)
25	1000	1222	835
20	1033	1270	861
15	1080	1332	895
6	1247	1575	1020
4	1337	1712	1082
2	1513	1980	1210

High Temperature Scale of Wanner Pyrometer

For a particular absorption glass used on this instrument the reading of the analyzer was 17.47 deg., when the pyrometer was directed toward a luminous source of constant intensity. When the absorption glass was removed the analyzer had to be turned through an angle of 49.05 deg. in order to produce a photometric balance.

Therefore,

$$\log R = \log \frac{\tan^2 \phi'}{\tan^2 \phi} = \log \frac{\tan^2 49.05}{\tan^2 17.47}$$

$$= 1.123.$$

By means of equation (7) Table II was constructed.

TABLE II.

	Temperature in degrees Centigrade.			
ϕ	No glass	One glass	Two glasses	Three glasses
10	910	1097	1358	1743
12	938	1127	1402	1810
..	....	....	....	....
..	....	....	....	....
..	....	....	....	....
..	....	....	....	....
78	1547	2053	2892	4752
80	1605	2148	3105	5314

In this case 45 deg. corresponds to a temperature of 1180 deg. C.

High Temperature Scale of H-K Pyrometer

This pyrometer must be calibrated empirically, since the intensity cannot be expressed by means of an equation. Its scale must, therefore, be extended by means of equation (8).

The wave-length of the red glass used before the eye-piece was determined by means of a Koenig spectrophotometer and found to be 0.650μ. For this wave-length the absorption factor was determined by means of the same instrument. $\text{Log}\, R = 1.597$. Hence K of equation (8) becomes

$$K = (\log R) \div K_2 = (1.597 \times 0.050) \div (14{,}500 \times 0.4343)$$
$$= 0.000166.$$

By means of the factor K the values of t' in Table III were determined. For example, suppose we have a calibration for the pyrometer, then we may assume various values of temperature from this calibration and calculate the corresponding temperature that will give the same intensity when an absorption glass is used.

From equation (8)

$$1/T' = (1/T) - 0.000166.$$

For 800 deg. C. or 1073 deg. absolute.

$$1/T' = (1/1073) - 0.000166.$$

Whence $T' = 1305$.

Therefore $t' = T' - 273 = 1032$.

TABLE III.

t deg. C.	T deg. abs.	T' deg. abs.	t' deg. C.
800	1073	1305	1032
1000	1273	1615	1342
1200	1473	1948	1675
1400	1673	2315	2042
1600	1873	2715	2442

A curve may now be plotted with the new values of temperature, column 4, and the current values corresponding to the old temperatures in column 1 (Table III).

This pyrometer has been greatly improved by Mendenhall for precision work. In its modified form the red transmission glass is replaced by a spectroscope eye-piece which renders the light used strictly monochromatic. The intensity is cut down by a rotating sector disk actuated by a small motor attached to the frame of the instrument.

The Electric Smelting of Zinc Ore[1]

By Walter Renton Ingalls.

The electric smelting of zinc ore during recent years has engaged much attention. It is not a new idea. The Cowles brothers tried it in 1885, which was the first attempt (so far as I am aware), and since then numerous experimenters have undertaken it. It is not my intention in this paper to trace their work, or go further into the history of the subject. It is sufficient for my present purpose to mention that C. P. G. De Laval[2] was the first to erect an electric zinc-smelting furnace on a commercial scale, this having been done in Scandinavia in 1901. Works were later erected at Sarpsborg, in Norway, and at Trollhättan, in Sweden. I do not know precisely the dates of their erection, but they were in operation as early as 1905. It was attempted at first to smelt ore, but for a long time this was not commercially successful, the product being chiefly zinc powder, which had to be subjected to resmelting, giving an impure spelter, which had to be refined. The works were continued in operation in a more or less irregular way and spelter from them came on the market, but this was the product of smelting dross, scrap and other secondary products rather than ore. Some progress in ore smelting was made, however, and during 1911 a considerable quantity of ore was smelted by a method to which I shall refer subsequently.

There is much misconception respecting both the ordinary art of zinc smelting, and the possibilities of electric smelting. In the first place, the ordinary art of zinc smelting is not extraordinarily backward, in spite of the small retorts to which we are limited; and although we are attracted by the possibility of conducting the distillation in a relatively large apparatus, electrically heated, I am not yet by any means prepared to say that electric smelting will offer any advantage over existing methods, even if the difficulties that are now in view can be overcome. In the second place, electric smelting is not to be expected to accomplish the establishment of any radically new metallurgical principle. If there be any dreams of an electric furnace analogous to the blast furnace, in which run-of-mine ore may be charged roughly and from which spelter, lead and perhaps also copper matte, may be obtained concurrently, I fear that there will be no realization of them.

Carbon Reduction and Iron Decomposition.

Whatever be done in electric smelting is generally expected to be based on the reduction of zinc oxide (or its compounds) by carbon (and carbon monoxide); but the decomposition of zinc sulphide by iron has also been contemplated. The former is the basis of ordinary practice. The latter has been exploited in the electric smelting of Coté-Pierron[3] and of Imbert-Thomson-Fitzgerald.[4] While the decomposition of zinc sulphide by iron has not found application in ordinary furnace work, it has been repeatedly suggested. Indeed, the Imbert process was originally such a suggestion, the use of an electric furnace for its execution being an afterthought.

The Coté & Pierron process was tried experimentally at Lyon, France, in 1906, and in 1907 at Arudy, in the Basses-Pyrenees, and was ephemerally the subject of many articles in the technical press, but lately it has not been mentioned, and I am inclined to think that the results were not satisfactory.

The Imbert-Thomson-Fitzgerald furnace has been in trial at Hohenlohehütte, Upper Silesia, during the last two years. No authoritative reports of the results recently obtained there have been made public. The imperfect news that seeps through professional and commercial channels is conflicting.

I shall not in this paper discuss either the Coté-Pierron or the Imbert-Thomson-Fitzgerald proposals, but shall confine myself to a consideration of the reduction of zinc oxide by carbon. In this discussion I shall draw upon general metallurgical experience, upon the information obtained in experimental electric zinc-smelting at McGill University, and upon the authentic reports of work that has been done elsewhere.

The reduction of zinc oxide is an endothermic process, i. e., heat must be supplied to it. This may be done either by the external heating of the retort containing the charge by the combustion of coal, or by internal heating by means of the electric current. The theoretical advantage of the latter rests in the possibility of developing the heat in the midst of the charge, i.e., in the heart of the place where the work is to be

done, a condition that does not exist in ordinary external heating.

The electric furnace may be of two types, namely, the arc furnace and the resistance furnace. To draw a familiar analogy, the arc furnace is exemplified by the ordinary arc lamp used for illumination; the resistance furnace by the ordinary incandescent lamp. Another type of furnace, namely, the induction furnace, will not here be taken into consideration.[5]

Types of Furnaces.

The original De Laval furnace was a simple arc furnace, in which the heat of an electric arc, formed between electrodes projecting horizontally into the furnace, acted upon the charge of ore lying under it. Among the various types of resistance furnace we may have that in which the current passes through a resistor of carbon (as in the Imbert-Thomson-Fitzgerald), or that in which the electrodes dip into the charge to be smelted, or into a bath of slag which serves as the resistor. It will be unnecessary for the present consideration to go any further into the subject of the types and design of furnaces. It is the fundamental metallurgical principles upon which it is still most important to center attention. In the present status of the art of electric zinc-ore smelting, the functions of the electrician are subordinate to those of the metallurgist.

In the earliest attempts to smelt zinc ore electrically, the conception was of an apparatus similar to an ordinary retort, but electrically heated. In some of our early experiments at McGill University, we used furnaces of analogous character. The rate of reduction in these furnaces was about on a parity with the rate in the ordinary retort, temperatures being equal, which was, of course, what was to be expected.

These experiments, made primarily for another purpose, confirmed the idea that if electric smelting were to offer any advantage, it must be conducted continuously. Here is introduced a departure from the conditions of ordinary smelting, which is an intermittent operation, conducted in two stages, the first comprising the expulsion of aqueous vapor, and the decomposition of hydro-carbons and carbonates; and the second being that of the reduction of the metallic oxides.

If zinc smelting is to be done continuously, it seems that the operation must be confined to the second stage, which implies that the things that ordinarily happen in the first stage must be caused to take place by a previous pre-heating. With such a preheating the actions in the furnace become essentially the same, save for certain important differences.

Differences from Ordinary Practice.

One of these differences pertains to the carbonaceous reduction material that is mixed with the ore. It has been shown by Boudouard that the permissible limit of carbon dioxide in the gas of the zinc retort is very low; varying with the temperature, but still very low at the very high temperature of 1500 deg. C., a temperature that is not attained in practice. When the permissible limit is exceeded, carbon dioxide acts oxidizingly upon the zinc, and coating the condensing globules of the latter prevents coalescence and forms powder.

The gas issuing from the zinc retort of practice is within the permissible limit of carbon dioxide, or nearly within it, and the zinc is condensed chiefly as molten metal. Conversely, all attempts to smelt zinc ore in the blast furnace have resulted only in the production of powder because of inability to control the percentage of carbon dioxide. Small quantities of molten zinc have been occasionally found in the blast furnace, undoubtedly due to the accidental occurrence of favorable conditions.

The uniformly favorable conditions of the ordinary zinc retort are due to its small size, its confined character, and the presence of an immense excess of carbon in the charge. Carbon dioxide, resulting from the reduction of zinc oxide, and from other reactions, is immediately exposed to the great surplus of finely divided, intimately admixed, incandescent carbon, and is reduced by it to monoxide.

Continuous charging implies discharging of the residue without interrupting the smelting operation. This in turn implies the discharging of the residue as a slag that will run. Both conditions imply the absence of any great excess of carbon, which cannot be slagged and cannot be permitted to accumulate in the furnace. In this important particular, the internally heated, continuously operated retort or furnace differs essentially from the externally heated, intermittently operated retort.

Carbon Dioxide.

In our experimental work at McGill University, we have commonly found high percentages of carbon dioxide in the gases from the furnace, much higher than exist in the gases from the ordinary retort. Besides this difference we have observed the presence of considerable quantities of carbon and ore-dust in the condensers, indicating another variation from the conditions of the ordinary retort. In the continuous feeding of the charge into the electric furnace, there is naturally stirred up some dust which may be, and probably is, carried out into the condenser by the relatively strong outrush of gas and vapor; the latter may indeed entrain some dust from the surface of the charge in the furnace. There may be some other physical disturbances.

The effect of the carbon dioxide in the gas has been recognized by Coté & Pierron, by Johnson,[6] and by other investigators who have caused the gas and vapor from the retort to pass through a column of incandescent carbon, the purpose of which is to act as a secondary reducer. This is believed to be, at least, ameliorative.

Except for the metallurgical differences that have been previously pointed out herein, the reactions and condition in the internally heated retort are essentially the same, providing that the charge introduced into the former be preheated to a degree corrsponding to the preheating that takes place in the first stage of the intermittent process. The gradually introduced charge, with its interstitial air, should not involve any new conditions, except those previously noted, inasmuch as the gas inside of the furnaces displaces the interstitial air before the charge enters into the smelting chamber. The reduction of lead and iron, developing carbon dioxide, and the multiplicity of complex side-reactions, take place in one kind of retort as well as in the other.

There is no positive evidence that the electric current passing through a furnace plays any metallurgical part other than thermic. Harbord reports no observed difference between the actions of the arc furnaces at Sarpsborg and the resistance furnaces at Trollhättan, except in the efficiency of the energy supplied.

At McGill University we observed arcking in the furnace when a resistor of fragments of carbon was used; and this arcking was followed by disturbance in the furnace that we have been unable to explain; but there was no such occurrence in a furnace with a continuous resistor or carbon, in which furnace the reduction of zinc oxide appeared to take place regularly and normally. This particular furnace was provided with a peep hole (closed by mica), through which the process of distillation could be observed. The resistor was vertical in position, the charge surrounding it. The distillation proceeded most actively around the resistor, the heating element, the charge coning down toward this as the zinc was expelled, and the interior of the furnace maintaining an even incandescence.

Speed of Reduction.

Our attmpts at McGill University to reduce zinc oxide in an intermittently charged, electrically heated retort, resulted in

[5] An induction furnace has been proposed by G. Gin, but it has not been tried, so far as I am aware. [For description of this furnace see this journal, Vol. VI, 75 (1908).—Ed.]

[6] See this journal, Vol. VIII, 688 (1910), IX, 264 (1911), X, 281 (1912).—Ed.

so slow a reduction that the prospect of advantage seemed to be insignificant. I refer to a retort in which the charge was introduced in the usual manner at the beginning of the operation, the residue to be discharged as an unfused ash. There was, of course, a possibility of converting this from an intermittent to a continuous operation, but, as I have already stated, the slowness of the reduction under these conditions dispelled any such idea.

When we changed to the scheme of starting the furnace with a bath of slag, continuously introducing the charge upon this bath, we found immediately that the reduction became relatively rapid. I am unable to offer an adequate explanation of the improvement in this respect. I can but state that a retort of small proportions smelts a surprisingly large quantity of charge by comparison with the retort of ordinary practice at an equivalent temperature.

With a furnace with a plumbago crucible 12 in. in diameter, we have been able to smelt 10 lb. per hour. With a furnace 18 x 18 in. in horizontal section we smelted 737 lb. in 23 hours. We have learned consequently that the claims of extraordinary capacity of electric zinc smelting furnaces of comparatively small size are well founded.

Bearing in mind the main difference between the conditions of ordinary and electric zinc smelting, we may pass on to a consideration of similarities. There is no reason to believe that the reduction of the metallic oxides, the reactions between metals, oxides, sulphides and sulphates, the scorification of oxides, and, in short, the multiplicity of complex reactions that we believe to take place in the externally heated retort, will be any different in the internally heated, the nature of the charge and the temperature remaining the same.

The Matter of Temperature

With respect to the matter of temperature, that of the electric furnace may be anything that it is pleased to make it, within the limitations of the material whereof the furnace may be constructed. In the ordinary practice of zinc smelting, the tendency in Europe during recent years has been to drive the furnace harder and harder.

A furnace temperature of 1400 deg. C. was once thought to be high, but now 1500 deg. C. and upward is reported. Such high temperatures imply, of course, the necessity for much more substantial furnace construction and a high class of refractory material. Of course, the average life of the retorts is reduced.

The actual smelting temperature, i.e., the temperature inside of the retorts, is about 100 to 200 deg. less than the furnace temperature. In this particular the electric furnace has the advantage that the full temperature of the furnace is ralized in just the place where the smelting is to be done.

The amount of zinc remaining in the residuum, whether the latter be an ash (loose or clinkered) or a slag, depends primarily upon the temperature of the smelting and the fluxing of the ore. Conditions favorable to low zinc retention are high temperature and highly calcareous slag. It is possible to discharge from the electric furnace a slag containing less than 1% of zinc. We have made such slags at McGill University and other experimenters also have done so.

The ability to do that does not, however, imply either commercial feasibility or advisability. It may be impossible to maintain a furnace in continuous operation under the conditions necessitated by the production of such a slag. This matter has not yet been worked out. The slag made at Trollhättan, during Mr. Harbord's test, was high in zinc.

We do not as yet know much respecting the shape that the smelting chamber of an electric furnace will naturally assume, the formation of refractory accretions on the walls, the deposition of sows of metallic iron (that doubtless will be produced in the same way as in the ordinary retort), and the difficulties that are likely to occur in continuous operation from these things.

Smelting at Trollhättan.

The operations at Trollhättan and at Sarpsborg were the subject of a report by F. W. Harbord, in 1911, which is the only recent source of technical information respecting them. Mr. Harbord's report was made privately for commercial purposes and did not go fully into the metallurgy of his subject. Mr. Harbord conducted a test at Trollhättan, during which 537 metric tons of ore were smelted, the test extending through 27½ days. This is the longest continuous run on a large scale that has been reported.

The ore was essentially a zinc lead ore, rather than a zinc ore, and was high in silver, containing 36% zinc, 24% lead and 30 oz. silver per ton. In making deductions from the experience in smelting this ore, we must hesitate in applying them too freely to the cases of what are more distinctly zinc ores. Mr. Harbord extracted 64% of zinc, 74% of lead and 46% of the silver as metals, which percentages would be slightly increased by further treatment of certain incidental products, but even so the metal recovery would still be relatively low. A summary of Mr. Harboard's report is to be found in the *Engineering and Mining Journal* of February 10, 1912.[1]

Briefly, the furnaces were of the resistance type, having one large vertical electrode passing through the roof, the other electrode being a carbon block bedded in the bottom of the furnace. Each furnace smelted about 2800 kg. of ore per 24 hours. The product was partly metal and partly blue powder and oxide, containing about 54% of zinc and 20% of lead.

This powder is mixed with fresh ore and recharged, when a larger percentage of the metal volatilized is recovered as metal. The first operation of smelting ore alone is to be regarded mainly as a concentrating process for the production of a rich oxide.

The regular charge was 100 kg. of roasted ore, 200 kg. of powder, 25 kg. of coke dust and 5 kg. of lime. Thus for every ton of ore smelted, two tons of powder had to be resmelted; indeed rather more than that, there having been an accumulation of powder during the run.

Recovery of Lead.

In the ordinary retort the lead content of the ore is reduced and is partly volatilized, condensing with the zinc, which it contamintes; and partly remains as metal in the residuum, from which it is recovered by smelting the latter, or by jigging and smelting the concentrate. The percentage of lead volatilized increases with the temperature. In the electric furnace lead behaves in the same way, but in fusing the residuum into a slag the lead is given an opportunity to separate and thus may be tapped separately, which in so far is an advantage. On the other hand, the desirability or necessity of smelting at a high temperature leads to the collection of a leady spelter, which must undergo a subsequent refining, and the experience at Trollhättan has indicated difficulties in the furnace construction because of the lead.

I am not greatly attracted by the possibility of smelting for lead and zinc in a single operation, much less by aiming also to make a matte (although that may be inevitable), which adds to the difficulties, nor do I see any good reason to head in that direction. In most kinds of mixed sulphide ores the galena is easily separated to a fair degree by gravity concentration, and no loss need be experienced in such a separation, inasmuch as the galena and the blende-pyrites may be easily collected in filter bins. It should be the policy first to subject the ore to this cheap process, very likely cutting out a portion of the gangue sufficiently clean to be discarded, and pass the galena on to ordinary lead smelting, also a relatively cheap process, rather than to deliver all of the ore to the zinc-smelting process, which must inevitably be relatively dear, whether it be the ordinary one or the electrothermic.

There will be, of course, from such a treatment a percentage

[1] Also in this journal, Vol. IX, 673 (1911).—Ed.

of lead in the blende-pyrites, and being there it will be desirable to extract it, but it is troublesome both in the roasting and in the smelting, and I conceive that the electric smelter, like the ordinary smelter, will rather have a zinc ore without lead than with it, unless it can be obtained on terms that compensate for the disadvantages. It may be accepted, however, that the electric furnace will probably obtain a higher extraction of the lead and at less cost than is possible in the ordinary method of smelting, and there are some ores wherein the galena and blende are so intimately mixed that mechanical separation is impossible, which may be treated more advantageously in the electric furnace than in any other way. I do not by any means regard this as a step in metallurgy that has yet been accomplished, but it is a possibility. The work at Trollhättan has been in this direction.

Condensation.

It has been assumed by some investigators that the difficulty of condensing the vapor resulting from the reduction of zinc oxide, lies chiefly in the condensing apparatus. It may be taken for granted that the condenser connected with an electric zinc-smelting furnace, required to deal with a relatively large quantity of vapor and operating under some conditions different from those existing in connection with the ordinary furnace, must be of dimensions and design conforming to the new conditions.[1]

It has been found possible to condense the zinc satisfactorily as spelter from the electric furnace treating zinc powder and galvanizers' dross. This had been done at Trollhättan, where, in the refining of crude zinc, but 9.8 per cent of powder has been collected. In refining 111,794 kg. of leady spelter, Mr. Harbord obtained only 11,209 kg. of powder. Charles A Weeks reported, in *Metallurgical and Chemical Engineering* of July, 1911, that in the refining of zinc dross in an electric arc furnace, during a run of 36 hours, no powder was made. In a private communication, Mr. Weeks informed me that this furnace was built and operated in the works of the General Electric Company at Schenectady, N. Y.

Accepting the foregoing evidence, the reason for the production of blue powder is to be sought not in the condenser proper, but in the character of the gas and vapor delivered to the condenser; in other words, to the conditions that exist and the reactions that take place inside of the furnace itself. It has been found that when metallic zinc is simply distilled, there is no great difficulty in condensing the vapor in a liquid form, but when the vapor originates from the reduction of zinc oxide, there is difficulty.

Nearly all experimenters in ore smelting by the reduction of zinc oxide by carbon have been baffled in the attempt to condense a commercial proportion of the zinc as molten metal. We have encountered this difficulty in our experimental work at McGill University, and have not yet been able to master it. The reason why zinc vapor from the electric furnace should condense in this way has not yet been satisfactorily explained. It may pertain to the differences between the conditions of ordinary smelting and electric smelting that I have already mentioned; it may pertain also to other conditions. I shall not advance hypotheses respecting this; I shall limit myself to the mere statement of the fact.

Blue Powder.

At the present time the matter of reducing and distilling the zinc and condensing the latter chiefly as spelter and blue powder, is the crucial point of electric zinc-ore smelting. Until that has been accomplished, I can see no future for the process, except under special conditions of extraordinarily cheap power, peculiar kinds of ores, etc.

[1] The condenser of the electric furnace receives no radiant heat from the front of the furnace nor from the glowing charge in the retort. On the other hand, the condensation of a large amount of zinc vapor liberates a relatively large amount of latent heat. The balance between these conditions has by no means been worked out. We find some experimenters having artificially to cool the condenser and others to heat it.

On the basis of ore alone, the consumption of power at Trollhättan was 2078 kw.-hr. per 100 kg. of ore, but for every ton of ore smelted about two tons of powder had to be resmelted. The smelting of 1000 kg. of ordinary zinc ore is reckoned to require from 900 to 1000 calories of heat, which is equivalent to 1047 to 1163 kw-hr. of electric energy, these figures representing the cases of ordinary ores containing 25 to 50 per cent zinc. In one run at McGill University, lasting 24 hours, with a resistance furnace, 18 x 18 in., Dr. Stansfield determined the power consumption per 2000 lb. of ore smelted as 1610 kw.-hr. (about 1771 per 1000 kg.).

It has been claimed that it is possible to smelt 2000 lb. of zinc ore with 1000 kw.-hr. While it is doubtful whether such a result has yet been actually realized by anyone, the claim is plausible with respect to certain kinds of ore, although even then it is necessary to assume a high furnace efficiency. It would seem that 1200 kw.-hr. per 2000 lb. of ore would be sufficiently brilliant realization. Even such a one would put electric smelting upon a sound basis in so far as power consumption is concerned.

Cost of Smelting.

The art of electric zinc smelting is still too much in its infancy to permit of much more than speculation respecting the probable cost. The only data of operation on a large scale continued for a considerable period of time that are available are those of Trollhättan, where electric power, labor, etc., are obtained very cheaply. If the Trollhättan figures be applied to the conditions of power at $20 per horsepower per annum, labor at $3 per eight hours, and other elements in proportion, electric zinc smelting on the basis of the metallurgic results obtained, there would be out of the question. If it becomes possible to smelt with 1200 kw.-hr. per ton of ore, to reduce materially the labor and electrode costs, and to extract 90 per cent of the metals, there will be some chance.

As to the probable cost of plant we are still greatly in the dark. It is hardly to be expected that the electric plant will be of any less cost than the coal-fired. Comparing operating costs, there will be the same expense for administration, general charges, yard labor and roasting in each case. Heating coal will stand against electric current, say 1 to 1.5 tons against 1200 kw.-hr. The relative consumption of reduction coal is uncertain. The retorts of ordinary practice will be dispensed with, but instead of them the electric smelter will have an electrode expense. The relative cost of repairs and renewals and miscellaneous supplies is uncertain; also the matter of labor.

At first thought it seems that the labor on a furnace smelting 6200 lb. of ore per day ought to be less than in connection with 80 Rhenish retorts or 150 Belgians, but the experience at Trollhättan does not yet confirm that idea, though, no doubt, improvement will be realized in this particular.

Limitations.

In the report of the Commission to Investigate the Zinc Resources of British Columbia, published in 1906, I made the following remarks:

> The successful smelting of zinc ore in the electric furnace is a matter which depends chiefly, indeed I may say solely, upon the cost of the process. De Laval has shown that it can be done. The doing of it profitably is quite another question. This is dependent chiefly upon the cost of power, the electrical efficiency of the furnace, and finally upon the purely metallurgical difficulties that pertain to the reduction of zinc oxide and the condensation of the metallic vapor.
>
> From the present development of electrothermic smelting of zinc ore, and the calculations respecting it, the following conclusions may be drawn:
>
> 1. Electric smelting will never displace ordinary smelting, if it be necessary to generate the power from coal.
> 2. Electric smelting may be, in the future, economically conducted at places where very cheap hydro-electric power is available.
> 3. Aside from the question of power, up to the present time certain peculiar and serious metallurgical difficulties in electric smelting have not been satisfactorily overcome.

During the six years that have elapsed since those words were written, much has been learned respcting their subject, but as generalizations they remain as true to-day as they were then.

The successful achievement of smelting zinc ore in an electric furnace will probably be the result of learning how to run the furnace; i.e., how to control the process, rather than of any distinct invention. I conceive that the electric zinc-ore smelting furnace will be an apparatus of general character, such as a blast-smelting furnace for lead ore, etc. This is to say: Lead ore may be successfully smelted in many forms of furnaces of the same generic character, but with variations in their lines that are of important economic effect. Once it has been learned how to run an electric furnace for zinc smelting, I believe it will be found that the process can be conducted in many forms of furnaces conforming to the general type, wherein the principle will be the same although the economic results may differ widely.

Electrical Resistances of Powdered Conductors—Variation with Temperature

By A. A. Somerville.

Contact resistance is a source of trouble in making electrical measurements. If two materials are fastened together the surfaces must be clean and sufficient pressure applied to render the contact resistance at the joint a negligible quantity.

A study of this phenomenon was thought desirable and carbon and silicon were chosen as favorable materials to investigate.

In order to make the contact resistance as prominent as possible the materials were finely powdered so as to make a large number of contacts.

The powder was of such a fineness that it would pass through a screen having forty meshes per inch. A porcelain tube was

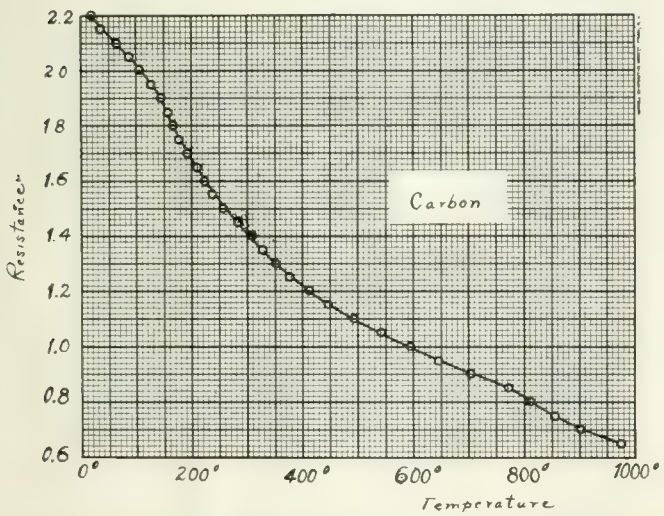

FIG. 1.—CHANGE OF ELECTRIC RESISTANCE OF POWDERED CARBON WITH TEMPERATURE.

filled with this powdered material and metal rods inserted into either end of the tube. The rods served as electrical leads or terminals and considerable pressure could be put upon the powdered carbon or silicon by transmitting the force through the metal rods.

It was found that there was practically no change in resistance after a pressure of about 850 pounds per square inch was reached. The resistance had decreased quite rapidly as pressure had been incresed up to that value. This part of the work has been described in the *Electrical World* of May, 1912.

Since then the work of measuring the variation of electrical resistance with temperature has been done.

The powdered material was placed in the porcelain tube as usual with the metal rods inserted in either end of the tube and the whole inserted into a tubular electrical resistance furnace. A pressure of about 3 lb. was put upon the rods and this pressure was held constant while the temperature of the furnace was varied from 20 deg. to 1000 or 1100 deg. C. The temperature was measured with a platinum resistance thermometer which lay alongside the specimen of carbon or silicon and the varying temperature indicated by an automatic temperature recorder to which the thermometer was connected.

Resistance of the specimen was measured on a dial bridge. Resistance of the lead wires was negligible. The length of the powdered specimen in the tube was 5 cm; cross section was 1 sq. cm.

At room temperature the resistance of the powdered carbon was 2.2 ohms; resistance of the silicon, 600,000 ohms. This is

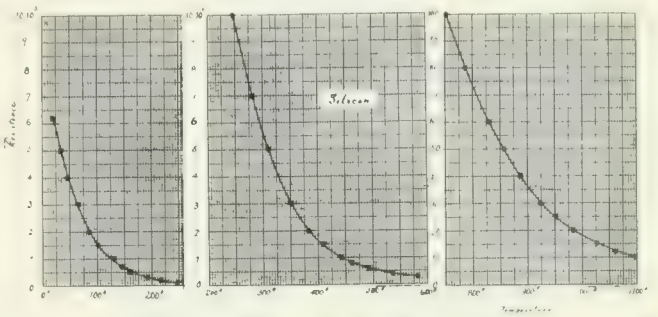

FIG. 2.—CHANGE OF ELECTRIC RESISTANCE OF POWDERED SILICON WITH TEMPERATURE.

approximately fifty times as much as the resistance of a solid piece of carbon of similar dimensions and 25,000 times as great as that of a similar piece of solid silicon.

The resistance of the carbon decreases until it is about .6 of an ohm at 1000 deg. C. The slope of the curve is exactly the same as that for a solid piece of carbon but the rate of change is more than twice as great when pulverized than when solid.

In the case of the silicon the decrease in resistance is much more rapid. In order to show the variation to advantage it is necessary to plot the different parts of the curve to different scales. The variation in resistance of a solid piece of silicon is unique being first negative then changing to a positive value and later to negative again, but the whole variation is always less than 50 per cent of the value at any time.

Recent Metallurgical and Chemical Patents.

Iron and Steel.

Open-Hearth Refining.—Heating with coal dust has been practised in open-hearth refining, but according to the claims of Gaston Barbanson and Max Lepersonne, of Brussels, Belgium, the methods in use have not profited by all the advantages of this mode of heating. The method of using highly heated air for the injection and combustion of the coal dust has resulted in partly gasifying the dust before ignition of the flame, thus giving gas-heating with so large a flame that it could not be concentrated on selected portions of the bath of metal. When working with cold air combustion chambers are necessary, and the heat being generated in a comparatively large space cannot be concentrated as desired. For these reasons the electric furnace has proved the most practical means of applying heat in a concentrated form for steel refining.

In order to utilize coal dust for the generation of heat, which can be applied as desired and in a manner approximating the same results to be obtained in the electric furnace, Barbanson and Lepersonne have invented means of injecting coal dust in a manner which overcomes the objections first mentioned. The nozzle through which the air and coal dust are injected is situated as short a distance from the bath as is feasible, the distance being a function of the mean length of the flame obtained, which may advantageously be about 40 in. The air used is not

highly heated, but only slightly preheated, in order to avoid the gasifying of the fuel as noted above. To obtain the highest possible temperature the two substances are injected in correct proportions for complete combustion, although for special purposes either air or fuel may be in excess. The flame impinges

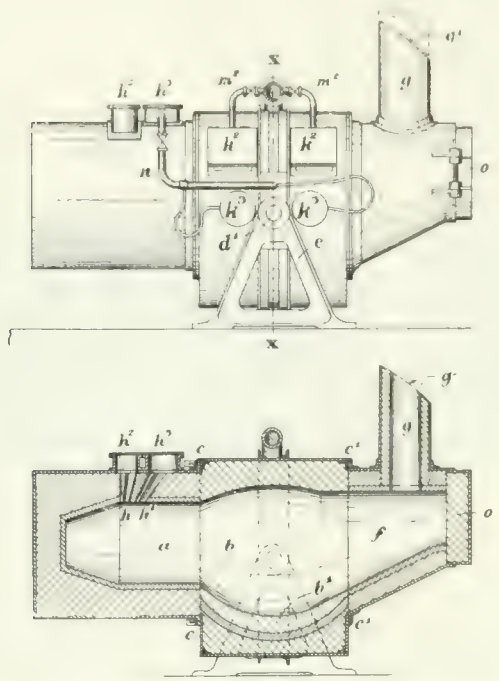

FIG. 1.—COMBINATION OF CONVERTER AND REVERBERATORY.

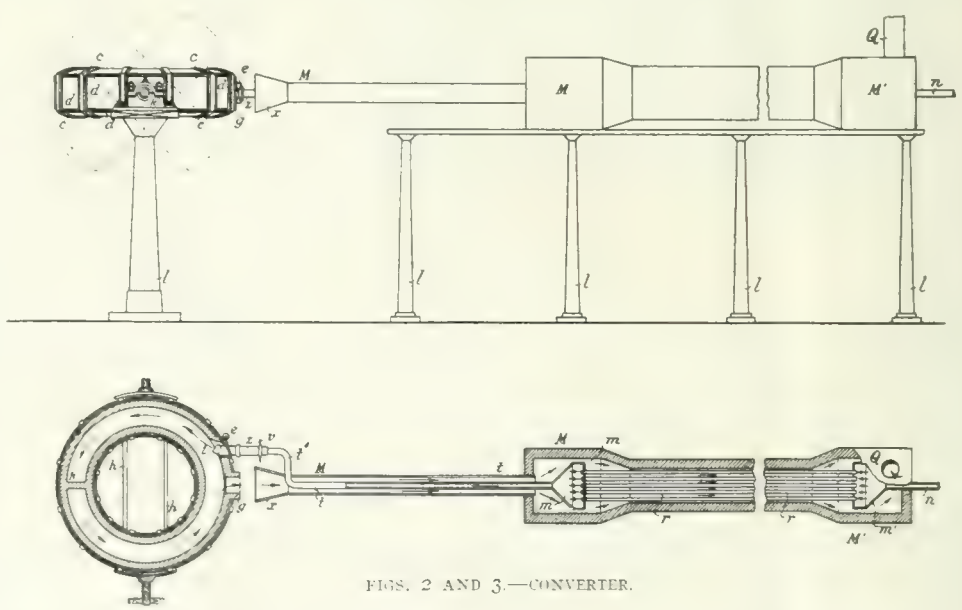
upon the bath so that the heat of combustion will act directly upon the latter. By this arrangement the inventors believe that more economical results will ensue than can be obtained from electric refining, and that the metallurgical results will be equally as good. (1,030,152, June 18, 1912.)

Manufacture of Steel.—Special apparatus designed to insure the production of castings free from blow holes, has been patented by T. D. MACKIE and G. F. FORWOOD, of Limpsfield, England. In the production of steel by the Bessemer process there is tendency for some of the iron to become oxidized, with the result that blow holes occur in finished castings. According to the present invention, the oxidized metal and slag from the converter are transferred to the hearth of a reverberatory furnace, and, after the removal of the slag, the metal is subjected to the action of a reducing gas, with the result that it becomes deoxidized.

In Fig. 1 is shown the apparatus designed by the inventors, consisting of a combination converter *a* and reverberatory *b*. The two parts are suitably joined at the line *cc*, and the whole apparatus is mounted on trunnions d^1, about which it may be rotated into either a vertical position for converting or a horizontal position for the second process of deoxidizing. Tuyeres for air and producer gas are located at *h* and h^1 respectively. The furnace is first heated while in the horizontal position, and then swung into a vertical position to receive a charge of metal. A blast of hot air is then introduced through the tuyere *h* or both *h* and h^1, and the blowing carried on until the percentage of silicon and manganese required in the finished product is approximately reached. The air blast is then shut off, and the converter swung into a horizontal position, bringing the metal onto the reverberatory hearth *b*. Air and producer gas are again admitted and adjusted to produce a long flame over the surface of the liquid. The charge on the hearth is now treated with oxide of iron as in an open hearth furnace, and after the slag has been thickened by the addition of suitable material, the furnace is tilted slightly to facilitate the removal of the slag. The furnace is again returned to the horizontal position, and the metal is exposed to the action of a hydrogen-carrying gas, containing 50 per cent hydrogen, nitroduced through the tuyere k^3, while an air supply is admitted through the higher tuyere k^2. The gaseous mixture ignites at the top of the furnace and maintains, by radiation, the temperature of the bath. Thus, although an oxidizing condition prevails at the top of the furnace, a stream of deoxidizing gas impinges on the surface of the metal and removes oxygen present in the metal. After this process has been completed, the usual additions of carbon, manganese or silicon can be made, and the charge is then ready for pouring. (1,024,999, Apr. 30, 1912.)

Converter.—An improved type of converter for turning pig iron into steel has been patented in the United States by SROL B. FRUMKIN, of Minsk, Russia. As illustrated in plan in Fig. 2 and in elevation in Fig. 3 it consists of an annular furnace hearth, which is the converter, connected with a heat regenerating apparatus in which the hot gases issuing from the converter yield their heat to the incoming air blast. The converter is placed on trunnions so that it can be tilted or revolved through an angle of 180 deg. if desired, for the purpose of receiving or discharging metal. Suitable openings are made in the body of the converter to admit fresh air and discharge the products of combustion, the former coming from the regenerator and the latter passing through it. The passage of air through the converter is shown by the arrows.

The inventor claims the following advantages for his converter: 1. Loss of iron is avoided by directing the blast toward the surface of the metal instead of through it as in the Bessemer process. 2. The gases developed from the metal bath are burned, converting CO into CO_2, thereby increasing the



FIGS. 2 AND 3.—CONVERTER.

temperature. 3. The gases act on the surface of the bath for a much longer time than in the Bessemer process. 4. Owing to absence of CO and increased percentage of CO_2 in the fire gases coming in contact with the molten metal, sulphur and other elements having passed into the slag are not able to re-

duce and return to the molten metal, as is possible in the Bessemer process. 5. Owing to the intense heating of the chamber and particularly the roof and upper walls, it is possible after the termination of the process to turn the apparatus through an angle of 180 deg. and allow the metal to rest on the glowing lining for a time, whereby absorbed gases can be driven out and the metal rendered more dense. At the same time the extraction of any FeO is completed by reaction with the contained carbon. 6. Cost of construction and operation is cheaper than with the Bessemer process.

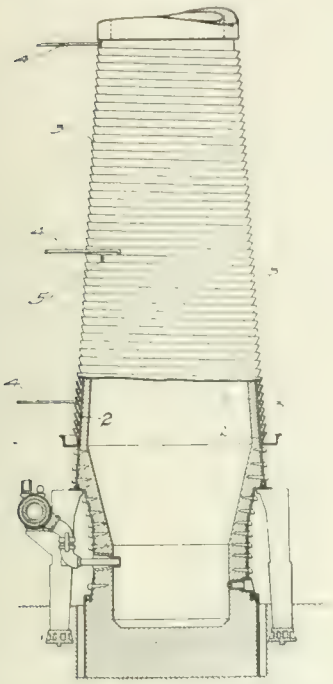


FIG. 4.—FURNACE COOLING DEVICE.

In addition to using the device as a converter the inventor also claims that it is an efficient device for roasting and reducing iron ores to metal. (1,025,260, May 7, 1912.)

Blast Furnace Construction.—A novel method of cooling thin-walled blast furnaces is proposed in specifications of a patent granted to Mr. FRANK C. ROBERTS, of Wynnewood, Pa. As shown in Fig. 4, the idea consists in surrounding the outer shell of the furnace with a helicoidal trough formed by a strip of sheet metal fastened to the furnace shell. The water used for cooling is delivered into the trough at various places from pipes 4, and flows down the spiral trough to collecting launders at the bottom. The bottom of the spiral trough may be more or less open along its bottom, so that the water need not follow a spiral path only, but a portion of it may pass vertically from trough to trough, thus covering the surface of the furnace. (1,030,792, June 25, 1912.)

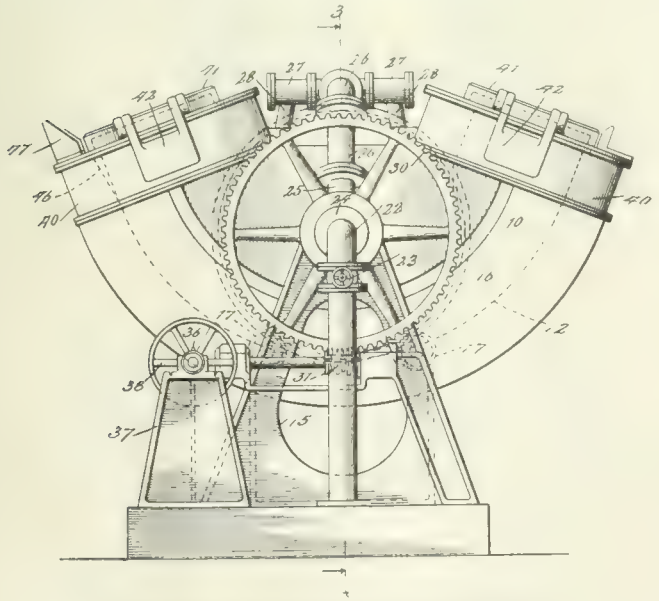

FIG. 5.—FURNACE FOR BALLING SCRAP METAL.

Balling Scrap Iron.—In Fig. 5 is shown a type of furnace designed and patented by MORRIS SELTERS and HAL M. NICHOLLS, of Chicago, Ill., to be used in welding scrap iron in a ball or spherical mass. The hearth is so mounted and actuated as to receive an oscillatory motion in opposite directions. The working chamber is constructed on an arc of preferably less than 180 deg., and is provided with openings for the introduction and discharge of material. Two such chambers may be mounted on the same shaft, so that one can be charged or discharged while the other is in operation. The relationship between the curvature of the hearth and the axis of rotation is such that the hearth in action will have a greater pitch than that represented by its curvature. Thus the curve of the hearth may be eccentric to the center of rotation and will give the balled mass considerable travel at each periodic oscillation of the hearth. The flame for heating is introduced at the top of the furnace, so that it may impinge downwardly against the metal or against surfaces which will reflect the heat against the metal. When the furnaces are used in pairs the exhaust from one may be used to minimize the cooling of the other or to preheat the charge in such other furnace. The general object and operation of the furnace will be apparent by reference to the figure without further designation of the parts. (1,029,234-5, June 11, 1912.)

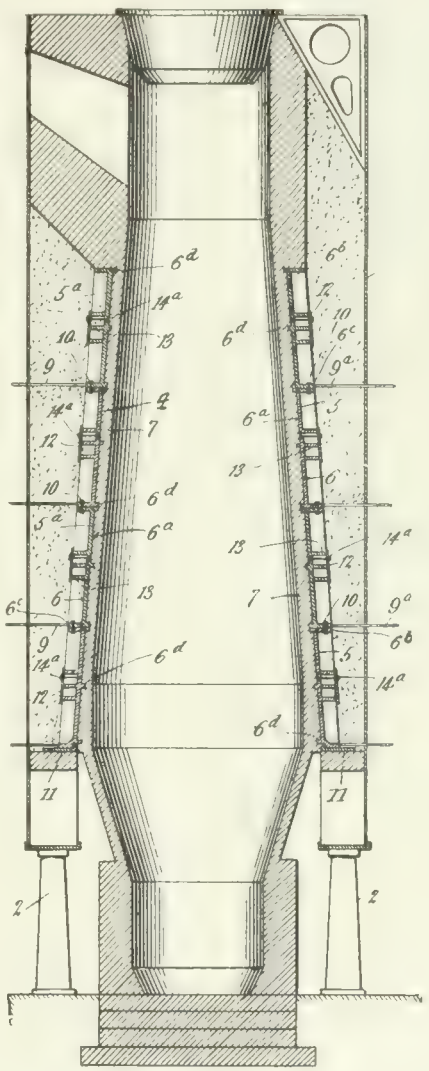

FIG. 6.—BLAST FURNACE CONSTRUCTION.

Blast Furnace Construction.—The reconstruction of the upper part of blast furnaces, whereby a thin artificially cooled wall is substituted for the older style of thick wall, is the subject of recent patents. J. B. LADD and DAVID BAKER, of Philadelphia, Pa., have designed the furnace shown in Fig. 6, which is fitted with water-cooled jackets shown in Fig. 7. The drawing of the furnace represents the usual external shell sup-

ported by columns. In applying the invention, there is erected within the shell and some distance therefrom, a wall 4 consisting of a number of superposed belts or sections 5, 5a, etc., each comprising a series of upright segmental plates. The wall thus formed is lined with fire brick 7, and is supported by the usual columns. In this manner there is provided a continuous circumferential space between the outer shell and inner wall. The plates of which the inner wall is composed are shown in detail in Fig. 6, and will be understood from the drawing. They rest upon each other in the different belts, and are adjacent to each other in the same belt, being held in place by bolts. The cooling is effected by passing water through the pipes contained in the jacket, as shown. The inlet and outlet are shown at 9 and 9a, these openings being connected with suitable pipes to convey water to and from the jackets. Any space left between the outer shell and new inner wall of the furnace may be filled with slag, loam or cement. The primary object of the invention is to substitute a thin wall for the usual massive wall of the furnace, and is especially designed to replace the latter when it has been rendered unfit for further use. By such replacement a great saving in expense is effected in the restoration of the damaged furnace. (1,027,738, May 28, 1912.)

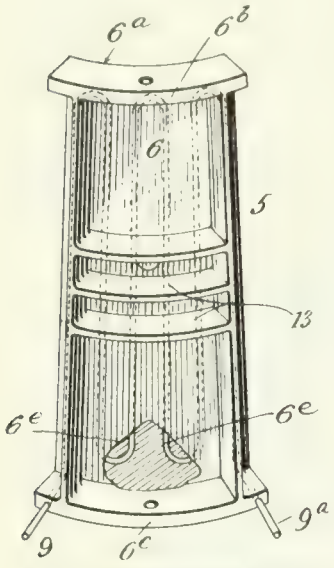

FIG. 7.—WATER-COOLED JACKET.

Another type of construction designed to effect the same result is shown in Fig. 8, wherein is shown the application of water sprays to the outside of the inner wall of a furnace. This design embodies the invention of MAX MCMURRAY, of Cleveland, Ohio. The outer shell of the furnace is represented at *A*, resting on the columns *BB*. The lining of the old furnace is completely removed, and there is substituted therefor an inner shell *C*, also of steel plates, which is provided with a comparatively thin lining *C'*, which extends down to the bosh. In the space between the two shells is provided a system of piping for the purpose of spraying the outside of the shell *C*. This consists of a series of perforated pipes *FF* connected with a suitable source of water supply. In order to have access to the spraying system a series of manholes can be arranged which will be accessible from platforms *H* secured to outer shell *A*. An annular trough can be provided near the bottom of the furnace to collect the water flowing down the sides of the furnace. By means of this construction an old furnace can be fitted with a thin, cooled lining without the necessity of removing or disturbing the hoist bridge or furnace top, which are supported by the old shell. (1,024,801, April 30, 1912.)

Sintering Fine Ores.—With the object of agglomerating fine ore, flue dust, mill scale and the like, Mr. JAMES G. WEST, JR., of Wilkinsburg, Pa., has patented a process differing from others which have been proposed for the same purpose. This apparatus consists of a furnace of the reverberatory type, having gas burners suitably placed in its sides. The hearth on which the sinter is to be made is movably mounted on wheels and adapted to be run into and out of the furnace on tracks. The bed of the hearth is of refractory material, and a layer of ore or dust is placed thereon before it is run into the furnace. As the agglomerating of this mass proceeds additional charges of the same material are fed through openings in the top of the furnace and spread over the area of the hearth by means of poles or rabbles inserted through the side of the furnace. When the sintered mass has been built up to the desired thickness the hearth is removed and dumped, the sinter being broken into pieces of suitable size while it is yet hot. The method may prove desirable in special cases, but does not appear to offer the advantages of the more common continuous types which have proved so successful. (1,031,153, July 2, 1912.)

Gold and Silver.

Continuous Vacuum Filter.—The principal forms of filter used in treating ore slime in the cyanide process are those in which a cake of slime is formed on a thin leaf of varying area or on the surface of a revolving drum. In Fig. 9 on page 489 is shown a horizontal type of vacuum filter, designed and patented by Mr. JOHN E. ROTHWELL, of Denver, Colo. It consists of a series of filters arranged radially in circular or polygonal form, each section having suitable connections with sources of vacuum and pressure. One of the sections is shown in the position assumed when the filtered slime is dumped.

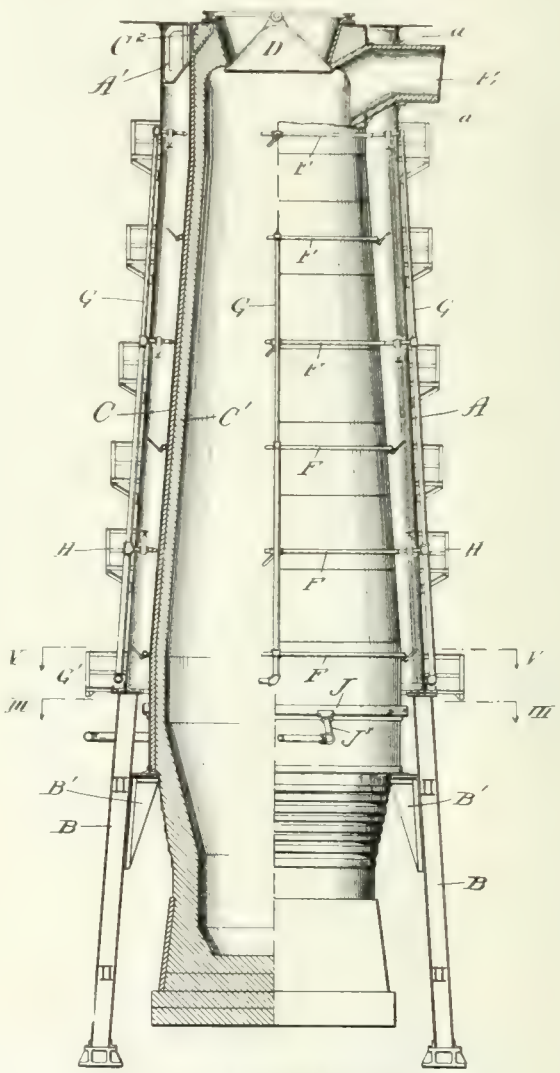

FIG. 8.—BLAST FURNACE CONSTRUCTION.

In operation the entire filter table is rotated by means of power applied through gearing at 9 and 9a. Slime-pulp is delivered to the filter through the feed-launder 2, from which it falls in an evenly distributed stream on to each section as it passes that point. The centrally-located valve is so designed that vacuum is applied to each section as it is loaded with pulp, whereby the valuable solution is withdrawn to a suitable receptacle. In the course of revolution wash solution may be applied at the point *x* and wash water at the point *y* for the

purpose of displacing as completely as possible the valuable solution retained by the slime. These solutions may be withdrawn into separate receptacles, and will not necessarily be

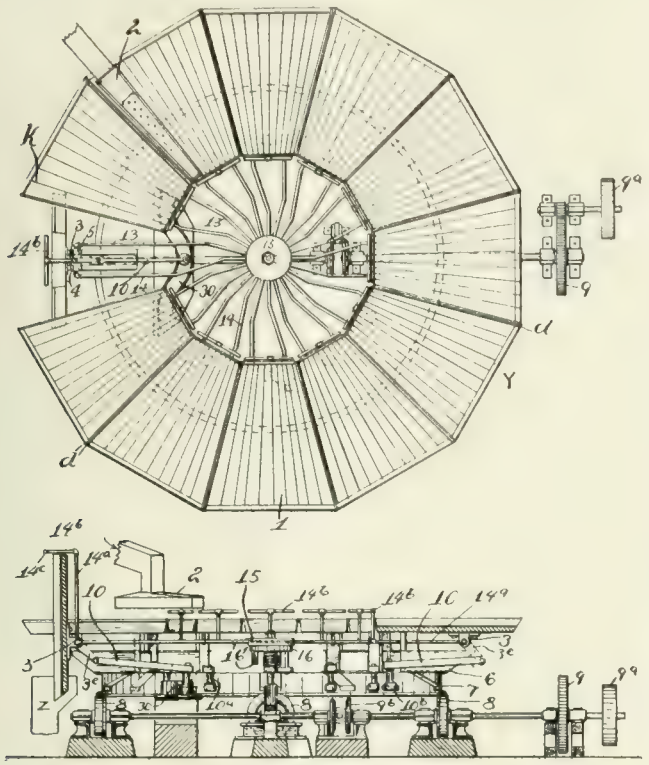

FIG. 9.—HORIZONTAL VACUUM FILTER.

mixed with the first rich solution. On arriving at the dumping point a roller on the end of the lever arm 10 becomes engaged by the curved track 30, which causes the section to be tilted outwardly, as shown. At the same time the central valve causes compressed air to be delivered beneath the filtering medium and the cake is blown off the cloth. For the further cleansing of the filtering surface a stream of water may be applied through the pipe 14^b and caused to play over the vertically tilted section. After the cake is dumped the section passes out of engagement with the curved track and assumed a horizontal position, ready to receive another charge of slime. The entire filter table is supported by a circular tire traveling on the wheels 8. (1,028,789, June 4, 1912.)

Another form of vacuum filter is shown in Fig. 10. It is a modification of one described in these columns December, 1911, page 660, and is the invention of BRUCE W. TRAYLOR, of

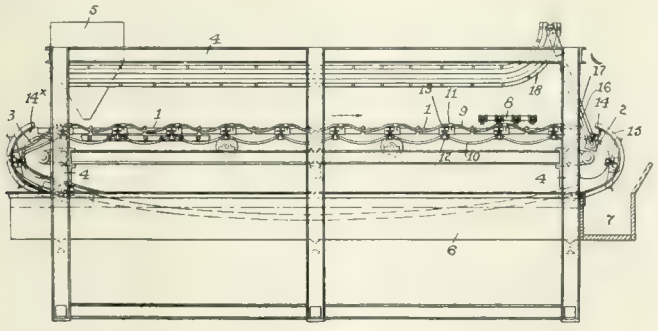

FIG. 10.—VACUUM FILTER.

New York, N. Y. It is composed of rectangular trays 1, arranged in the form of an endless chain. Flexible tubes 9 and 10 provide connections for each tray with the pipes 16 and 17, which, in turn have flexible connections with sources of vacuum and pressure. The valves which provide for alternating connection of each tray with vacuum and pressure, are shown as star-wheels 13. In operation, slime-pulp is delivered to the traveling filter through a feed-hopper 5 and falls on to each tray as it passes beneath the hopper. At this time, and during the period of travel across the filter in the direction of the arrow, vacuum is applied to each filter-tray, and the valuable solution is suitably collected. Wash water can be applied at 8. As each section approaches the turning point at the right, the star-wheel is turned by the guide 14, and pressure is turned on under the filter fabric, thus discharging the cake into the launder 7. On the return trip, the sections travel beneath the tracks and are washed by water contained in a tank 6. On emerging therefrom, the star-wheel is again actuated by the guide 14^e, and vacuum is applied. During the movement of the endless chain of filters, the pipes 16 and 17, which connect with vacuum and pressure, travel back and forth, being guided by the track 18. (1,029,155, June 11, 1912).

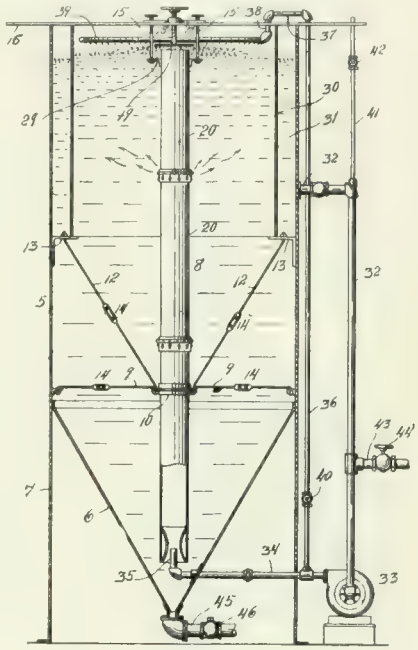

FIG. 11.—PULP AGITATOR.

Pulp Agitator.—Letters patent have been issued to WILLIAM HAMMOND, of Warren, Pa., in the matter of an agitator for ore pulps in cyanide solution. The agitator is illustrated in Fig. 11. It consists of the usual tall, cylindrical tank with cone bottom and central tube. In this case, agitation and circulation are accomplished by means of a centrifugal pump 33 which has the following connections. It receives pulp from the annular space 31 which is formed by the circular apron 30 within the tank. The pulp flows from this space through pipe 32, enters the pump and is discharged through pipe 34 leading to the central tube, with a small quantity passing through valve 40 and pipe 36 to the spray pipe 39 at the top of the tank. At the same time that pulp is drawn into the pump, air may be drawn also through pipe 41, which is an extension of the pipe 32. In this way aeration is accomplished simultaneously with agitation. By diverting a portion of the pumped pulp to the top of the tank, and discharging it through the circular perforated pipe 39, the inventor claims to secure what he terms "cross agitation." This is claimed to result also from the arrangement in the central tube, whereby a portion of the rising pulp can issue from an annular series of holes bored in sleeves surrounding the movable sections of the standpipe, as shown at two points intermediate the top and bottom of the tube. These movable sections can be raised or lowered by means of screws 15. When raised, pulp can issue from the holes in the sleeved surrounding the joint. (1,026,578, May 14, 1912.)

Electrolytic Precipitation of Gold from Cyanide Solutions.—An improved form of electrolytic cell for precipitating the precious metals from solutions obtained in the cyanide or chlorination processes is shown in side and sectional elevations in Figs. 12 and 13 respectively. It is the invention of WILLIAM H. DAVIS, of Boulder, Colo., and will be used in the mill now under construction for the United States Gold Corporation. In other forms of cells for gold precipitation the

electrodes are disposed parallel with the flow of the solution, and as the ionic migration is slow compared with the velocity of flow of solution through the cell, these cells must be of considerable length to insure complete precipitation. It is the

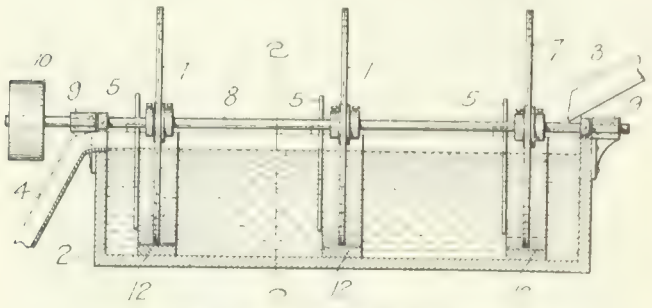

FIG. 12.—ELECTROLYTIC CELL.

object of the present invention to construct a cell in which the flow of solution is an additive quantity to the ionic migration, with the result that time, electric energy and the size of the cell are reduced. This is attained by placing permeable electrodes transversely to the flow of solution, so that every particle of solution must pass through the foramina of the electrode substance, or in such close proximity to the same that the space to be traveled by the ions is reduced to a minimum.

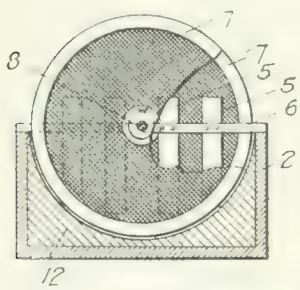

FIG. 13.—SECTION ON LINE 2-2 OF FIG. 5.

In Fig. 12 the cell 2 receives its solution from the launder 3 and discharges it through the launder 4. The anodes 5 are bars suspended from beams extending across the tank, as shown more clearly in Fig. 13. The cathodes 7 are circular, and adapted to be rotated by power applied to the pulley 10. A partition 12 prevents the solution from flowing under the circular cathodes, and forces it to travel through them. A suitable substance of which to construct the cathodes is wire screen. (1,015,546. Jan. 23, 1912.)

Ore Roaster.—The extraction of gold from sulpho-telluride ores by cyanide is facilitated by a preliminary roast. Time and temperature are two elements in the roasting operation which must be properly regulated. Messrs. WILLIAM H. DAVIS and E. A. CLARK, of Boulder, Colo., have found by experiment and miroscopic observation that a temperature of about 500° C. for a period of two hours is required for proper

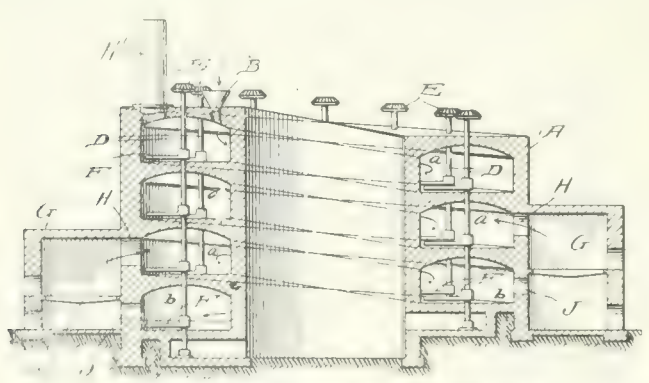

FIG. 14.—HELIXOIDAL ROASTING FURNACE.

roasting. They have designed and patented a type of roasting furnace and cooling hearth, which they term "helixoidal," referring to the structure of its continuous hearth returning to a position vertically below the initial point, whatever the travel of the ore may be. The object is to obtain a form of roaster which will combine a maximum length of hearth with a minimum of floor space.

The form of the roaster is shown in Fig. 14 which is a vertical section. Vertical shafts D are driven from gears E. Attached to these shafts on the hearth are rabbles F, which rotate in opposite directions and effect the mixing and progression of the ore along the hearth. The lower passage *b* is the cooling hearth. Fireboxes G are arranged at suitable places and in number sufficient to provide heat for the roast. The inventors claim economy in operating cost by a greater utilization of the heat units from the fuel. (1,029,667, June 18, 1912.)

Zinc.

Electric Reduction of Zinc.—Among the recent proposals for the utilization of the electric furnace for the reduction of zinc ores is that of CHARLES V. THIERRY, of Paris, France. His proposed furnace is illustrated in section in Fig. 15. His process involves the previous treatment of the ore by fire concentration, whereby an enriched zinc oxide of commercial grade can be obtained and reduced in the furnace with an admixture of carbonaceous fuel. The advantages of this procedure are: (1) The treatment of a product containing a high percentage of zinc; (2) the elimination of those substances which form the slag or residue now obtained in ordinary zinc reduction, and (3) the creation of conditions most favorable for the use of the electric furnace.

Referring to Fig. 15, B represents a furnace retort of suitable construction. A resistor C of particles of carbon is placed on the hearth and suitably connected with a source of current not shown. The ore and carbon mixture is shown at

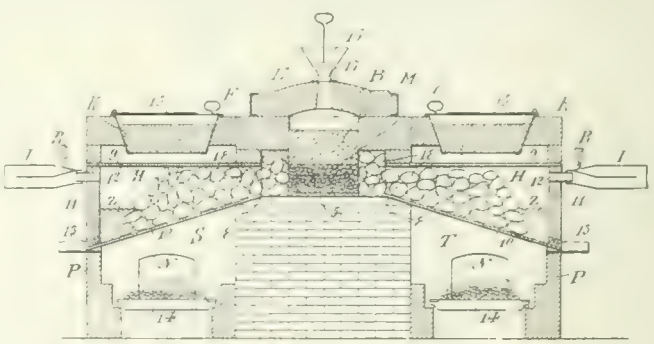

FIG. 15.—ELECTRIC FURNACE FOR REDUCING ZINC.

M resting on the resistor. The retort is provided with a feed-hopper and plug as shown. Openings F from the retort communicate with the condenser H, the latter being filled with coarse coke 18. A tap-hole is shown at 13, and a means for the escape of gas at 12. K represents receptacles for preliminary drying and pre-heating of the charge by utilizing radiated heat. Fireboxes 14 are provided to supply additional heat, if such is necessary to keep the condenser properly warm, or above the melting point of zinc.

In operation, the resistor is brought to the proper temperature, and a charge of ore is placed thereon. As distillation proceeds, the zinc fumes pass through the bed of ore and the resistor into the condenser, where it passes through the carbon therein contained. The metallic fume is thus constantly in contact with reducing substance. The feeding intervals will be indicated by a volt meter, for when a charge is approaching exhaustion the normal resistance will be affected and will serve as an indication that more charge is needed. The determining factor which limits the capacity of the furnace is the condenser. Hence, the construction is such as will give a high rate of production. The inventor states that he has demonstrated the efficiency of this process by running continuously for weeks, producing zinc at the rate of about 75 lb. per hour: that by reason of the comparative purity of the product smelted, most of it being converted into the gases of zinc and carbon monoxide, little slag or residue is formed, and the retort need

not be cleaned save at long intervals. (1,030,349-50, June 25, 1912.)

Treatment of Blue Powder.—The production and retreatment of blue powder formed in zinc reduction has always constituted one of the principal difficulties in the metallurgy of zinc. Mr. Charles V. Thierry, of Paris, France, proposes to treat the blue powder with a dilute solution of hydrochloric acid, in proper proportion to just dissolve the zinc oxide present and leave the zinc in a condition to be dried and melted. He states that he has confirmed his belief that the proper quantity of acid will dissolve merely the film of oxide on the surface of each particle of metal, and leave it in a condition to be melted. The process is designed to be cheaper than resmelting, and to recover the zinc more rapidly. (1,030,351, June 25, 1912.)

Alloys.

Casting Magnesium Alloys.—The difficulties in casting alloys containing magnesium arise from the affinity of that metal for oxygen. Berthold Hoffman and Robert Suchy, of Griesheim, Germany, have discovered that this reaction is mitigated by the addition of a small quantity of calcium to the alloy. Alloys thus formed may be cast without any oxide or nitride of magnesium being formed, or any other injurious action taking place. Thus, for instance, magnesium and its alloys, when mixed with from 0.1 per cent to 0.5 per cent of calcium, flow in a silver-white stream without burning taking place or a dark skin forming on the surface of the metal. The castings fill the molds in a perfect manner, and do not effloresce in the air. The property given by the calcium is not lost on repeated melting and casting. The presence of the calcium further makes possible the casting of magnesium or its alloys free from hydrogen bubbles. It is not necessary to use calcium in the metallic form, as it can be applied as powdered burned lime. It may be added also during the electrolytic manufacture of magnesium. Being used in such small amounts, it does not impart to the alloy any of the characteristics of a calcium alloy. (1,028,216, June 4, 1912.)

Synopsis of Metallurgical and Chemical Literature.

Gold and Silver.

Parks Electrocyanide Process.—Among the several proposals for the use of electricity in connection with cyanidation is that of Mr. John R. Parks, of Hollywood, Calif., who describes his system in the July, 1912, *Quarterly* of the Columbia School of Mines. The system is intermittent and yields the precious metals in the form of an amalgam in a single operation, thus eliminating filtering and precipitating devices.

The electrocyanide vat consists of a wooden tub, 15 ft. diameter and 30 in deep, through the center of which projects a small conical casting for the passage of the working shafts. Practically the entire bottom of the pan is covered by an amalgamated copper plate, to which quicksilver is added in proportion demand by the ore. This plate is the cathode. About nine inches above the cathode is a cast-iron anode plate equal in area to the cathode, mechanically suspended in a suitable manner. The anode plate is divided into two annular parts, the outer one containing 60 per cent. and the inner one 40 per cent. of the anode area. These annular anodes revolve in the same direction, and independently, by means of pulleys, gears and a solid and hollow shaft. Wooden paddles are fastened on the underside of the anode, extending to within 2 in. of the cathode plate. The compound rotary motion of the anodes and their paddles gives a swirling motion to the ore pulp, causing it to travel toward the periphery of the vat where it passes upward between the anode and side of the vat, and thence back to the center. Air jets at the periphery of the tank supply oxygen to the solution.

Current is supplied by a 10 to 20-volt, 400-ampere D. C. generator. The positive wire, in four branches, is brought into contact with collecting rings on the shafts which rotate the anodes, and the current is thus distributed to the anode plates. The negative wire is similarly connected to the four sections of the cathode.

In operation, the ore is treated with a cyanide solution of suitable strength, with protective alkali, and a quantity of salt. Complex chemical reactions occur when the current is applied, chief among which is the decomposition of the salt. The sodium liberated is constantly precipitated on the cathode, forming sodium amalgam; the sodium is converted into sodium hydroxide which reacts with the acid constituents of the ore and prevents excessive consumption of cyanide. The cyanide is decomposed also, but there is no question of the subsequent restoration of cyanide, as the author has frequently found more free cyanide of potassium or sodium in a sample of solution taken an hour or so after a previous sample. Mercury should not be lost in the process, but in practice a small loss is observed; in one case this amounted to about 5 lb. in treating 2500 tons ore. Base metals are precipitated as well as the gold and silver, and base bullion can be produced.

The power required for a single vat is 0.6 hp for mechanical agitation, 1 to 1.5 hp for compressed air, and 4.5 to 6 hp for electric current. A single charge, of 1.1 pulp, is 7½ tons, and the time of treatment varies from 2½ to 4 hours. The daily capacity of a vat, including time taken for discharging, is from 35 to 60 tons.

The author appends a few examples of results obtained on different ores, which show recoveries of from 86 to 97 per cent. of the gold and from 62 to 91 per cent. of the silver, as amalgam.

Electric Melting of Gold Precipitate, and Smelting of Concentrate.—The Lluvia de Oro Gold Mining Co., Lluvia de Oro, Chihuahua, Mexico, uses electric resistance furnaces for melting the gold and silver precipitate from cyanide solution, and for smelting roasted gold and silver concentrate. The work is described by H. R. Conklin, manager for the company, in the *Eng. & Min. Jour.*, June 15, 1912.

The four furnaces are rectangular in section and have the following inside dimensions: 16 in. square and 4 ft. deep. The side and back walls are of solid adobe. All bricks, except the front course, are liners. Chrome dust, with sodium silicate as a binder, was first used for lining, but lasted only about thirty hours. Good firebrick, laid with ends exposed to the charge, and having the joints floated full of fireclay, last about 200 hours. In an effort to improve this, one lining was tried of carborundum firesand, rammed 3 in. thick, with 5 per cent sodium silicate of 52 deg. B. for a binder. This was too good a conductor and reduced the capacity of the furnace. The life was about the same as for firebrick, but cost twice as much. For a tap-hole, the brick lining in front is built with a tapered channel leading from the furnace for 3 in. or 4 in. to an iron plate with a ⅞-in. hole. A spout of angle-iron is laid from the plate to guide the flowing metal to the molds.

Alternating current of 60 cycles is used at 110 volts. Acheson graphite electrodes have given the best service. On account of revolutionary troubles in 1911 iron electrodes were used for a time, but they are objectionable in smelting concentrate on account of adding iron to the metal and causing difficulties in discharging the furnace.

Fluxing of the precipitate is varied according to its character. A customary charge is 100 parts precipitate, 5 of lime, 15 of sand, 10 of borax and 10 of soda. In starting the furnace all resistance is cut into the circuit and the upper electrode lowered to the bottom of the furnace in one corner. A handful of powdered graphite is thrown in between the electrodes, followed by borax and powdered slag until the bottom of the furnace is covered with melted slag. As slag accumulates the upper electrode is raised. The resistance is gradually cut out, and is usually all out in thirty to fifty minutes, with a pool of

molten slag in the furnace about 1 ft deep. Fluxed precipitate is then added until the furnace is full, and the resulting bullion cast into molds. The bullion runs about 900 fine.

Short zinc is roasted, fluxed and melted. The resulting bullion is remelted with precipitate.

Concentrate at this mine is worth about $1,500 per ton. Formerly it was sacked and shipped to the smelter, but it is now reconcentrated and smelted electrically after roasting. The cost of marketing concentrate was about 5 per cent higher than the cost of marketing the same value of bullion. The present process consists in reconcentrating to a value of about $3,000 per ton, roasting off nearly all the sulphur in a small reverberatory furnace, fluxing and smelting in the electric furnace. A charge contains 100 parts concentrate, 15 of lime, 30 of sand, and 15 of slag from precipitate melting. The products are bullion and a high-iron slag.

Only bullion is shipped from the mine. Slag from precipitate is used as flux for concentrate, or sent back to the mill for treatment by cyanidation. Slag from short zinc is sent back to the mill. Slag from concentrate is stored until a sufficient quantity has accumulated to warrant separate treatment in the mill. Furnace refuse, bricks, clay, sweepings, etc., are sent to the mill. It should be added that the company owns its hydroelectric power plant, the operating cost of which is constant whether the output is a maximum or a minimum.

Regeneration of Cyanide Solutions.—Cyanide solutions which become foul in treating cupriferous ore may be regenerated, and the copper recovered, according to a method practiced by Mr. W. D. WILLIAMSON, who has communicated his ideas to the *Journal* of the Chem. Met and Min. Soc. of S. Africa, April, 1912. The addition of sulphuric acid to such a solution will cause the following reaction:

$$Cu_2(CN)_2 \cdot 2KCN + H_2SO_4 = Cu_2(CN)_2 + K_2SO_4 + 2HCN$$

The insoluble copper cyanide can be separated by filtration, and the filtrate neutralized by a slight excess of alkali. It is obvious, however, that there is still cyanogen in the copper precipitate which ought to be recovered if possible. If the precipitate be suspended in water, and treated with hydrogen sulphide the following reaction occurs:

$$Cu_2(CN)_2 + H_2S = Cu_2S + 2HCN$$

The solution resulting from filtration of the mixture can then be neutralized with alkali and used as solvent for fresh ore.

Finally the author combined the two reactions by adding sodium sulphide and the requisite amount of acid to the cupriferous cyanide solution, with this reaction:

$$2KCN \cdot Cu_2(CN)_2 + Na_2S + 2H_2SO_4 = Cu_2S + 4HCN + Na_2SO_4 + K_2SO_4.$$

The precipitated copper cyanide carries down with the precious metals and can be collected, dried and shipped to the smelter. The clear liquor is then neutralized with a slight excess of alkali to combine with the free HCN.

Synthetic Rubber.

Prof. Wm. H. PERKIN'S paper, recently presented before the Society of Chemical Industry in England on "the production and polymerization of isoprene and its homologues" has resulted in a great deal of newspaper articles and also some discussions in the British technical and especially electrical journals, in view of the importance of rubber for the electrical industry.

The London *Electrician* of June 28 writes as follows: "The first step in the process is the production of fusel oil and acetone from starch-containing substances by fermentation. The next operation consists in subjecting isoamyl alcohol, which is obtained by distillation from the fermentation products, to the action of hydrochloric acid, while in the third the vapor of the isoamyl mono-chloride thus obtained is treated with chlorine gas, resulting in the production of isoamyl dichloride. This latter substance is then passed over lime heated in an iron tube and the isoprene so formed is polymerised into rubber by contact with metallic sodium, the change being assisted by heat and taking place in a few hours, weeks or days according to the temperature employed. In this way it is possible to build up by a true synthetic process a rubber closely resembling the latex that comes from the tree." . . .

The editorial then continues to say: "The company which is being formed to work the processes detailed above will, we are informed, for the present confine itself to the synthetic production of acetone and fusel oil alone, two substances which it will be able to put on the market at prices much lower than those at present existing. This should have a great effect especially in the explosives industry where large supplies of acetone are required. Fusel oil, also, has risen in price very greatly during the last few years. But as regards rubber no steps are at present to be taken, so that cable manufacturers are not yet likely to be able to obtain this commodiy at a low price; while, on the other hand, those of our readers who own shares in rubber companies may sleep quietly in their beds."

The London *Electrical Review*, of June 28, writes as follows:

Prof. Wm. H. Perkin's paper "essentially consisted of an historical review of the attempts to make rubber artificially, followed by an account of the work conducted by an organization of chemists directed by Messrs. Strange and Graham, working in conjunction with Prof. Perkin and later with Prof. Fernbach, of the Pasteur Institute, Paris. Prior to the advent of Prof. Fernbach on the scene Sir William Ramsay had already become associated with the group as consultant. The history of synthetic rubber may be said to have started with the discovery by an Englishman, namely, Greville Williams, in 1860, of the fact that among the products obtained by the dry distillation of rubber was a substance, subsequently termed isoprene, which on standing in a sealed veessel thickened and became viscous. In 1875 Bouchardat, of Paris, discovered that by the action of hydrochloric acid on isoprene (also obtained from rubber), a substance which closely resembled natural rubber could be obtained. Subsequently Prof. Tilden found that isoprene could be derived not only from rubber, but from another natural product—namely, turpentine—by passing this substance through a heated tube under certain conditions, and from the isoprene so prepared Prof. Tilden was able by two processes to obtain a material, the qualities of which appeared to be much the same as those of natural rubber. The next step was to clear up the constitution of the material isoprene, and, to pass over all the intermediary stages, it may be stated that this substance has been proved to be a methyl-butadiene—that is to say, a chain compound containing five carbon atoms and two double linkages. For a time the views of Tilden regarding the basis substances of natural rubber were strenuously combatted by a German school of chemists, headed by Prof. Harries, and the failure of Harries to obtain rubber from isoprene as described by Tilden led him to express a serious doubt doubt as to whether Tilden had not been wrong in his observations, or had not drawn wrong deductions from his experiments.

"Not the least interesting part of Professor Perkin's discourse consisted in the production of some of the original specimens of the rubber-like material prepared by Prof. Tilden, and the refutation of the claims of the chemists of the German school to the effect that they were the original and true discoverers of the synthesis of rubber. That isoprene can be converted into rubber is now acknowledged by the German school, inasmuch as recent researches have enabled them to convert this material into the substance in question."

The London *Electrician* of July 12, contains an article by C. J. BEAVER (of W. T. Glover & Company) who emphasizes that "no synthetic rubber appears to have yet been produced which is comparable with high-grade natural rubber as regards physical properties and perhaps at this stage it is hardly fair to expect it."

Mr. Beaver also thinks that lower prices will naturally arise in due time owing to new rubber plantations, thus rendering synthetic rubber less necessary commercially.

The "Clam Shell" Filter.

By Ernest J. Sweetland.

Since the Sweetland filter press was first introduced there has been an increasing demand for a modification of the principle that would lend itself to conditions where dry discharge of the residual matter is required. True, a number of large Sweetland presses of the frame type have been adapted for dry discharge and are doing the work for which they were designed. These have been constructed with a large door in the lower end of the press, and while the cakes are held in place on the leaves by a partial vacuum, a tray is inserted through the door and the cakes caused to fall. The tray with its load is then removed, the door closed, and the press again charged. In some cases the use of the tray is dispensed with and the residual matter withdrawn with a hoe like ashes from the door of a furnace. Most of the machines of this type have been placed where the bulk of residual matter is comparatively small, that is, where the cakes formed were thin and the weight of solid matter to be withdrawn moderate.

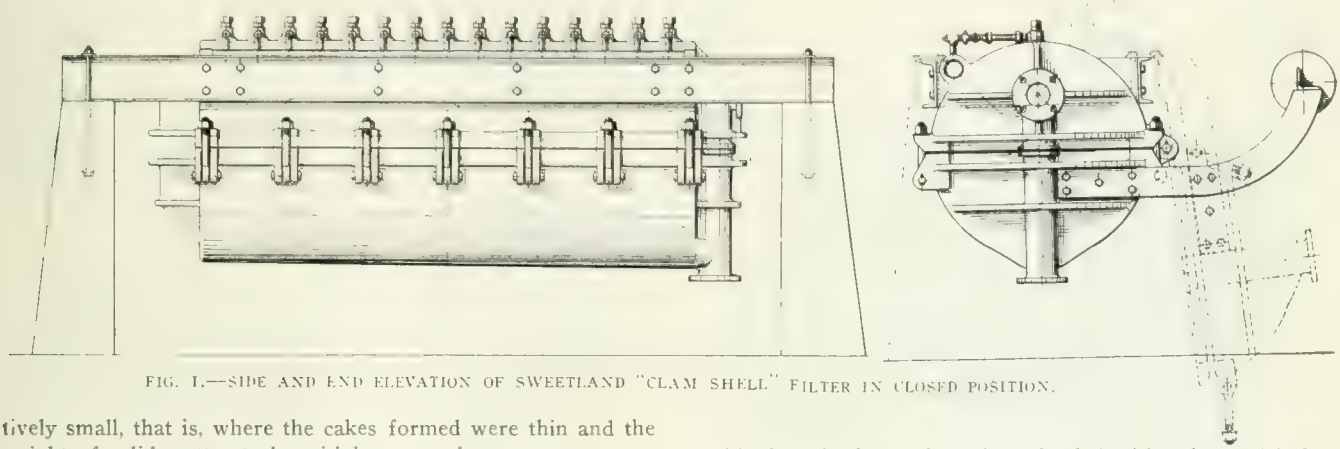

FIG. 1.—SIDE AND END ELEVATION OF SWEETLAND "CLAM SHELL" FILTER IN CLOSED POSITION.

For some time the writer has been engaged in the development of a filter that would accomplish the following important objects, and at the same time not sacrifice the advantages that have been gained in previous types. These objects are:

First.—"Dry"* discharge of the cakes without handling (mechanical or otherwise) and without moving the filter leaves.

Second.—To overcome the objection of having a quantity of excess or surplus unfiltered liquid to handle with each operation.

*The word "dry" as used here is not to be taken in its literal sense, but refers to the filter press cake discharged from the filter in its natural condition, without being disintegrated and flushed out with water, as is the case with the sluicing type.

It is an important point in many processes to have the filter press cake as dry as possible. For example, if precipitated carbonate of lime is to be recovered from its solutions to be reburned, each unit of moisture that remains in the cake must be evaporated. Therefore the drier the cake is discharged from the filter the less fuel will be required. For such a purpose a sluicing type filter would be useless, for the act of disintegrating the cake with water in discharging would defeat the purpose for which the filter is required.

The excess unfiltered liquid referred to under the second head is that liquid which lies in the filter chamber between and below the cakes.

To better illustrate this point, suppose a filter chamber to contain a series of filter leaves located in the upper portion. If a space is left in the bottom of the chamber to make room for a discharge tray, conveyor, or otherwise to facilitate discharging, this unoccupied space contains surplus unfiltered liquid after the leaves have been loaded with cake, and before the cakes can be washed this space must be drained. Then when washing has been finished this space contains surplus water which must be withdrawn before a "dry" discharge could be attempted.

This surplus or excess liquid is the cause of more complications than are visible on the surface, not the least important of which is the enrichment of the wash water. It is not ordinarily permissible to use fresh wash water each charge and discard the excess remaining in the chamber; therefore the excess must be used over and over. Each time the excess comes in contact with a batch of cakes pregnant with a strong solution, a certain amount of the strong solution mixes with the wash water, gradually enriching it until eventually this

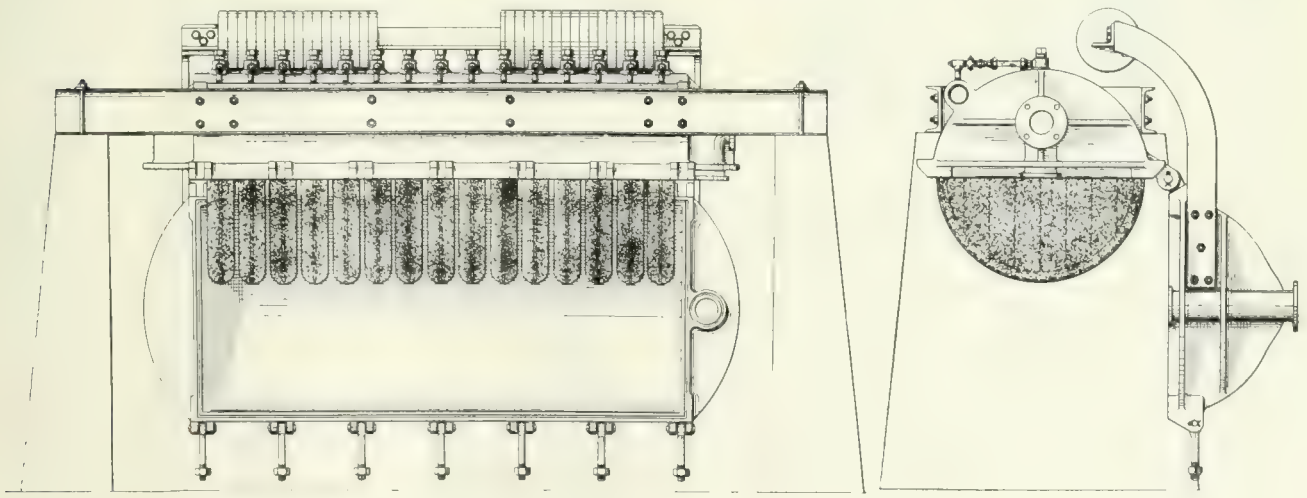

FIG. 2.—SIDE AND END ELEVATION OF SWEETLAND "CLAM SHELL" FILTER, OPEN, READY FOR DISCHARGE OF CAKES.

wash water becomes weak solution and the efficiency of the wash is impaired. Suppose, for instance, the cakes contain a strong solution of caustic soda, and it is desired to displace this solution in the cakes with water. If pure water is available for washing it is possible to completely remove the caustic soda from the cakes; but if the wash water contains caustic soda in solution, then washing ceases to be effective when the effluent is reduced to the strength of the ingoing wash water.

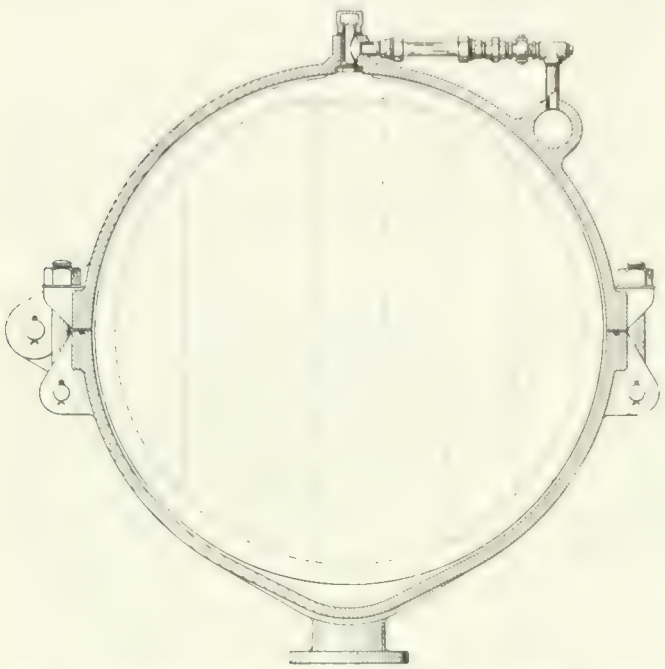

FIG. 3.—SECTIONAL VIEW OF SWEETLAND "CLAM SHELL" FILTER, SHOWING GLASS DELIVERY TUBE AND FILTER LEAF CONNECTIONS.

When this point is reached caustic soda is being washed *into* the cake exactly as fast as it is being washed out. The same applies to an even greater extent in the cyanide process. In this process it is important to have wash water free from gold or silver in solution, as otherwise an appreciable amount of recoverable values are lost with each discharge.

In addition to this, simplicity and convenience in operation are promoted by doing away with excess solutions. Accessory equipment is minimized and the possibility of an inexperienced operator allowing the cakes to fall while withdrawing the excess sludge is removed, the time required for each cycle is reduced and the daily capacity of the installation per square foot of filter area is increased. When there is no excess solution to deal with, the end of filling the press and beginning of washing is marked by the attendant simply turning a three-way valve on the suction of the feed pump, which cuts off the sludge and connects the wash water.

A comparison of the number of steps required for each operation with and without excess solution illustrates the point:

WITH EXCESS.	WITHOUT EXCESS.
Form cakes.	Form cakes.
Withdraw excess.	Wash cakes.
Fill with wash water.	Dry with compressed air.
Wash cakes.	Discharge.
Withdraw excess wash water.	
Dry with compressed air.	
Discharge.	

The above shows that by eliminating the excess the number of steps is reduced from seven to four. Furthermore, it is usually necessary to have a vacuum pump and receiver for use in holding the cakes to the leaves during the transfer of excess solutions, and this equipment is unnecessary when excess solutions are eliminated.

To eliminate excess, or surplus solutions, the "dead" space in the filter chamber must be done away with, that is, when the filter is charged the cakes and the leaves which support them should fill the entire chamber, with the exception of a narrow slit between adjacent cakes to permit the wash water to distribute itself. There should be no pockets to retain unfiltered solution.

The cylindrical form chamber with circular leaves equally spaced and disposed at right angles to the axis of the cylinder makes the accomplishment of the above objects possible. The cylindrical form is of especial advantage because it gives the maximum strength for a given weight, exposes the leaves to view when opened, and permits of easy discharge of residues.

The Sweetland "clam shell" construction reduces void space to such an extent that surplus solutions are reduced to a negligible quantity. The body consists of two semi-cylindrical shells hinged together. The upper member is supported in a stationary position upon the foundations. The lower member is balanced on its hinges by counterweights so that it will swing freely and remain in any desired position. The filter leaves are held in the upper member by a lock-nut on the outside of each; they have no connection whatever with the lower member. (See Fig. 3.)

The construction of the filter leaf varies widely, and must be selected to suit the material in hand. A simple form of leaf is made with a circular supporting frame of flattened seamless steel tubing, perforated on the inner periphery. The ends are united in a casting which receives the outlet nipple. The outlet nipple has a side opening which aligns with the delivery pipe. This frame carries a web of two layers of screen which provides the necessary drainage for filtrate. The whole is surrounded by a bag of suitable filter cloth or duck through which the outlet nipple passes. A locknut on this nipple screws down on the cloth, preventing leakage where the nipple passes through. The delivery pipe carries a shut-off cock and section of gauge glass which renders the delivery from each leaf visible and controllable. Any leaf may be cut off without interference with the rest. The filtrate from all leaves is delivered into a general conduit on the side of the stationary member. Any leaf may be removed from the open filter by removing the locknut at the top.

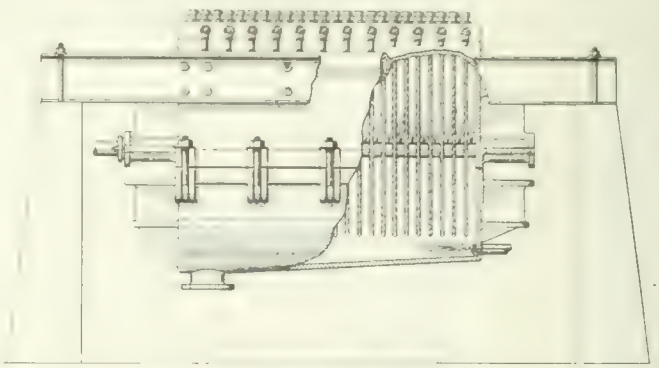

FIG. 4.—SIDE ELEVATION OF SWEETLAND "CLAM SHELL" FILTER, SLUICING TYPE, SHOWING CENTRAL ROTATABLE FLUSHING PIPE FOR WASHING LEAVES AND "BOOSTER" NOZZLE IN THE BOTTOM.

Limited space makes it impossible to go into details regarding the mechanical closing and locking device employed on large units. The moderate-size units are held closed by swing bolts as shown. In all cases the lower member carries an inserted rubber gasket which abuts against the smooth surface of the upper member, forming a water-tight joint. The operation of the filter is as follows:

The liquid to be filtered is forced into the filter body either by pump or monte-jus through an inlet in the stationary member, a slight depression in the bottom of the lower member forming a gutter which permits the liquid to flow along the bot-

tom and enter freely between the leaves. The entire body of the filter is filled before the air vent at the top is closed. The pressure of liquid bears equally against the sides of all the filter leaves and causes the liquid content to pass through the filter cloth while the solid matter deposits on the surface, forming cakes. A testing device enables the attendant to gauge the thickness of the cake at any time. When they have arrived at such a thickness that there is but a small space between adjacent cakes, the supply of sludge is shut off and wash water turned on simultaneously. This change is made so quickly that the pressure in the filter chamber is steadily maintained.

The wash water first displaces the small quantity of liquid between the cakes, depositing upon the cakes the solid matter which it contained. The wash water continues to percolate through the cakes until the solution in the cakes is almost, or entirely, displaced. The washing completed, compressed air is

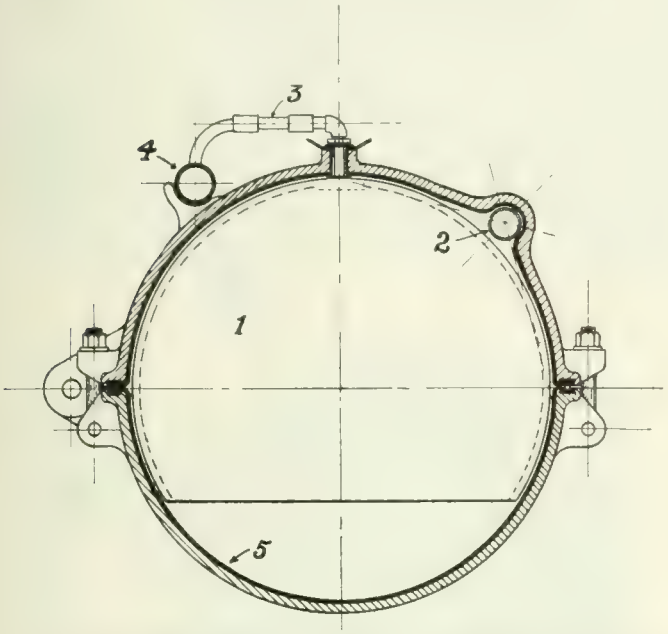

FIG. 5.—SECTIONAL VIEW OF SWEETLAND "CLAM SHELL" FILTER, LEAD-LINED SLUICING TYPE FOR ACID SOLUTIONS.

1, Filter leaf. 2, Flushing pipe. 3, Glass tube. 4, Lead pipe. 5, Lead lining.

admitted, which drives the small amount of liquid remaining out through the cakes, leaving them compact and free from excess moisture.

The final operation is discharging. This is done by unlocking and swinging the lower portion of the shell open and admitting compressed air to the interior of the leaves. The sudden rush of air from the interior of the leaves outward dislodges the cakes, causing them to fall into a truck or conveyor below. If desired a moderate vacuum may be maintained in the leaves while the lower half of the shell is swung open to prevent the possibility of the cakes falling prematurely.

That class of filtration sometimes designated as clarification demands different treatment. Under this head comes the filtration of liquids containing a very small percentage of solid matter, and usually the recovery of the clear filtrate is the desired object, the solid content being refuse to be disposed of by the quickest and cheapest means. In such cases the general construction described is retained, and a small space is left below the leaves, and a rotatable flushing pipe having a nozzle adapted to project a stream along the surface of each leaf passes through the shell from end to end. In this type the adhering slime is flushed from the leaves almost instantly by the streams from the nozzles sweeping forcibly over the surfaces of the leaves as the pipe is rotated. The cleansing action may be assisted by admitting air under moderate pressure to the interior of the leaves. A "booster" nozzle at one end sweeps the fallen slime out of the space below the leaves and through the discharge valve on the bottom. Thus the body of the filter and the filter cloths are quickly cleaned while in normal working position.

A cross-section of a lead-lined filter of this type for acid solutions, constructed with the sluicing pipe at the side of the leaves, is shown in Fig. 5.

This filter and various modifications are fully protected by patents and pending applications owned by the Sweetland Filter Press Company, New York.

An Electric Furnace for the Treatment of Tin Dross, Concentrates from Cyanide Mills and Other Metallurgical Work.

By R. S. Will

The old and still the most prevalent way of smelting tin drosses is in the reverberatory furnace, which causes varying but large losses of tin owing to the nature of the furnace.

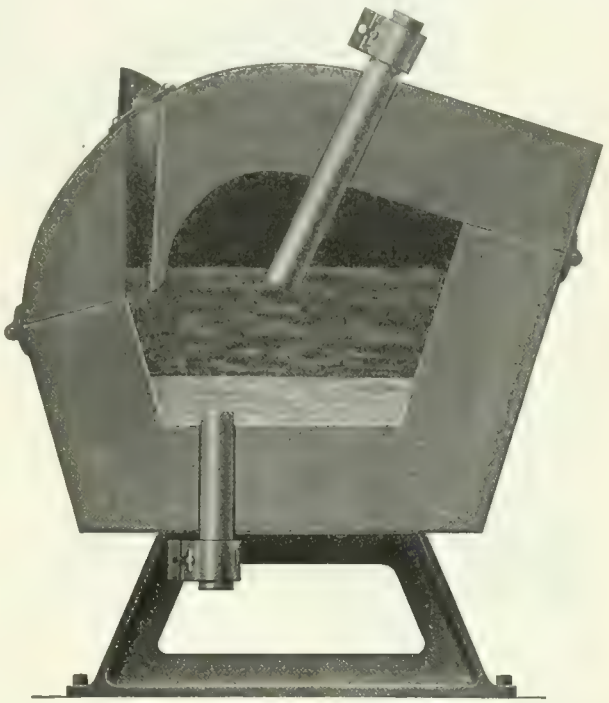

FIG. 1.—ELECTRIC FURNACE IN OPERATION.

The average loss is in the neighborhood of 8 per cent and then it is necessary to add lead in order to keep the loss so low. This of course makes the metal unfit for straight tinning and it is used for terne plating instead.

In 1908 we tried some experiments in reducing this class of material in the electric furnace and very early hit upon the plan which we have followed in most all of our types of furnaces since then. This dross contained from 36 to 56 per cent tin, 9 to 15 per cent zinc, and 10 to 18 per cent iron, with alumina and other impurities included. The dross was a by-product of tinplate mills and was the residue obtained after all the metallic tin, which was gathered with it in skimming the tin pots, had been melted out. Because of the zinc, lime and iron, it was extremely difficult to recover the tin in a comparatively pure state without great loss, and that this loss did occur is readily comprehended from the foregoing.

In the style of furnace we adopted, we decided to melt the slag first. This is not feasible in a reverberatory furnace, because it will chill when the cold dross is thrown in and it is then almost impossible to remelt it. After this slag was melted in the electric furnace, which was of the shaft type (the slag having a depth of three to four feet, depending upon

the size of the furnace, and in any event taking up half the height of the furnace), the dross mixed with the proper amount of carbon and with enough silica to flux the impurities was thrown in on top and the furnace completely filled. The dross stays on top of the slag and the molten tin trickles through it and is tapped from the bottom. There is no volatilization, as all fumes are condensed in the colder portions of the dross, the only gases escaping being those caused by the reduction, which bubble up through the dross without carrying any metallic fumes with them.

We found out some very interesting things in connection with the smelting. Of course, we knew we could cause a quicker reduction by using more current, but one of the things we learned was that by increasing the temperature of the furnace we decreased the loss of metal. By employing pyrometers we found that we, too, could have a loss of 8 per

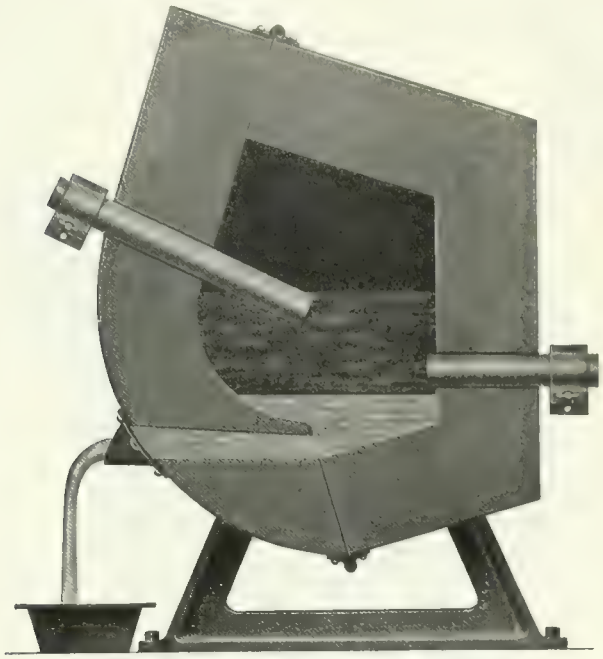

FIG. 2.—ELECTRIC FURNACE TILTED.

cent by running the furnace at 3000 to 3600 degrees Fahreheit, but by increasing this to 4200 degrees the loss was in the neighborhood of one-half of 1 per cent. As a consequence we ran the furnace at the higher temperature, using more current, of course, but obtaining more metal to offset this and very materially reducing the loss. Slightly better results were obtained from direct current than from alternating, not only because there were no induction losses, but because the direction of the current could be changed at will, making the top or bottom positive as desired and consequently, hotter at the point of entry. It might be well to state that in using alternating current we get a power factor of at least 93 per cent, because the voltage employed is rather high for furnace work, varying between 110 and 220.

While working a set of these furnaces, the writer was visited by Mr. H. R. Conklin, of the Lluvia de Oro Gold Mining Company, of Lluvia de Oro, Chihuahua, Mexico, who thought our type of furnace would be adaptable to the melting of the finely divided gold obtained from cyanide plants. He ordered a set of these furnaces for this purpose and aside from some slight changes in regard to size and material of construction, these furnaces have been working ever since then, and in fact have been increased in number from two to four. These furnaces are smelting their concentrates as well as melting the zinc precipitates.

We have done a great amount of experimenting on ore and concentrate smelting and find that this type of furnace is not only feasible in many cases, but absolutely necessary in some. Take, for instance, an ore with a low copper content, high in zinc, and a gangue material of lime and iron garnet. All these have about the same specific gravity and magnetic separation is too expensive because of the low value of the ore. We have found that an ore of this kind can be handled very easily, using about 180 to 200 kilowatts per ton. The zinc and lime in the ore coupled with the low value, make it almost impossible to treat any other way. Apart from this, however, is the saving in operation where fuel is scarce and waterpower is not. It was this item that caused the Lluvia de Oro to change their method of melting their precipitates.

In melting the zinc precipitates the operation is similar to the dross smelting, the slag is very similar and the material added in the same manner, the difference being the absence of carbonaceous material as in the case of drosses. The bullion is tapped out into molds, and the slag, which contains very little values, after being used for a very long time, is either milled or used in concentrate smelting.

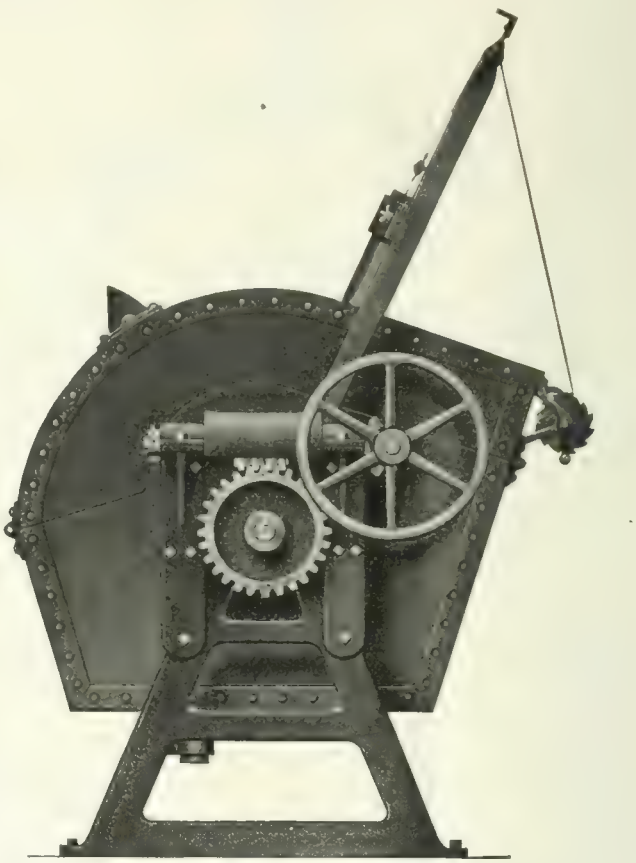

FIG. 3.—OUTSIDE VIEW OF TILTING ELECTRIC FURNACE.

In concentrate smelting where there is a preliminary roast, we have for some time adopted the idea of blowing a jet of air through the taphole to oxidize the remaining sulphur. This has been effective and does away with any sulphides becoming mixed with the bullion. We can do this to a large extent with concentrates running low in sulphur, such as lead-silver concentrates. The slag loss is low in this case also and only about $3.00 value is left after milling.

Ore smelting in the electric furnace is new and conditions are vastly different from those in other furnaces, and while we have tested our furnaces on various types of ores and have worked these out satisfactorily, we are not resting but are working out new ones all the time. Some are not suited to the electric furnace, but a good many are and in the end our work may have been of some assistance in solving vexatious problems.

Pittsburgh Electric Furnace Company,
Pittsburgh, Pa

Recent Improvements in Uehling Carbon Dioxide Meters

The Uehling Instrument Company, of Passaic, N. J., have recently introduced several novel improvements in their CO_2 recorders and waste meters. To make a CO_2 meter of real value in a boiler room it must be foolproof and must operate without the attention or care of an expert. A great deal of the repairs and attendance required to keep a CO_2 recorder in first-class condition centers around troubles due to the use of a caustic solution and the necessity for its renewal, corrections for errors due to its evaporation or changes in temperature. Thus the principal object of the improvement sought by the Uehling Instrument Company, was to eliminate the caustic solution.

FIG. 1.—VIEW OF ONE BOILER PLANT OF THE CORN PRODUCTS REFINING COMPANY, EDGEWATER, N. J., WITH UEHLING DC WASTE METERS.

The use of any absorbent for CO_2, other than a liquid, would be impossible with any analyzer or CO_2 recorder in which the volumetric displacement of the caustic enters into the measurement of volume of gases. However, as the Uehling CO_2 apparatus does not measure CO_2 by measurement of volume of samples of gas but by a measurement of drop in pressure between two orifices where the CO_2 is removed, it is evident that a dry method of CO_2 absorption would be just as effective as the older or liquid method. Accordingly for some time past investigations have been made in the laboratory of the Uehling Instrument Company covering tests on different types of dry absorbent cartons, with special reference to their adaptability for simple renewal and effectiveness under different operation conditions.

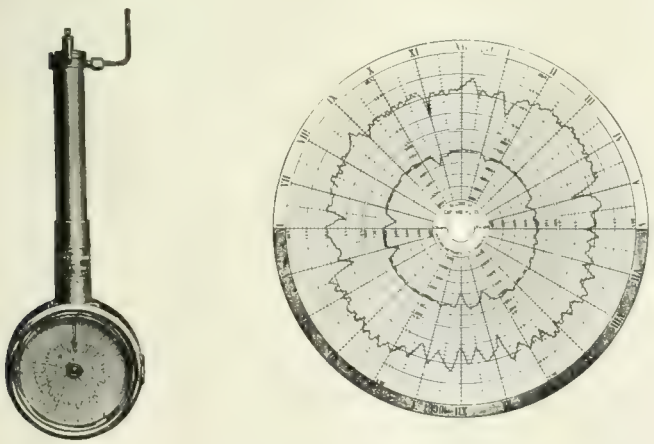

FIG. 3.—THE UEHLING M RECORDER, GIVING A CHART OF CO_2 OR TEMPERATURE, OR IF DESIRED, A COMBINED RECORD ON ONE CHART OF CO_2 AND FLUE GAS TEMPERATURE AS SHOWN IN FIG. 4.

FIG. 4.—CHART FROM UEHLING COMBINED CO_2 AND TEMPERATURE RECORDER.

Experimental work was completed about a year ago, and since then dry absorbers have been installed on practically every CO_2 apparatus out in service, and have been furnished with all new equipments. An installation of this type, which is also provided with the new type M recorder, further described below, is in the boiler plant of the Corn Products Refining Company, at Edgewater, N. J., where all of the twenty-four boilers are equipped with Uehling waste meters for measuring CO_2 and flue gas temperature, one boiler room being illustrated in Fig. 1.

The dry absorber cartons are cylindrical in shape, about 3 in. in diameter and 1½ ft. long, encased in a wax press board, so that they are handled, shipped and stored like ordinary dry batteries, for instance. The absorbent is a specially manufactured flaky substance named natron, carefully packed in layers within the carton. The carton is placed in the cylindrical chamber at the right of the machine, shown in Fig. 2, which illustrates the style S C machine, the operation consisting simply in removing a few wing nuts, removing the used carton and inserting the new one.

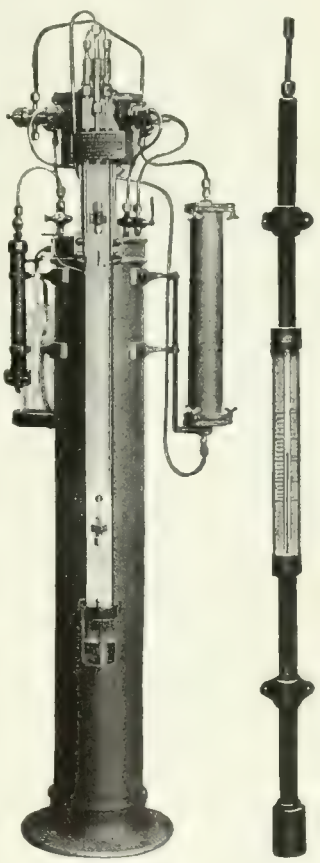

FIG. 2.—UEHLING SC WASTE METER WHICH IS A COMBINED CO_2 MACHINE AND FLUE GAS PYROMETER.

FIG. 5.—UEHLING CO_2 INDICATOR FOR LOCATION AT THE BOILER FRONT.

Other improvements in connection with Uehling CO_2 meters center around the recording devices proper. The Uehling CO_2 equipment consists of the machine in which the CO_2 is absorbed and the percentage of CO_2 measured pneumatically by changes in vacuum between two orifices, and then this vacuum is transferred to recorders or indicators situated where desired. The new type M recorder is shown in Fig. 3. It is for service in connection with CO_2 meters or the pneumatic pyrometer (operating on a similar principle) or the waste meter which measures both CO_2 and temperature. The type M recorder is simply a light pressure or vacuum recorder for vacuum or pressures, or both, from 0 in. to 60 in. of water column. When this is supplied for recording CO_2, the chart is calibrated from 0 to 20 per cent CO_2, and when supplied for recording temperature it is calibrated up to 1000 deg. or for other ranges as desired. This recorder supersedes a somewhat larger gage used in the past, but operated on the same principle, viz.: the U-tube principle being filled with a

special oil and involving no levers, pins, springs or similar devices.

In connection with Uehling waste meters, the CO_2 and temperature may be recorded on separate type M instruments properly calibrated, or else a new instrument just developed may be used and the temperature and CO_2 recorded on the same chart. This instrument, the type D M, is built on the same principle as the type M, but carries two pens and gives a chart as shown in Fig. 4.

Fuel Economy in Zinc Metallurgy, Power Production and Mining

By Joseph A. Dunn.

The problem of securing the greatest amount of energy from the fuel consumed for manufacturing purposes, or, in other words, burning everything burnable in the fuel and applying every unit of heat to some direct and definite end, whether that end be the heating of water for steam power, the roasting or smelting or ore, or some kindred purpose, has occupied the attention of engineers and fuel users for many decades. The manufacturer who got the greatest returns from the fuel consumed in the shape of heat energy had the cheapest power. In some instances the question of cheap power has meant success or failure to the manufacturer.

The cheapest power obtainable has been held to be water-power and next to that, in the minds of most manufacturers and engineers, has been natural gas. That ordinary coal can be burned cheaper than natural gas, even when the user of the gas can secure it at the rate of 3 cents per 1000 cu. ft. of gas, is a surprise to most users of fuel, but that this can be done has been successfully demonstrated in the gas fields of Pittsburg, Kan., by the International Engineering Corporation, of Denver, Col., which has installed several of the Parkison patent furnaces, owned by the corporation, under zinc ore roasters and smelters in that section.

A brief account of the furnace and the company will be given first and then concrete instances of commercial users of the furnace, with their opinions of it.

The Parkison furnace, patented and owned by the International Engineering Corporation, was invented by Colorado men to meet a special need in the mining regions of that state. Cheap lignite coal was plentiful near the Colorado Springs and Cripple Creek regions, while the higher-priced bituminous coal was shipped from a distance. Mine owners and engineers were seeking a means of burning this lignite coal. This means was found by J. Elmer Parkison, inventor of the furnace, and improved upon by Samual G. Porter and William Manhire.

The principle on which the inventors worked was a simple one. Scientists told them that the ordinary lignite coal should give better results than the bituminous coal as there was more gas in it to be consumed. Under the old furnace practice this gas, which is given off at a low temperature, was not consumed in the furnace but went up the chimney in the shape of thick, heavy smoke.

The problem of the inventors was to find some method of burning this gas in the firebox and applying the heat to the making of steam. This was done by a different method of firing the furnace, and instead of a thin layer of coal a deep fire-bed was used. The fire-bed in the Parkison furnace ranged from 18 to 24 in. in depth. This allows for slow combustion of the coal.

In addition to this deep fire-bed the Parkison furnace is constructed in a different manner from the ordinary furnace, in that it has two fire-boxes; the primary fire-box, where the heat from the carbon in the coal is used, and the secondary fire-box, where the gases, that ordinarily are allowed to escape up the chimney, are consumed. The only matter that escapes from the smokestack is the unburnable gas, which is practically the same color as the air, so that the furnace not only consumes everything burnable in the coal, but also acts as the most perfect smoke-consumer on the market.

The ashpit on the Parkison furnace is sealed and the door of it is not allowed to stand open. Only enough air to assist in the actual combustion of the coal is allowed to pass into the primary fire-box. This current is automatically regulated by a fan. With this air, which is introduced under the fire-bed, is a current of exhaust steam. The purpose of this steam is to decompose the coal, with the attending result that there are no clinkers to be removed from the fire-box of the furnace.

Another current of air, also automatically regulated, is allowed to pass into the secondary fire-box to assist in the combustion of the volatile gases that are given off from the coal in the process of burning. The temperature of this fire-box is ordinarily from 300 to 700 deg. higher than in the primary fire-box, showing that the best part of the coal is wasted in the ordinary flat-grate furnace practice.

The Western furnace company was organized to exploit the invention of Messrs. Parkison, Porter and Manhire. The company installed the furnace on a simple guarantee of delivering power from the use of lignite coal. Furnaces were installed under boilers in the Cripple Creek district and under roasters at the mills in Colorado City. Only lignite coal was used at this time and the furnace was exploited purely on its merits as a means to burn lignite coal. A strike in the lignite coal fields of Colorado cut off this supply and only bituminous coal was available. This fuel was used, and the furnace was discovered to be adaptable to it. Further experiments with the different fuels showed that the Parkison furnace could burn the different coals in Colorado at a great saving over the ordinary flat-grate practice or over any automatic-stoker practice in use.

The officers and directors of the Western furnace company then made experiments with the coals from other states and it was found that the furnace would burn at a saving all lignite coal, all the semi-bituminous coals and all the bituminous coals. In other words, it was discovered that the Parkison furnace could burn 90 per cent of the varieties of coal at a guaranteed saving of at least 15 per cent over almost every practice in use.

The International Engineering Corporation was then formed and the Western Furnace Company was made one of its subsidiary companies. The International Engineering Corporation is the parent company of the different subsidiary concerns that are being organized in the different manufacturing centers of America for the exploitation of the Parkison furnace.

The Parkison furnace is adaptable for use under all types of boilers. In addition to the actual fuel saving effected in burning all burnable qualities in the coal, builder's rating of the boiler is guaranteed. In fact, many installations of the furnace have been made on the contract that an overload of the builder's rating and a certain percentage of efficiency should be made in addition to a percentage of saving in the fuel bills.

The method of firing the Parkison furnace, and its different arrangement, not only eliminates clinkers in any kind of coal used, but reduces the percentage of combustible matter in the ashes. The ash removed from the ashpit of the furnace has the appearance of wood ashes, and there is not as much of it as under any other furnace now in use. In addition to this, chemical tests show that the ash will average less than 5 per cent combustible matter.

The Parkison furnace was recently installed in the smelters of the Pittsburg Zinc Company, of Pittsburg, Kan., to take the place of natural gas, which had been used by that concern for many years. The natural gas supply is becoming exhausted and the fact that the company could not renew its contracts for gas at 3 cents per 1000 cu. ft., or, in fact, could not get a guaranteed supply of the gas at any rate, caused the officers of the zinc company to look for a substitute for gas. They investigated the claims made for the Parkison furnace and decided to install four furnaces under one of their zinc roasters.

Using natural gas it cost the Pittsburg Zinc Company $1.75 per ton to roast their ore. This expense was divided as follows:

In a twenty four-hour day 1,500,000 ft. of natural gas at 3 cents per 1000 cu. ft. cost $45. This roasted 28 tons of ore. The services of two men at $2 per day brought the expense of roasting the 28 tons to $49—or $1.75 per ton.

The Parkison furnaces installed roasts the zinc ore at a cost of $1 per ton. This expense is divided as follows:

Six men at $2 per day, $12; 8 tons of coal at $1 per ton, $8; ore roasted in one twenty-four-hour day, 20 tons; or a total of $20 for the roasting of 20 tons of ore, which makes the cost per ton $1.

The experience of the engineer of the International Engineering Corporation at the plant of the Western Alkali Manufacturing Company, at Green River, Wyo., shows in a convincing way the fact that all the burnable matter in the coal is consumed and only waste material goes into the ashpit. The furnace was installed under a 282-hp boiler. The ashpit was sealed for forty-eight hours and the boiler was forced to deliver 312 hp. At the end of the forty-eight hours one ordinary wheelbarrow load of ashes was removed from the ashpit.

The management of the Vindicator Gold Mining Company, of Independence, Col., in the Cripple Creek district, says that the company saves approximately $1,000 per month with the use of the Parkison furnace under three of their boilers.

The Golden Cycle Mining Company, of Colorado Springs and Victor, Col., has thirty-six Parkison furnaces in its mill at Colorado City and its mine at Victor. The management of the company admits a saving of $1,300 a month under four boilers at Victor, and says that where the coal bill amounted to $3,800 per month before the installation of the furnace it is now only $2,500. At the mill in Colorado City the company has the Parkison furnace under ten Edwards ore roasters. Here the coal bill has been cut practically in two. The saving effected at the Golden Cycle mill is in the neighborhood of $200,000 a year.

The Crescent Mill & Elevator Company, of Denver, Col., is saved between 20 and 30 per cent in the fuel bill by the use of the Parkison furnace. In addition to this saving the engineers at the mill are able to secure an increase of 25 per cent in the coarse grain production and an increase of 15 per cent in the mill with the same boilers through the increased efficiency given by the furnace.

The Pewabic Consolidated Gold Mines Company, of Central City, Col., had the first repairs to make on a Parkison furnace after using it for three years. In addition to this the management of the company admits a saving in the fuel bills effected by the furnace to be over 35 per cent.

The management of the United Hydro-Electric Company, Georgetown, Col., figured that the furnace paid for itself in five months with the saving effected by it. This company supplies the towns of Georgetown and Idaho Springs, Col., with electricity. The plant is near Georgetown, and after the installation of the Parkison furnace the Western Furnace Company received a letter from the town officials of Georgetown thanking it for the elimination of the smoke nuisance from the electric plant through the use of the furnace.

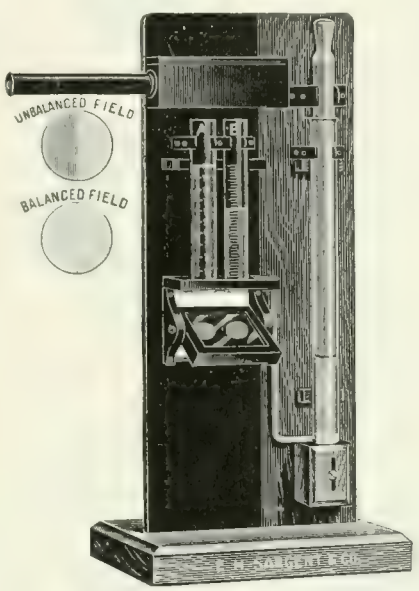
The Bull Hill Mining & Development Company, of Cripple Creek, saves 30 per cent in its fuel bills by the use of the Parkison furnace and, according to the management, has an absolutely smokeless stack.

The Darbyshire-Harvie Iron & Machine Company, of El Paso, Tex., has had the Parkison furnace in its plant for four years. The management of this concern says that the amount expended for repairs during that time has been trifling. According to W. C. Harvie, the manager, a statement that the furnace had saved the company 50 per cent in its fuel bills would be moderate. The furnace burns refuse from the city streets, and runs of ten hours are frequently made using no coal whatever.

The officers of the International Engineering Corporation are Samuel G. Porter, president; H. G. Cunningham, first vice-president; George P. Mason, second vice-president and general manager sales department, and Walter G. Christie, secretary and treasurer.

The Campbell-Hurley Colorimeter

The Campbell-Hurley colorimeter, which is shown in the adjoining illustration and which has just been placed on the market by Messrs. E. H. Sargent & Co., of Chicago, is a modification of the well-known Kennicott-Sargent colorimeter, the modification being in the telescope arrangement by which a person looking through the eyepiece observes a single circular field divided vertically by an almost imperceptible line when the two solutions are of the same intensity. By manipulating the plunger the level of the liquid in tube B can be easily raised or lowered, thus causing the right half of the image to assume a darker or lighter shade at will. The unknown solution is placed in the left-hand tube A, which is 19 centimeters long and 3 centimeters in diameter, and graduated for 15 cm., this graduation being subdivided into 10 divisions. The standard solution is placed in the right-hand tube B, which is the same size as A, the graduated portion being divided into 100 divisions of 1.5 millimeters each. The tube B is permanently connected by a glass tube with the reservoir, in which works the glass plunger. As the tube B and reservoir are made in one piece the liquid used for the standard solution comes in contact with glass only, thus preventing any possibility of chemical change due to contact with the container.



CAMPBELL-HURLEY COLORIMETER.

Tubes A and B, with the connecting reservoir, are held in position by the spring clamps, which allow the glass parts to be readily removed for cleaning and filling. The light for illuminating the solution is reflected upward through tubes A and B by means of the adjustable mirror. The light passing through these tubes impinges on two mirrors cemented to brass plates sliding in grooves cut at an angle of 45 deg. in the sides of the wooden box. This box is supplied with a loose-fitting cover, thus allowing easy access for the purpose of removing and cleaning the mirrors. One-half of the circular field of light from the tube B is cut off by one of the mirrors, the vertical edge of which acts as a dividing line between the two halves of the circular field. The image of the half of the tube B is then observed in juxtaposition to the opposite half of the image of the tube A. Concerning other details reference may be had to the *Journal* of the American Chemical Society, July, 1911.

Hydrocarbons in California.—According to the statistics of the California State Mining Bureau, hydrocarbons—including petroleum, natural gas, bituminous rock, exclusive of asphalt and all other refined products—were produced during 1911 in California to the value of $41,161,226. This includes: petroleum sold in 1911 or in stock at the end of the year $37,920,820, petroleum used as fuel in the field $2,631,268, natural gas $491,859, bituminous rock $117,279.

A New Vacuum Pump.

A new vacuum pump which should be especially valuable for chemical purposes has been placed on the market by the May-Nelson Rotary Pump, 508 Wilkins Building, Washington, D. C. It is of compact construction, not liable to damage, and capable of producing quickly a reasonably good vacuum, say a pressure of 0.1 to 1 mm of mercury or about one-thousandth of an atmosphere.

The May-Nelson rotary pump works on a new principle and differs considerably from any other pump now on the market.

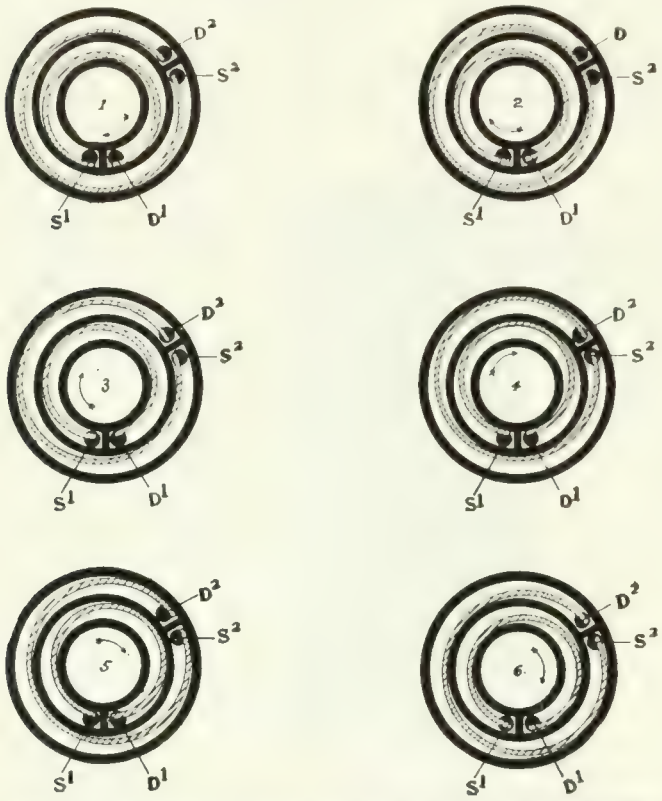


FIG. 1.—DIAGRAM ILLUSTRATING SUCCESSIVE STEPS IN OPERATION OF VACUUM PUMP.

It consists essentially of three parts only—the body, the impeller, or movable part, and the shaft, the whole being so arranged that rotation of the shaft imparts an eccentric motion to the impeller. In both body and impeller are cut a series of accurately concentric, equidistant, and similar grooves (for vacuum work, either two or three), so arranged that each of the projecting rings thus formed on either part dips into a corresponding groove on the other part. In each of the grooves cut in the body of the pump is inserted a radial dividing wall, on either side of which are drilled down the two parts corresponding to that ring; and corresponding portions of the projecting rings are cut away.

The mode of action of the pump depends upon the rolling contact made between the external cylindrical surfaces of either piece and the adjacent internal cylindrical surfaces. The principle is readily seen from Fig. 1, which represents a right section through body and impeller, in a plane close to the foot of the grooves in the body, in a series of six equidistant positions during one complete revolution of the shaft.

In the diagrams the cross-hatched rings represent the projecting rings on the impeller, which dip down into the corresponding grooves cut in the body of the pump, and in action roll against the adjacent cylindrical surfaces, those, namely, of the solid black rings.

In each diagram the position of the shaft is one-sixth of a revolution ahead of that in the preceding diagram. S_1 is the port connected with the vessel to be evacuated; D_1 is connected with S_2, and D_2 is the discharge.

Suppose that the direction of rotation of the shaft is such that the rolling contacts progress in the clockwise direction, and consider, for the time being, only the inner impeller ring and the contact which it makes with the innermost black ring. From the series of diagrams it is evident that the advance of this rolling contact is accompanied by the formation, adjacent to the port S_1, of a crescent-shaped space; this space first increases in size, thus sucking air in through the port S_1, is then successively closed off from S_1 and brought into connection with the discharge port D_1; finally, it decreases in size, thus forcing the air out through D_1. At the same time, though half a revolution later, the same process is going on at the contact between the outer cylindrical surface of the inner impeller ring and the surface adjacent to it (the inner surface of the middle black ring). Each ring is therefore double-acting; that is, it is effective at both its inner and outer cylindrical surfaces.

The air forced out through D_1 passes to S_2, thence round the outer ring, and is ultimately discharged through D_2. We thus have in such a pump two double-acting rings working in series. The dividing walls are set 120 deg. apart, in order that several of the contacts may always be effective obstacles in preventing the air from rushing backward; in other words, this arrangement prevents back-firing. The action of the three-ring pump is the same; the air passes round a third ring in series with the other two before it is finally discharged.

The action of the May-Nelson vacuum pump, therefore, depends upon the fact that the rolling contacts between the adjacent cylindrical surfaces push out the air ahead of them and ultimately force it out of the discharge ports. That the arrangement made use of in this pump should suck air at all seems at first sight somewhat surprising. Its effectiveness would appear to be due to the fact that we have a rather long contact, since it is between two surfaces of nearly the same radius of curvature; this, combined with the considerable viscosity of air and the high speed at which the pump may be driven, insures that the air is always pushed ahead of the rolling contact, and thus determines the action of the pump.

Fig 2. is a vertical section through the pump, scale about one-third. Driven by a ¼-hp., 800-r.p.m. motor, this pump evacuates a vessel holding 6 liters down to a pressure of about 0.1 mm of mercury in less than 2 minutes. It is capable of reducing the pressure, as measured on the McLeod gauge, down to 0.5 mm of mercury. Under favorable conditions it will

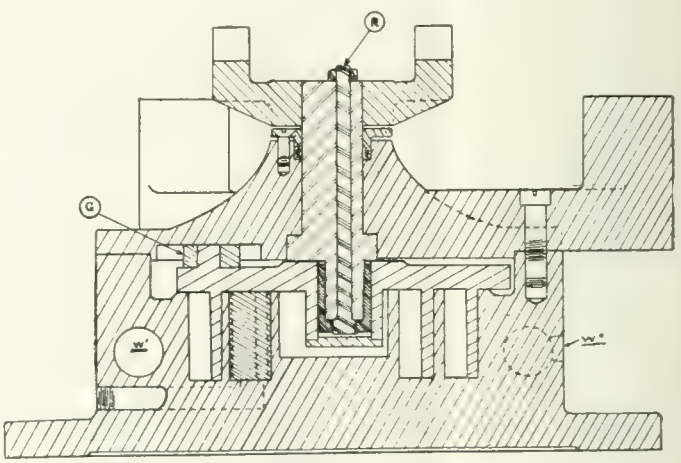

FIG. 2.—SECTIONAL DIAGRAM OF VACUUM PUMP.

produce pressures of the order of one-hundredth of a millimeter. Connections for efficient water cooling are provided; the cooling water circulates in the core W_1W_2, but it need not be used unless the pump is to be run for several hours continuously.

The section of Fig. 2 which is in the plane of the dividing wall on the inner ring exhibits the general dimensions of the rings and grooves and illustrates the mode of adjustment. When adjustment is required (which will be very seldom) it is necessary only to unscrew the lock nut on the eccentric adjustment rod R, to loosen this adjustment by tapping with a light hammer, and then to rotate the rod R clockwise until one feels that the impeller just touches the body of the pump. This figure also shows the guide-blocks G, the function of which is to prevent the ends of the impeller rings from knocking against the dividing walls on the pump body.

Fig. 3 is a view of the pump, complete with motor (scale about one-sixth). It shows the pump ready for action. A yoke joint is employed for connecting the pump with the motor; its employment saves trouble in accurately centering the motor, and admits of a slight vertical motion of the impeller.

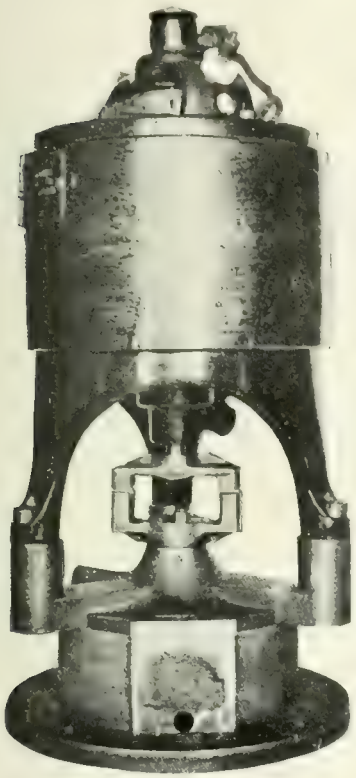

FIG. 3.—OUTSIDE VIEW OF VACUUM PUMP AND MOTOR.

The vessel to be evacuated is connected to the threaded hole.

The mechanical advantages of the pump are due to its compact construction. It has only one moving part, besides the driving shaft; hence it is easy to work and always in order. It is unbreakable, is direct connected to the motor, and requires no especial base; it may be set anywhere and does not need to be fastened down. It is entirely valveless, and in consequence requires but very little attention, lubrication or adjustment. Its action is rapid, and yet it gives a vacuum sufficient for all chemical, and for most other, purposes.

By leaving the suction side open, the pump produces a blast sufficient for several laboratory blowpipes; when driven by a motor of sufficient power the pump can be used to produce air pressure up to 100 lb. per square inch.

For chemical purposes the following fact is of especial interest: Water, or, indeed, any liquid which does not corrode the metal (iron), may be sucked through the pump without ill effect; in a very few minutes the pump will eject it all and evacuate as satisfactory as ever. This behavior renders this pump especially suited for vacuum distillations, since no intermediate condenser is required.

Electric Transformer Crucible Furnace.

To supply the demand which exists for a furnace midway between the small laboratory electric furnaces with a capacity measured in grams and the large commercial electric furnaces, the Allgemeine Elektricitäts Gessellschaft of Berlin has developed a furnace type which has just been placed on the market under the name of "transformer crucible furnace." With the exception of the smallest type, these furnaces are constructed in sizes for taking charges from 1 kg (2.2 lb.) up to 100 kg (220 lb.).

Each furnace unit is a combination of a transformer with a carbon crucible. The crucible itself forms the resistor. The secondary terminals of the transformer are connected by flexible copper conductors with two water-cooled contacts gripping the crucible, so that the secondary current from the transformer passes through the crucible and heats it. The carbon crucible is lined in a special way to prevent the carbon from having any effect on the charge and to prevent the current from passing through the charge.

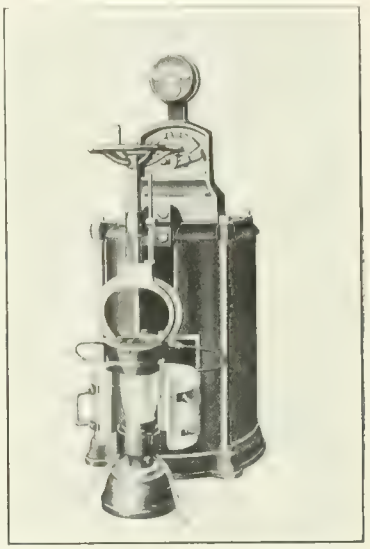

FIG. 1.—LABORATORY ELECTRIC CRUCIBLE FURNACE.

The transformer can be regulated so that up to twenty-four different rates of heating can be obtained. Besides the regulating switch an ammeter is provided for all except the smallest sizes.

This furnace has already been introduced in Germany into various industries, especially in gunmetal, copper, bronze, and iron foundries, for melting precious metals, glass, and enamels, in steel laboratories, and chemical and other industrial establishments.

The smallest size of this furnace, type TO, 00 has been designed specially for the use of dentists; if required tappings can be provided which enable the furnace to be operated at 1000 deg., 1400 deg., and 1800 deg. It is used especially by dentists for melting enamel, porcelain, gold, platinum, and the compounds employed for artificial teeth. All expensive auxiliary apparatus, such as ammeters, etc., are dispensed with in this type. The only part subjected to wear, is the carbon crucible, which is cheap and can be easily replaced by another one.

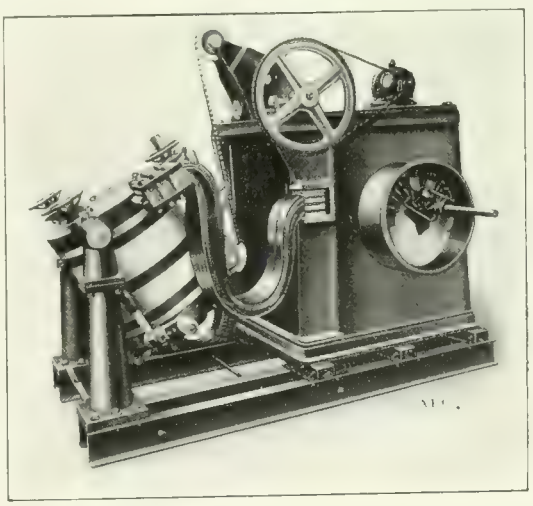

FIG. 2.—ELECTRIC CRUCIBLE FURNACE WITH TILTING DEVICE.

Fertilizer Convention.

The National Fertilizer Association and the Southern Fertilizer Association held their 19th annual convention in Atlantic City from July 15th to 19th.

The program of addresses and papers included the presidential address by President W. W. Hubbard, of the Peerless Fertilizer Company, of Chestertown, Md.; an address by Dr. Frank K. Cameron, of the U. S. Department of Agriculture.

on the present status of fertilizer enquiries, practical and theoretical; by Mr. W. H. Waggaman, of the Bureau of Soils, on the new phosphate deposits of America; by Prof. H. G. Bell, on the work of the Middle West Soil Improvement Committee of the National Fertilizer Association, and by Mr. Hoyt S. Gale on the U. S. Geological Survey's searches for possible sources of potash. The program also included two papers by Mr. J. S. Brogdon, Atlanta, Ga., on "the chemist versus the analyst," and by Mr. E. P. Verner, of Charleston, S. C., on "organic ammoniates and their availability," as well as addresses by Mr. W. W. Finley, president of the Southern Railway; Congressman A. F. Lever, and Prof. Andrew M. Soule, of the Georgia State College of Agriculture.

The entertainment committee went to a great deal of trouble to give the members and guests a good time, and was very successful in accomplishing this result. Young's Million Dollar Pier was the scene of most of the activities. A very interesting and carefully prepared Fertilizer Exposition on this Pier proved a particularly pleasant feature of the convention.

At the entrance of the exhibition was the fine exhibit of the Sturtevant Mill Company, which had the largest display of all. Other attractive and effective exhibits were made by Walker & Elliott, Stedman's Foundry & Machine Works, Kent Mill Company, Automatic Weighing Machine Company, H. W. Johns-Manville Company, American Cyanamid Company, Gardner Crusher Company, Gruendler Machine Company, Main Belting Company, Duryea Manufacturing Company, Jeffrey Manufacturing Company, Lehigh Car Wheel & Axle Company, Wiley & Company, Norton & Company, Schutte & Koerting, and many others.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (Continued).

568,099, Sept. 22, 1896, Louis Pelatan, of Paris, France, and Fabrizio Clerici, of Milan, Italy.

Relates to an apparatus for the extraction of gold or silver from their ores or compounds. The ores are pulverized and mixed with a solvent such as alkaline cyanid containing some sodium chlorid. The electrolytic cell consists of a rectangular vessel in which is a traveling endless belt, the surface of the belt provided with agitating arms. The belt may be made of metal and connected as an anode, or the belt may be of non-conducting material and a metallic anode inserted in the cell. The cathode is of mercury or of amalgamated metal, such as copper. In the operation, the endless belt, with its agitating arms, keep the ore and solution in constant agitation and the electric current assists in extracting the precious metals. When the operation is completed, the gold may be extracted from the mercury in any usual manner.

568,724, Oct. 6, 1896, Emile Andreoli, of London, England.

Relates to an electrolytic cell for decomposing cyanide of gold solution or similar solutions. The cell may be divided into compartments by suitable diaphragms and the bottom of the cell covered with mercury connected as cathode. A plurality of perforated plates or wire gauze sheets are electrically connected to the cathode. The cyanid of gold solution is applied to the cathode compartment and in the positive compartment there may be cyanid of gold solution or preferably a caustic potash or caustic soda solution. The anodes may be of iron or peroxidized lead, such as a positive plate. The cathodes are amalgamated by contact with the mercury, and present an enormous surface to the cyanid of gold solution. The gold solution enters the tank at the bottom above the mercury cathode and escapes in outlets at the upper part of the cell, from which is supplied to a second cell where the electrolysis is repeated. When the operation is completed, the plates are cleaned up and mercury recovered and retorted in the ordinary way.

568,741, Oct. 6, 1896, Henry R. Cassel, of New York, N. Y. York.

Relates to a process for extracting gold from its ores and other compounds by means of bromin solutions and means to regenerate such solution. A solution of a bromid of a suitable alkali metal is electrolyzed in a decomposing-tank containing anodes and cathodes of carbon or any material not affected by the solution. The cell also contains a diaphragm of asbestos forming anode and cathode compartments. The electrolysis accumulates bromin in the anode compartments, while potassium hydrate accumulates in the cathode compartment. Water is also decomposed, oxygen being set free at the anodes and there forms, with the bromin, an oxygenated or oxybromid solution. The pulverized ore, with the bromin solution, is placed in a rotating cylinder and therein thoroughly mixed until all the gold has been dissolved. After filtering, the tailings are leached by means of the potash solution above referred to. The potash combines with the bromin and with the bromid of gold remaining therein, and both are leached out The gold bromid solution is run through scrap iron and pieces of carbon and the gold rapidly precipitated thereby in a finely divided state. The resulting bromid solution from the iron and carbon treatment is re-electrolyzed, the process being continuous.

568,843, Oct. 6, 1896, Victor Engelhardt & Adolf Nettel, of Vienna, Austria-Hungary.

Relates to the extraction of metals, such as antimony, arsenic, and mercury, from their sulfur compounds. The metallic sulfid or compound is treated in a tank provided with a stirrer, with a soluble sulfid of the alkali or alkaline earth metals in aqueous solution, in order to convert the metal into a soluble double sulfid. The resulting solution of double sulfids is filtered, and the solution then decomposed by electrolysis, the metal being obtained in a solid form and sulfureted-hydrogen gas liberated.

571,468, November 17, 1896, Thomas P. Barbour, of San Antonio, Texas.

Relates to processes of treating gold and silver ores and recovering their metals by chlorination. The ore is first pulverized to eighty-mesh fineness and is then fed into a chlorinating tank. Within the tank, at the ends thereof, are electrodes of copper serving as poles for the transmission of the electric currents through the fluid pulp. The tank charged with the proper quantity of pulverized ore has added to it finely pulverized black oxid of copper in the proportion of about six or eight pounds to a ton of the ore and mixed with sufficient water to make a pulp of the consistency of thin mortar. To this is added sulfuric acid in a quantity equaling about two-thirds of the weight of the copper oxid added. The tank is then rotated for about an hour and a half. After this treatment, the rotation is stopped and a second charge introduced into the same, consisting of eight pounds of black oxid of manganese, thirty pounds of salt and twelve pounds of sulfuric acid. The tank is again rotated and an electric current is passed through the pulp until the chlorination is complete, after which the circuit is broken and the tank completely emptied. The gold and silver of the ore are held in solution as chlorids and are removed from the chlorinating vessel. The remaining pulp and wash-water are conveyed to the metal-precipitating tank, heated by steam which contains agitating-arms of metallic zinc. The electric current is passed through the solution from the agitating arms to electrodes at the periphery of the tank. The electric current quickly precipitates any remaining metallic silver and the zinc also serves to precipitate silver. When the precipitation is complete, the current is discontinued and the solution drawn off. The tank is now filled with water and agitation again commenced and continued for a suitable time, after which the pulp is allowed to

settle and the clear solution drawn off into a vessel containing the original gold solution. More water is now added to the pulp to give the same a suitable consistency and salt and granulated zinc are added. The mass is now taken to an amalgamating-pan for treatment. Mercury is added in the usual way, and the agitation in the amalgamation-pan is kept up until treatment is complete. The amalgam is collected and retorted as usual. To the gold solution, above noted, is added ferrous-sulfate solution, and the gold precipitated as a dark brown powder which is collected and fused. If copper is present in the ores, the solution from the zinc treatment is now treated with scrap-iron in the ordinary manner for precipitating copper.

573,233, Dec. 15, 1896, Max Netto, of Almazarron, Spain.

Relates to processes for precipitating silver and gold from their cyanid solutions and regenerating the cyanid solution. A cyanid solution containing gold and silver in the form of alkali double cyanids is acidulated with hydrochloric acid until a slightly acid reaction is obtained. Silver chlorid is thereby precipitated while the gold remains in the solution. The precipitation of silver chlorid is obtained according to the following equation, in which, for example, the combination of potassium cyanid with silver cyanid is assumed:

$$AgK(CN)_2 + 2HCl = 2HCN + KCl + AgCl.$$

The solution from which the silver chlorid has been separated still contains gold and is subjected to electrolysis, whereby this metal is deposited on the cathodes. Care has to be taken that the gold-containing solution contains a sufficient quantity of hydrochloric acid. After electrolysis, the solution is next mixed with caustic alkali until a slightly alkaline reaction takes place and the alkali cyanid thereby regenerated.

NOTES.

Ozocerite deposits occur in Utah in the vicinity of Colton and Midway Station, near Soldier Summit. The manner of separating the mineral from the associated shale and sandstone is to crush the rock and subject it to heat in boiling water. Ozocerite melts at from 54 to 70 deg. C., rises to the surface of the water and flows into receiving vessels. After cooling it is again melted to remove moisture, and is then cast in molds.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in April, 1912, was sixty-one. The quantity of ore milled during that period was 2,106,150 tons. There were 9991 stamps in operation, with an average duty of 8.20 per twenty-four hours. Tube mills in commission numbered 263. The yield for the month was 737,660 fine ounces gold. The quantity of ore treated and the gold recovered show a slight decrease compared with the preceding month, but a large increase over the corresponding month of last year.

A map of the Western mining districts has been prepared by the United States Geological Survey. Many of these mining districts are well known and have well-recognized boundaries, but others are more obscure. Bulletin 507, of which the map is a part, contains an introduction on geology and two plates showing the area covered by the Survey in geologic and topographic work. A separate map of each of the fourteen states shows the location and area of over 1400 mining districts. California is shown in two maps, the northern portion containing the largest number of mining sections, viz., 222. The smallest is the map showing the trans-Pecos section of Texas and contains only eleven districts. Copies of the Bulletin can be obtained free on application to the Directory of the Survey, Washington, D. C.

Tin and aluminium hold different positions in popular estimation. The former is regarded as quite common and the latter as less so. The price of the former is, however, twice that of the latter. The annual production of aluminium is far below that of tin, but the rate of production of the former is increasing about fifteen times as fast as the production of the latter. Twenty years ago aluminium cost about $1 per pound in Europe, having then just dropped from $4. At the same time tin cost 18 cents per pound. To-day the position is reversed, and tin is now worth in this country about 45 cents and aluminium 23 cents per pound.

Venezuelan iron ore mined by the Imataca Ore Company is said to be of a superior grade, averaging as high as 67 per cent iron.

The tenor of zinc and lead sulphide concentrates produced in Missouri in 1911 is shown in the following tabulation, which has been prepared by the United States Geological Survey:

	Per Cent Crude Lead	Metal Ore, Zinc.	Per Cent Lead in Lead Conc.	Per Cent Zinc in Zinc Conc.	Value per Ton Lead Conc.	Value per Ton Zinc Conc.
Southwest:						
Soft ground..	0.3	2.3	79.9	58.9	$54.41	$40.80

Southeast	3.7	. .	67.3	.	46.94	.....

The Bureau of Mines has recently published some interesting pamphlets. "Government Coal Purchases Under Specifications" is the title of Bulletin 41. "The Slagging Type of Gas Producer" is discussed in Technical Paper 20. "The Behavior of Nitroglycerin When Heated" is the subject of an investigation published in Technical Paper 12.

The First National Copper Company, which owns a copper smelter in California, is reported to be contemplating measures for re-opening the plant, which was closed in the recent agitation against smelter smoke. If possible, steps will be taken to bring the operation within the limit of the law.

The Ford Motor Company, of Detroit, Mich., for their new foundry for making automobile engines have contracted with the Rockwell Furnace Company, New York, for one of the largest installations of small core ovens in the automobile field. This installation consists of 24 ovens containing 88 shelves. The ovens are of the type known as the "reel type" core ovens, each shelf being a complete circle about 5 ft. in diameter, turning independently on a central axis. One-half the shelf is in the oven with the cores on it being baked while the other half of the shelf is outside, serving as a rack. Producer gas will be used as fuel. This type of core oven is especially adapted for automobile work in that it does away with the jar and jolt which arises when car-type ovens are used.

Water-proof Paints.—The 1912 edition of the "Red Book" of Messrs. Toch Brothers of New York City has just been issued. Profusely and nicely illustrated, it tells an interesting story on the Toch R. I. W. paints in an interesting manner. R. I. W. stands for "remember it's waterproof." These paints are the outcome of 64 years of researches and experience of Toch Brothers. Details are given of the properties of various of these paints for damp-proofing, water-proofing, steel protection and decorative purposes, with illustrations of some of the many modern buildings and skyscrapers in which the R. I. W. paints are used for such purposes.

PERSONAL.

Mr. W. J. Sharwood, chemist for the Homestake Mining Company, Lead, S. D., has been on leave of absence for six months, during which time he has been making investigations for the Bureau of Mines. He was in Denver about the middle of July en route west.

Mr. Walter L. Reid, superintendent of cyanide plant for the Smuggler-Union Mining Company, Telluride, Col., recently made a trip to Oregon, where he is erecting a modern cyanide mill.

Prof. S. B. Christy, dean of the school of mining, University of California, has been re-elected corresponding member of the Institution of Mining and Metallurgy, London.

Mr. D. N. Muir, who has charge of the interests of the United States Smelting, Refining & Mining Company in Arizona and at Needles, Cal., has removed his office from Kingman to Gold Rock, Ariz.

Mr. Arthur H. Carpenter, of Denver, has accepted a position on the chemical staff of the American Vanadium Company, Pittsburgh, Pa.

Mr. M. W. von Bernewitz, metallurgist of Kalgoorlie, Western Australia, sailed early in July for San Francisco.

Dr. F. G. Cottrell, of San Francisco, who is in charge of metallurgical investigations of the Bureau of Mines, expects to attend the International Congress of Applied Chemistry in New York in September. His route east will take him through Montana and Michigan.

Mr. D. C. Jacking, of Salt Lake City, has gone to Alaska. Before starting north he made an inspection of the Butte & Superior Company's mine and mill at Butte.

Mr. Arthur H. Roller, of Idaho Springs, Col., manager for the Hudson Reduction Company, has been appointed to a similar position with the Argo Ore Purchasing & Reduction Company and will build a new mill for the latter company.

Mr. Victor G. Hills, of Denver, is making a professional trip into the Yukon Territory, Canada.

Mr. E. C. Van Diest, of Colorado Springs, Col., has been appointed by the governor of the state to serve as trustee of the Colorado School of Mines, vice Franklin Guiterman, resigned.

Mr. W. W. Fisher, chief engineer of the Standard Underground Cable Company at Perth Amboy, N. J., was elected president at the meeting of the fifth international convention of the Esperanto Association of North America.

BOOK REVIEWS.

Systematic Treatment of Metalliferous Waste. By **L. Parry.** 12 mo., 14 x 21½ cm., 121 pages; price 5 shillings (in New York, $2,00). London: The Mining Journal.

An interesting book for the metal handler, poorly written as far as style goes, somewhat alchemistical in its formulae and terminology, rambling in plan and unsystematic in detail, and yet worth while. Without knowing the author, the book seems to warrant the guess that he is an eminently practical man of the old school, one who has known and worked with metals, drosses, wastes and junk all his life, who has not been blessed with a modern chemical education, but who knows metals by that long experience which engenders intuitions.

The materials considered are lead, tin, antimony, copper, nickel, and zinc wastes of all sorts. The information about reducing and refining these is very practical, but the reader must dig it out, avoiding being misled by odd forms of expression and queer ways of putting things. The author's experience and enthusiasm atone for the many literary defects of the book, and his willingness to impart his hard-won knowledge and to share it with the world are certainly worthy of commendation.

* * *

Die elektrolytische Alkalichloridzerlegung mit starren Metallkathoden. By Dr. **Jean Billiter.** Part I: Patent Literature. 16 x 24 cm., 284 pages, 189 illustrations; price, 16.50 marks (in New York, $5.50). Halle: Wilhelm Knapp.

This is a compilation of German, British, and American patents on the electrolytic decomposition of alkaline chlorides, using solid metal cathodes. In each case the patent claims are given *verbatim,* followed in most cases by an illustrated description of the subject matter of the patent. Part II., which is to appear this year, will contain a description of industrial plants operating these processes.

* * *

Eisenhochofenschlacken, ihre Eigenschaften und ihre Verwendung. By Ing. Chem. **Hans Fleissner.** 19 x 28 cm., 57 pages, 32 illustrations, 3 plates; price, 3 marks (in New York, $0.75). Halle: Wilhelm Knapp.

This brochure is directed particularly towards the qualities of blast-furnace slag, which determine its suitableness for Portland cement. The estimation or description of slag from this point of view is very practical whenever cement is to be made from them, and it also gives a new point of view from which to regard slag characteristics. For the latter reason the wide-awake blast-furnace metallurgist will find his knowledge of slags in general increased by reading this book.

The labors of Vogt and Doelter are satisfactorily utilized in explaining the constitution, fusibility diagrams and surfaces are discussed, and texture and color are considered.

The practical part includes granulation, utilization for slag-wool, pumice, glass, road-metal, bricks, hydraulic cement, and Portland cement. The information contained is valuable to any man interested in these lines.

* * *

Der Praktische Hochofenbetrieb. By **Theodor Bender.** 17 x 24 cm., 124 pages, 16 illustrations; price, 2 marks; in New York, $2.10. Halle: Wilhelm Knapp.

An eminently practical book on the blast furnace by a practical metallurgist. The various chapters deal with the building of the furnace and accessories, raw materials, products, blowing-in, regular running and changing the running, repairs, interruptions, banking, blowing-out. Throughout economic considerations are more in evidence than scientific explanations. The spiegeleisen practice, discussed at some length, will particularly interest our blast-furnace men. Our chief criticism is that the operation discussed is rather small-scale practice in Germany, which does not fit exactly the general economic and commercial conditions of America.

* * *

Gemeinfassliche Darstellung des Eisenhüttenwesens. By the Verein Deutscher Eisenhüttenleute. 8th edition. 15 x 24 cm., 416 pages, 63 illustrations, numerous diagrams; price, 5 marks (in New York, $1.60). Düsseldorf: Verlag Stahleisen, m.b.H.

The first part, 180 pages, is beautifully printed and illustrated on calendered paper, and forms an elementary treatise on the metallurgy of iron. It is well written and the illustrations are works of art. This part alone is well worth the price of the whole book to a student or general reader.

The second part, over 200 pages, contains commercial statistics of the iron industry, including coal and coke, in 30 different countries, brought up to the close of 1910; also statistics of international commerce in ore, iron, steel, and scrap, with information as to tariffs brought up to 1912.

An appendix of 30 pages gives more detailed statistics of iron and steel works and foundries in Germany. It is a most excellent work, cheap and good.

* * *

Chemical Works, Their Design, Erection, and Equipment. By **S. S. Dyson** and **S. S. Clarkson.** Octavo, 15 x 25 cm., 207 pages, 80 illustrations, 9 plates; price, 21 shillings (in New York, $7.50 net). London: Scott, Greenwood and Son. New York: D. Van Nostrand Company.

The authors have aimed to give the fruit of twenty years' experience in designing chemical plants, including even working drawings of typical installations. Starting with the site, foundations, roads and trackage, the general lay-out of the plant is discussed, then power house and other accessories.

The actual chemical plant is illustrated by the following types: Sulphuric acid, hydrochloric acid, nitric acid, high explosives, ammonium sulphate, fertilizer works. The concluding chapters deal with other generally used equipment not previously described, saw-mill and box department, the Alkali and Chemical Works Regulation Act of Great Britain, and general remarks on profit sharing.

It is an exceedingly practical book, which will be highly valuable to the beginner in chemical engineering and useful to every works manager or engineer in the chemical engineering profession.

Metallurgical and Chemical Engineering

A Consolidation of Electrochemical and Metallurgical Industry and Iron and Steel Magazine.

Vol. X | New York, September, 1912. | No. 9

PUBLISHED MONTHLY BY THE

Electrochemical Publishing Company

J. W. Richards, Ph.D., President.
James H. McGraw, Vice-President.

This month, besides the regular September number, an extra issue will be published on September 12, the day before the close of the Eighth International Congress of Applied Chemistry. It will contain a complete report of the Congress proceedings up to the evening of September 11. It will be distributed at the Congress and mailed to all regular subscribers.

Congress Eve.

Now that the Eighth International Congress of Applied Chemistry is about to convene, the individual responsibilities and individual opportunities of every American chemist loom large. For the first time in the series of these Congresses the United States is to take the pleasant part of the hostess. The organizing committees have finished their work and if most careful and systematic organization can assure success, a great success is assured for the Congress as a whole. The duties of the individual now become of decisive moment.

The object of the Congress is twofold—the promotion of the discussion of professional questions and problems and social intercourse. The national chemical societies of the different countries have done much through their meetings and publications to break down the secretiveness which modern chemistry inherited from medieval alchemy. An international congress must be able to accomplish a great deal more. Its members are enabled directly to put themselves in touch with the chemical knowledge of all the rest of the world, to derive inspiration from meeting the leaders of chemical thought from many countries and to benefit by their free and generous criticism.

Twenty-four volumes of papers printed in advance, one for each section of the Congress, will be available when the Congress meets. For the first time in the history of the Congresses a committee on papers and publications has been given an opportunity to rule with an iron hand. None but papers passed by this committee will be on the program. Their number is some 700. The result is a finished program. When the sectional meetings start they will be able to proceed in medias res. The fact that many papers are printed in advance, and the further fact that the time for presentation of the papers is limited, should insure good and extended discussions. And it is, after all, the discussions of the papers, not their presentation, which must be of prime importance.

However important the serious professional discussions, the social functions of the Congress will be of equal moment. The presence of so many visitors from abroad will afford an opportunity for cultivating that close personal international intercourse upon which all mutual action for the common good of mankind must be based.

A true American welcome awaits our visitors from abroad. Nothing will be left undone to promote their comfort and happinees and to make them quickly and wholly feel at home

in America. We hope that they will enjoy their stay in our country, that they will improve their opportunities of getting a personal insight into our civilization and the spirit of our people, and that in their visits to American chemical works they may perceive the American individuality.

To the hearty words of welcome by Dr. Backeland, Dr. Doremus, and Dr. Maynard, printed elsewhere in this issue, we need add nothing. What Europe has done for American chemistry is history. The welcome that greets our European friends is but an echo of the welcome that Europe has extended to so many chemists in years past. Love begetteth love.

The Cosmopolitan Quality of Metallurgical Engineering.

The practice of the art of metallurgy is world-wide, and its rapid progress is due to the achievements of many men in many places. Metallurgists have become a cosmopolitan lot, at least through name and reputation, if not by actual travel and residence. A moment's reflection will afford striking instances of the extent to which practice has been modified the world over by the inventions of men once obscure, but later known to the whole fraternity. In some cases we have witnessed a veritable triumphal march of a process or machine from the place of its origin to every country on the globe where it was applicable.

Take stock, for example, of advanced cyanide practice, and its method of application in almost any modern mill. We find in use a chemical principle discovered and developed in Scotland; air-lift agitators invented in New Zealand; tube-mills adapted from the cement industry and first extensively used in gold metallurgy in western Australia; vacuum filters, of one sort or another, the pioneer type of which originated in Utah; slime thickeners and zinc-dust precipitation apparatus, also developed in the United States, and many accessories adopted from world-wide practice. Further argument is not required to show that exponents of good metallurgy have been free from provincial prejudice in constructing plans and executing designs, and have shown themselves ready to adopt ideas from a foreign land.

Other instances of the world-wide adoption of locally invented machines and processes could be multiplied. There are well known examples, also, showing a keenness on the part of metallurgists to adopt principles from other industries. The metallurgy of zinc as originally devised by German and Belgian engineers, is standard practice in the United States and other spelter producing countries; and despite the efforts constantly being made to devise some new and more efficient process, it is likely to lead the way for a few more years to come. This process combines adaptions from other important industries. The manufacture of retorts is a branch of the potter's art; the distillation process bears an analogy to the distillation of other gases, and the calcining of zinc carbonate ore is similar in chemical and mechanical aspects to the burning of lime, and has been carried on in the same manner. Latterly, the manufacture of sulphuric acid has become an important branch of zinc metallurgy, thus reaching into the domain of the chemical engineer. Among machines which have found a wide use in ore-reduction, may be cited German ball-mills in Australia, California stamps on the Rand, and Colorado-made concentrating tables in every country where the concentration of ore is an important industry.

Obviously, such a widespread use of machines, and uniformity of processes, could not have been accomplished by personal effort or without some medium for the rapid transmission of ideas. In this respect, numerous societies, congresses and technical journals have played their important part in promoting the cosmopolitan character of metallurgists and their art. Engineers have contributed freely of their knowledge and experience, often traveling great distances to present personally their ideas. The printed record of their work is distributed all over the world, for every prominent metallurgical society, wherever situated, finds members in foreign countries, eager to learn what their fellow-workers are doing elsewhere. This mutual exchange of knowledge and experience has been the most potent factor in our progress.

In the United States we are on the eve of a convention which exemplifies in the highest degree the cosmopolitan spirit of which we have been speaking. The International Congress of Applied Chemistry meets in this country for the first time. Berlin, Rome, and London have been the scenes of former meetings. Chemists from every country will be gathered in New York in September, for mutual profit and pleasure, and the result should be still further to cement fraternal ties, and wipe out international lines as far as science is concerned.

A Note on Modern Mill Construction.

The use of concrete and structural steel has revolutionized the style and method of building large mills for ore treatment. Advantages have appeared in convenience, cleanliness and beauty. Machines have been more appropriately placed in relation to each other; they are usually accessible for repairs and observation of the work they are doing; ore pulps and water are confined in iron pipes and concrete launders, and there is a welcome absence of the sloppy conditions which formerly characterized many mills. And finally, all of the equipment is housed in a large, airy, well-lighted and comfortable building, in which the attendants work under agreeable conditions, and the casual visitor finds it possible to view operations without being arrayed in overalls and rubber boots.

But with all these features, desirable as they are, the use of concrete and steel may be carried to an extreme in mill construction. The economic limit is set by the fact that the present is an age of rapid progress and radical change in ore treatment, and the mill which is built along such rigid lines that it cannot readily be adapted to improvement, will be handicapped by its inflexibility. The cost of altering or removing concrete and steel structures is not small, and this very fact may necessitate a continuance of operations under conditions which are known to be deficient and not in accord with the best practice.

We do not recall an important mill which has not undergone alterations more or less extensive, involving either a rearrangement of the machinery first used or a complete substitution of different machines to effect better results. The point to be observed is that progress is rapid and change is inevitable, and construction should proceed with that in view. Here is no argument for cheap construction, but a caution against designing and building a mill, and arranging the machinery and its foundations, as though the last word had been spoken in the particular process employed. To-morrow may bring to light an improvement which ought to be adopted. It becomes neces-

sary then to investigate the possibility of adopting that improvement, balancing the extra profit to be gained against the cost of the change. It may be found that the very excellence of the original construction has introduced an obstacle which cannot readily be overcome without excessive expense, which otherwise might have been avoided. There is an economic limit beyond which refinement and permanency of construction should not be carried, keeping in mind the strong probability that alterations will be required by future progress.

The Iron Industry and the United States

From the commencement of the manufacture of "sowe iron" at Lynn, Mass., in 1645, America has certainly made much progress. It was no handicap to America that in many other countries the manufacture of iron was established many centuries earlier, for the whole alignment of the industry has been recast so often that experience has furnished little aid. It has, indeed, been an advantage to the American industry that its large increase in capacity has been in such recent times, for this has permitted the adoption of the most recent ideas in the new construction. Unfortunately there are no statistics to show when the United States passed in tonnage the countries which had earlier established their iron industries. The earliest statistics of the production of pig iron which we have at hand show the United States as holding second place in the family of nations, and in 1890 first place was assumed. It is interesting to observe the pace at which pig iron production was then increasing in the United States. In 1890 this country made 9,202,703 gross tons of pig iron, to England's 7,904,214 tons, and yet that was the first year in which the United States made more iron than England. What is remarkable is that the maximum output of the United Kingdom had occurred eight years earlier, with 8,586,680 tons in 1882, a year in which the United States produced only 4,623,323 tons. Germany in 1890 produced only 4,658,450 metric tons of pig iron. In the present year the United States will make about 29,000,000 tons of pig iron to Germany's 17,000,000 tons and Great Britain's 10,000,000 tons. The production of the United States will thus exceed the combined output of its two nearest rivals, and will indeed constitute more than 40 per cent. of the world's output, which will be in the neighborhood of 70,000,000 tons.

It is not a detached circumstance in the rationale of development of the American iron and steel industry that the tonnage has thus enormously increased. There is an intimate relation between this rapid increase in the tonnage and the manner in which the commercial material has been made. We do not assume that the great increase in tonnage has been due primarily to the activity of the producers, but assume rather that it has been due to the ability of the country to consume. Backed by the necessary raw materials, the producers have simply met the demand. In meeting the rapidly increasing requirements they have not had time to develop any great metallurgical processes, but have rather adopted them ready made from the older countries. What they have done is to practice everything on the largest scale. When they learned how to build blast furnaces, they built them larger than their teachers, and so through all the processes they have adopted, winding up in recent months with the largest electric steel refining units in the world.

We would not slight the part which the possession of magnificent raw materials has played in permitting this remarkably rapid development of the American iron industry. Connellsville coke, of remarkable purity and excellent physical structure, was a necessity in the years when there were no chemists to tell the manufacturers what could be used under this and that set of conditions, and Lake Superior ore, pure, cheaply mined and abundant, was a necessity to the industry which has doubled its tonnage production every decade since that remarkable group of ore deposits was discovered a little more than half a century ago.

In the parallel development of iron mining and steel making there has been what appears to us, however, as a curious piece of luck. In the early days of rapid railroad building the universal demand was for Bessemer steel rails. Given the ore, they were cheaply made, and were incomparably harder and more durable than the iron rails which preceded them, and the United States found itself, in the Lake Superior region, fortified with what seemed to be an unlimited supply of pure Bessemer ores. As time passed, engineers began to express a preference, in many cases, for open-hearth over Bessemer steel and—here the curious coincidence—it began to be discovered that there was not an unlimited supply of Bessemer ores in the Lake Superior region, but that there was a much larger quantity of non-Bessemer ores, above the phosphorus limit for the acid Bessemer process and quite suitable for the basic open-hearth process, though in no case have any Lake Superior ores been found of sufficiently high phosphorus for the practice of the basic Bessemer process so much used abroad. The raw material at the one end and the critical engineer at the other both dictated a change. The engineer at first looked at the basic open-hearth steel askance when the steel maker first cheerfully proffered it to him as a substitute, and had the steel maker wavered the engineer might have triumphed. He could not waver, for though he could have made acid open-hearth steel for a time, eventually the scarcity of ore would have curtailed the growth of the industry. He made good basic open-hearth steel and the engineer accepted it. Thus we find that the maximum production of Bessemer steel occurred six years ago, in 1906, and while this year's production of steel promises to be fully one-third greater than that of 1906, the production of Bessemer steel will not be more than two-thirds as large. The rough sketch of the contest of the processes may be completed by observing that the output of acid open-hearth steel is practically no larger than it was a decade ago, while the output of basic open-hearth steel is double what it was in 1906, quadruple what it was in 1903 and twenty times what it was in 1897, only 15 years ago.

Since the first inception of steel making in the United States the industry has seen alternate periods of capacity exceeding demand, and of demand exceeding capacity. After the rush of 1907 it was thought that for a period of years, perhaps half a dozen, capacity would prove in excess of demand and with reduced prices in the domestic market foreign markets were sought with renewed vigor, the result being that while for several years exports had averaged but slightly more than a million tons a year, in the past few months they have averaged a rate of more than 3,000,000 tons annually, and the United States is beginning to take its place with England and Germany as an important exporter of iron and steel products.

Non-Ferrous Metal Market.

The August market has been generally dull and without feature. In some cases lower prices have prevailed, while in others the prices have been maintained in anticipation of future business. Consumers seem to be well supplied, both at home and abroad, and sales are made for immediate requirements only.

Copper.—The market has been unusually dull, but prices have been maintained by the leading agencies. Lake copper has been in nominal demand only, and its price has been approached closely by electrolytic. The latest reports are: Lake, 17½ to 17¾ cents, and electrolytic, 17.45 to 17.50.

Tin.—The foreign market declined after the Banka sale, and the domestic market has been without feature. Prices for August delivery averaged about .45⅛ cents.

Lead.—Prices have fallen since our last report. On Aug. 5 the American Smelting & Refining Company reduced its price to 4.50 cents, and a better demand has resulted. The closing quotations are: 4.50 cents, New York, and 4.35 to 4.37½ St. Louis.

Spelter.—The premium on spot metal has disappeared and most of the transactions are for future delivery. Some business has been done for the fourth quarter of the year. Prices are slightly lower, averaging 6.90 to 7 cents, New York, and 6.75 to 6.85 cents, St. Louis.

Other Metals.—A more active market is noted in aluminium, antimony and quicksilver. Fair sales of aluminium have been made at 24¼ to 24½ cents, New York, and prices are firm. Business in antimony continues active, with prices ranging from 7.50 to 8.50 cents for various grades. A premium has been asked for spot metal of Cookson's brand. In quicksilver, the New York market quotes flasks of 75 lb. at $42.50, with slightly higher prices for small lots. At San Francisco the quotation is $42 for domestic and $39.50 for export business.

The Iron and Steel Market.

The finished steel market has been passing through one of the most remarkable periods in its history, for in July and August, which normally are very dull months, prices have been steadily advancing, specifications have been very heavy and the attitude of sellers has been increasingly optimistic. Producers of steel express the opinion that the course of the market has been absolutely without a parallel. They deny any similarity with the movement in 1909, when as may readily be recalled the market improved rapidly and steadily from June until almost the close of the year, prices advancing by an average of about $5 a ton. It is possible that their refusal to admit that there is any similarity is due to their recollection that the 1909 improvement was short lived, being followed by a year of sagging prices and decreasing production, so that if present conditions are similar to those which obtained in 1909 the outlook is distinctly unfavorable, rather than extremely favorable, as is generally claimed. While the statement is freely made that conditions are not similar to those obtaining in the summer and fall of 1909, it is not possible to back up the statement with concrete facts, for in the ultimate analysis the question is whether buyers are buying speculatively, whether any large part of the increased demand is due to buyers replenishing stocks, anticipating requirements by filling specifications early, depending on the crowded condition of mills to delay delivery, and actually accumulating stocks for speculative purposes. In 1909 it was denied that such conditions existed, yet the experience of 1910 showed that they had existed. Time will tell, and meanwhile it may be observed that neither buyers nor sellers are evincing any disposition to be conservative. The former are advancing prices and the latter are buying freely.

Throughout the industry stoppages for repairs in July were as short as possible, and production was but little reduced from this cause. Hot weather also caused a slight curtailment. By August repairs were practically all completed, and weather conditions in the month were unusually good for the season so that August production showed a material increase, closely approximating, if not actually exceeding, the June rate. There is every prospect that the steel mills will operate at substantially full capacity through the balance of the year. Merchant blast furnace operations, which represented not more than 60 per cent of capacity, have increased, and further increase is promised in the next month or two.

Bars, plates and shapes were advanced at the beginning of August by $1 a ton, and about August 20 another increase of $1 a ton became effective upon plates and shapes. The exact *modus operandi* of these advances is not fully understood. The public is frequently assured that there is no semblance of a price agreement in the finished steel trade, whereas the suddenness of the advances, which occur almost overnight, does not suggest entirely open market conditions. Only in a market of extreme strength could advances become universal in such short periods.

A composite of the leading finished steel products, including bars, plates, shapes, tubular goods, wire products, sheets and tin plates, shows that the low point in the present year (a point slightly higher than the November low point of last year) obtained in the latter part of February and the early part of March, while from then to the middle of June there was an average advance of $2 a ton and from the middle of June to the close of August there was an advance averaging slightly more than $2 a ton, so that prices advanced more rapidly in what is usually a dull period than they did in what is usually an active period.

Pig Iron.

Pig iron has shown a more sharply advancing tendency than at any previous time in this upward movement, which began about the first of the year. The recent advances are attributable not so much to there being a large tonnage bought as to demand closely approximating, if any actually exceeding, the current rate of output. At such a critical stage a small variation in either demand or production makes a very large change in the course of the market. For many months demand slowly increased while stocks decreased and production remained almost stationary. It is possible that the current melt of merchant pig iron is now in excess of the current make. As a rule idle furnaces do not readily get into blast, as prices are still low, and the idle furnaces are largely those which were forced out of the running long ago, before prices had declined to the extreme low point. The principal pig iron advances since late in July have been: Southern and Chicago foundry iron, 50 cents; Eastern foundry, 25 cents; Eastern basic, 50 cents; valley foundry and basic, 50 cents; valley Bessemer, 25 cents. We now quote: Southern foundry, Birmingham, $12; foundry iron, f. o. b. Chicago furnaces, $15.50; No. 2X, delivered Philadelphia, $15.75; basic, delivered eastern Pennsylvania, $16; foundry, basic and malleable, f. o. b. valley furnaces, $14; Bessemer, valley, $14.75.

Steel.

Unfinished steel has grown extremely scarce in the different markets. Several months ago the Chicago district mills withdrew as regular sellers of billets. Later most of the Pittsburgh mills withdrew and then steel became scarce at Youngstown and in the East, leading to a condition in August in which there was little steel obtainable in the Central West, except occasionally from brokers and small mills, the Eastern mills remaining as sellers, but at advanced prices. The market stands approximately as follows, f. o. b. maker's mill, Pittsburgh or Chicago: Bessemer billets, $22.50; Bessemer sheet bars, $23; open-hearth billets, $23; open-hearth sheet bars, $23.75 to $24; rods, $25 to $26. Large consumers had large contracts for the current quarter, but their requirements have been so heavy that they have specified the maximum tonnages permitted in the contracts, and have endeavored to buy additional tonnages, but as prices have been much above the contract level the purchases have been relatively light.

Finished Steel.

A summary of advances in this movement in steel tubular goods is as follows, each advance being one point or about $2 a ton: Boiler tubes, May 21 and August 1; Merchant pipe, June 1 as to 6 in. and under, July 1 as to sizes above 6 in.; July 25 as to all sizes; Oil country goods, June 1 as to 6 in. and under, July 1 as to sizes over 6 in.; August 1 as to all sizes. The total advance in all steel tubular goods in this movement has thus been about $4 a ton.

Current prices, f. o. b. Pittsburgh, unless otherwise stated.

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Light rails, 16 and 20 lb., 1.24 cents; 25 to 45 lb., 1.19 cents.

Plates, tank quality, ¼ in. and heavier, 1.40 cents.

Shapes, 1.40 cents.

Steel bars, 1.30 to 1.35 cents.

Steel hoops, 1.40 cents.

Iron bars, 1.40 cents, Pittsburgh; 1.35 cents, Philadelphia; 1.40 to 1.45 cents, Chicago.

Sheets, blue annealed, 10 gage, 1.50 cents; black, 28 gage, 2.05 cents; galvanized, 28 gage, 3.15 cents; painted corrugated, 28 gage, 2.20 to 2.25 cents; galvanized corrugated, 28 gage, 3.10 to 3.20 cents.

Tin plates, $3.50 for 100-lb. cokes.

Merchant steel pipe, ¾ to 1½ in., 79 per cent off list.

Steel boiler tubes, 3½ to 4½ in., 73 per cent off list.

Standard railroad spikes, 1.65 cents, Pittsburgh; 1.75 cents, Chicago.

Electric Steel Refining at Bethlehem Steel Co.

The Bethlehem Steel Company, of South Bethlehem, Pa., manufacturers of tool steel, armor plate, projectiles, and other lines of high-grade steels, have decided to install the Girod electric furnace which shall enable them to produce a much

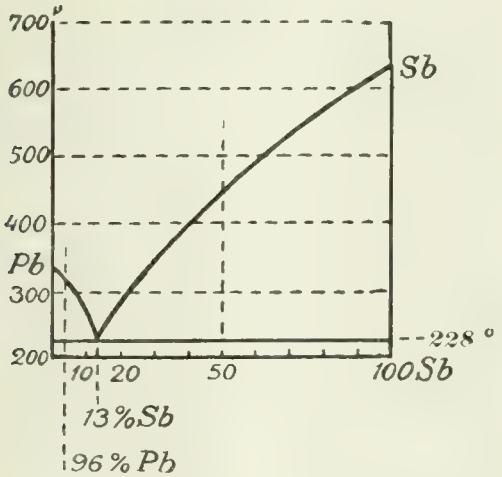

FIG. 1.—MELTING-POINT DIAGRAM.

larger quantity of special steel. The first Girod furnace to be installed by the Bethlehem Steel Company will have a melting capacity of 10 tons per heat.

Among the European users of the Girod furnace is the famous firm of Freidr. Krupp, of Essen, Germany.

The design of the Girod furnace and the progress which it has made in practice, have been the subject of numerous notes and articles in former volumes of this journal, among which should be especially noted the paper by the inventor himself, Mr. Paul Girod, in our vol. VII, p. 259 (1909), the description of the electric steel plant of the Société Anonyme Electrométallurgique Procédés Paul Girod in Ugine Savoy, France, in our vol. VII, p. 9 (1909), and the paper by Mr. Müller on Girod furnace practice in Gutehoffnungshütte, Germany, in our vol. IX, p. 581 (1911).

The Production of Porous Metals*

A Novel Application of Eutectic Alloys for the Production of Storage Battery Plates.

By H. I. HANNOVER.

The eutectic alloys has the lowest melting point of all the alloys that can be made of the same two metals.

Fig. 1 shows a diagram of the conditions of solidifying for all the alloys of *lead* and *antimony*. The abscissas give the composition of the alloys, in percentage of the antimony, and the ordinates the temperatures of solidifying. Thus the ordinate to the left refers to pure lead (0 per cent Sb) with a melting point of 328 deg. C. and the ordinate to the right to 100 per cent antimony with a melting point of 630 deg. C.

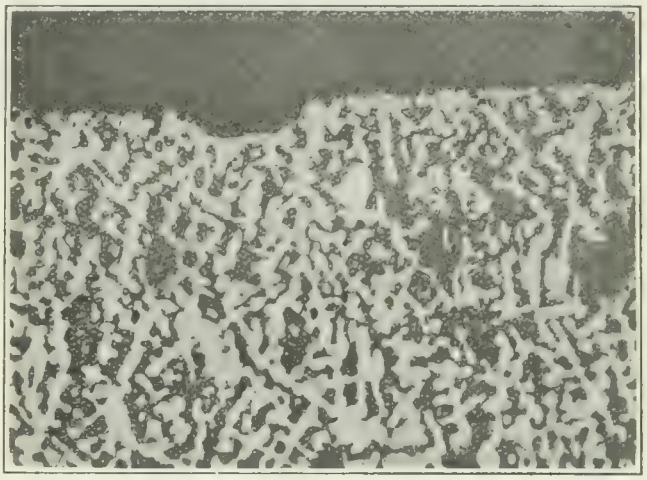

FIG. 2.—POROUS LEAD PLATE.

It will be seen from the diagram that the alloy with 13 per cent antimony and 87 per cent lead has the lowest melting or solidifying temperature of all the alloys 228 deg. C. This is the eutectic alloy. After solidifying it shows up in microscope as alternating leaves of lead and antimony. All other alloys of the two metals may be considered composed of the eutectic alloy and lead, or the eutectic alloy and antimony. If, for instance, an alloy with 50 per cent antimony has been melted and is allowed to cool, lumps of antimony will begin to form, at a temperature of about 450 deg. C. As the temperature goes further down the mass becomes more and more lumpy. When the temperature of 228 deg. C., is reached, all tre antimony has solidified, which does not belong to the eutectic alloy, and at this temperature the eutectic alloy solidifies at once.

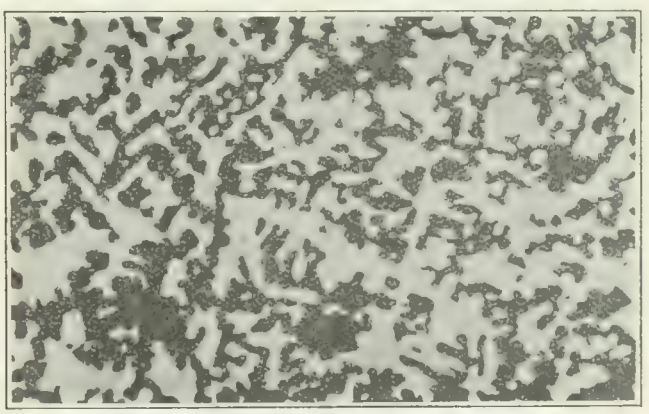

FIG. 3.—POROUS TIN PLATE.

If on the other hand an alloy consisting of 4 per cent an-

*Translated in abstract from *Zeitschrift*, June 15, 1912.

timony and 96 per cent of lead is completely melted and is cooled down, then at about 315 deg. C. crystals of lead begin to form, and as the temperature goes further down, more and more crystals are formed, until a coherent body of lead crystals is produced. However, in this are still millions of fine pores

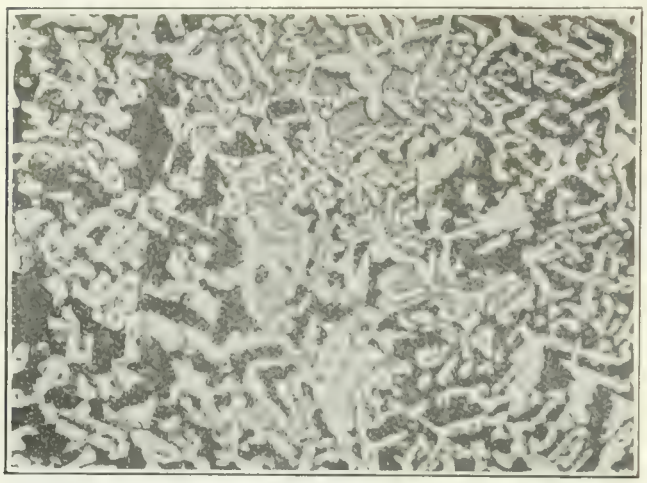

FIG. 4.—POROUS ANTIMONY PLATE.

filled with the melted eutectic alloy. As soon as the temperature has gone down to 228 deg. C., the content of the pores, the eutectic alloy, solidifies at once. This contains all of the four per cent of antimony, which must be connected with $4 \times 87/13 = 27$ per cent lead. The previously solidified lead was therefore $100 - (4 + 27) = 69$ per cent of the whole amount of the alloy.

Inversely, if a solidified plate is heated, the veins of the eutectic alloy will melt first. This is the basic principle of my new process for the production of porous metals.

After trying different methods for removing the melted eutectic alloy from the lead (or antimony) body, I finally adopted a centrifugal separator.

When I first started these experiments, it was from purely scientific interest. Not until I had the method fairly well in hand, it occurred to me that there might be a practical field for such porous plates as material for electric storage batteries.

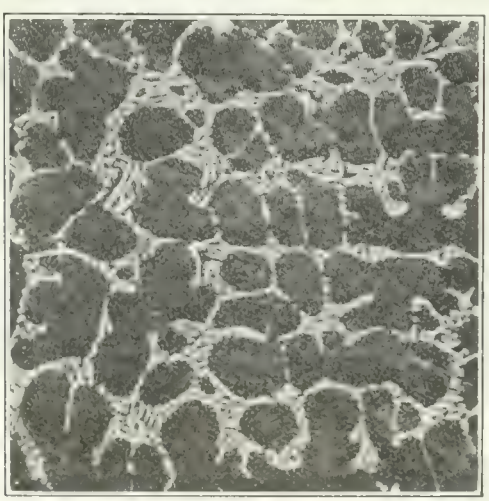

FIG. 5.—94 LEAD, 6 ANTIMONY ALLOY.

I made some experiments with bismuth and cadmium, but finding that they were too high in price to be considered for any practical purpose, I have since confined myself to the lead-antimony alloys. With a percentage of lead of 96 per cent, as described above, almost all the antimony is driven out with the eutectic alloy; but a very thin film of this remains on the walls of the pores, and after solidifying it strengthens the lead plate, without decreasing noticeably its efficiency as accumulator plate. According to tests made by Professor Rung, accumulators of such porous lead have 4 to 4½ times as high a capacity as an ordinary accumulator of the same weight.

Professor Henry LeChatelier in Paris, has taken much interest in the results obtained so far, and has made the invention the subject of a lecture before the Academie des Sciences, and by his courtesy the accompanying micro-photographs of

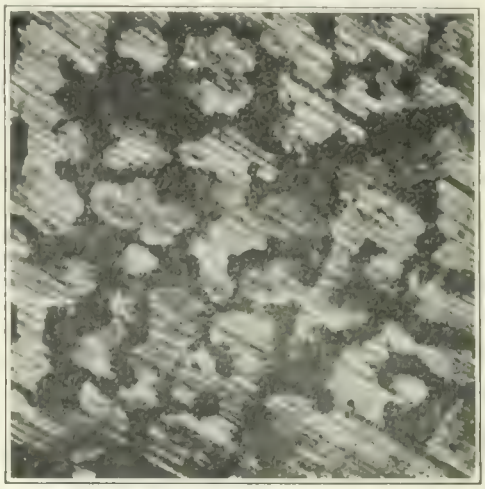

FIG. 6.—SAME PLATE AS FIG. 5 AFTER REMOVAL OF EUTECTIC ALLOY.

cuts through some of my porous plates have been made. Fig. 2 shows a cut through a porous lead plate, Fig. 3, through a porous tin plate, and Fig. 4 through a porous antimony plate. From the latter the eutectic alloy had not been driven out properly; what had been left in the pores shows up gray in the cut. The magnification for all of these photographs is 40 diameters.

Fig. 5 shows a cut through an alloy of 94 per cent lead and 6 per cent antimony, as it will solidify if not interefered with. Fig. 6 shows the same after heating, melting of the eutectic alloy, and removal of the same. The last photograph does not show up clearly on account of a poor microtom-knife having been used for cutting through the plate. For the last two photographs the magnification was 15 diameters.

The future will show if this invention is to be of any practical value. But I do not think I am claiming too much in claiming for it some scientific interest. For thousands of years man has known massive metals, but only a few special cases of porous metals, in small amounts, as for instance, spongy platinum, and now at once we are enabled to produce a number of metals as porous metals and in large quantities. Furthermore, this is an invention which a man with purely practical education would not have been able to make, as he is without knowledge of the microscopical structure of the alloys.

CORRESPONDENCE.

Drying Air for Blast Furnaces.

To the Editor of Metallurgical and Chemical Engineering.

Sir: The paper by Mr. Bruce Walter on his new dry blast process, presented before the Engineers' Society of Western Pennsylvania and published in your August issue, p. 471, is certainly of considerable interest. But I cannot help but think that the discussion would have been more complete if someone had taken the pains to refer to the admirable paper by Mr. J. E. Johnson, Jr., read before the Iron and Steel Institute in 1906, and abstracted in your volume IV, p. 349 (September, 1906).

In this paper Mr. Johnson showed the absolute necessity for

two-stage refrigeration, both from the point of view of low first cost and operating efficiency, and the necessity, from the same points of view, of doing away with the indirect system of brine circulation. He also gave methods of calculating power requirements which are almost childishly simple as compared with those of either Mr. Walter or Mr. Carrier, although the latter's contribution to the discussion is quite remarkable.

Mr. Johnson's paper of six years ago seems to have been a little ahead of the time. But even now Mr. Johnson's paper deserves the most careful attention of everyone interested in the subject, since in that paper the fundamental principles which must guide all future inventors are clearly outlined.

East Orange, N. J. EDWARD BERL.

Some Observations on the Amount of Combined Carbon in Pig Iron.

To the Editor of Metallurgical and Chemical Engineering.

Sir: In the August issue of your magazine were published two very interesting photomicrographs of electric pig iron, with a discussion of its properties. The unusual features are the absence of sulphur, and manganese, the low percentage of phosphorus, and the total absence of combined carbon.

The latter fact directs our attention to the omission of data concerning the conditions under which the iron was cooled, particularly from solidification, to the pearlite transformation point. Though this omission is quite common in the literature of the subject, the matter is none the less important for the correct application of the micro-structure to the physical properties of castings made from the iron.

It is well known that current furnace practice varies widely on the rate of cooling hot metal from a liquid condition to ordinary temperatures. The extreme example is the pig machine, which does the job in a very few minutes. Probably the average practice in sand cast furnaces is to allow the iron to cool in the sand for an hour or less, and then chill with water from a

FIG. 1.—MICROPHOTOGRAPH OF ORIGINAL PIG. 10 DIAMETERS.

more or less bright red heat in about 40 minutes. At the other extreme might be cited a furnace that runs cinder over the pig beds after the iron is run, and allows the latter to cool by radiation entirely, taking at least three times the average.

That a change in the rate of cooling will exercise an important influence on the amount of carbon remaining combined with the iron, is only another way of stating the well-known fact that the reactions $\left.\begin{matrix}\text{cementite}\\ \text{austenite}\end{matrix}\right\} \longleftrightarrow \left\{\begin{matrix}\text{austenite}\\ \text{pearlite}\end{matrix}\right.$ will show a considerable lag if the rate of cooling is accelerated.

This is well illustrated by Figs. 1 and 2. Fig. 1 is a section cut from the center of a sand cast pig that had been cooled in the regular manner practiced at that furnace. The pig was then melted in an ordinary pot furnace in a plumbago crucible, with the usual precautions to prevent oxidation. About 75 lbs. was used, and from the melt, a short pig was poured in fairly dry cast house sand. This pig was allowed to cool by radiation without being removed from the sand. At the end of 2½ hours, the pig could be handled with the hands, and was therefore well below the transformation range. The cooling of this second

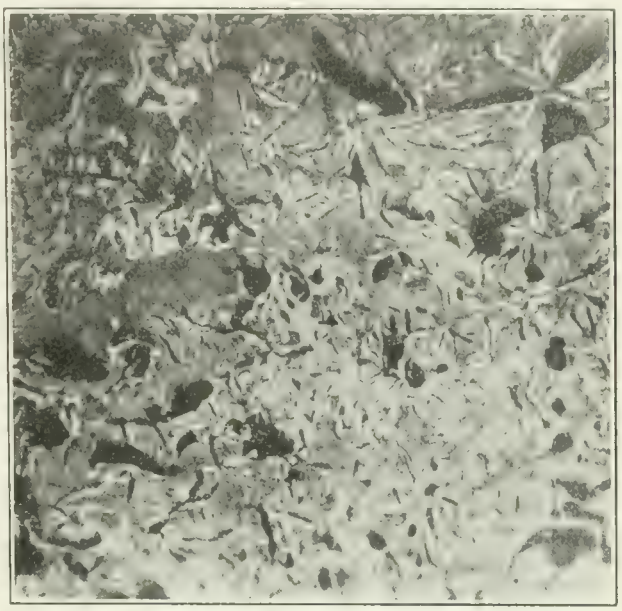

FIG. 2.—MICROPHOTOGRAPH OF NO. 1 AFTER REMELTING AND COOLING NATURALLY. 10 DIAMETERS.

pig, then, could not have been more than 1 hr. slower than that of the first pig at the furnace. Fig. 2 is a section from the center of the remelt. Both samples were etched with 5 per cent picric acid solution in alcohol, and photographed at 70 diameters.

Fig. 1 shows nearly eutectoid pearlite, with a small amount of excess ferrite, and some phosphide eutectic. Fig. 2 however, shows a marked difference, in that there is a large amount of excess ferrite, and a correspondingly smaller amount of pearlite. The phosphide eutectic is present in about the same proportion as in the former sample. The following analysis, made by another chemist, will show that the change in combined carbon cannot be attributed to a different proportion of metalloids in the second sample.

Fig. 1.		Fig. 2.	
Si	1.20	Si	1.10
P	.256	P	.250
Mn	.40	Mn	.38
S	.035	S	.038
T.C.	4.00	T.C.	3.91
Graphite	3.26	Graphite	3.35
C.C.	.74	C.C.	.56

It will be noted that only 0.10 per cent of the silicon has been oxidized and only 0.09 per cent of carbon. The fact that phosphide eutectic appears in both samples would tend to eliminate phosphorus as a factor. Therefore, it seems safe to conclude that the slower rate of cooling in the remelt has resulted in materially lowering the combined carbon. This conclusion has been confirmed on samples containing widely varying proportions of the metalloids.

It is believed that a further study of the conditions affecting the proportion of combined carbon to graphite and to total carbon will prove extremely useful in solving some of the practical problems in the complex metallurgy of cast iron. In view

of the fact that the microscope is just beginning to assume practical importance in this field, it would seem that we could not be too careful to study out and record all the conditions that may have a bearing.

Pittsburgh, Pa. C. T. Dawkins.

* * *

To the Editor of Metallurgical and Chemical Engineering.

Sir: Replying to Mr. Dawkin's friendly criticism of the article by Mr. F. C. Langenberg and myself upon a "Microscopic Study of California Electric Furnace Pig Iron," the writer would say that he is fully aware of the influence which the rate of cooling has upon the structure of iron and upon its relative graphitic and combined carbon content. However, as it was impossible to obtain exact data as to the manner in which the pig was cooled from which the specimen was taken, and which was used in making the microphotographs, we made no mention of this point in our article, but we expect in a future study of this subject to fully take this factor into account.

Pittsburgh, Pa. D. A. Lyon.

The Present Situation in the American Institute of Mining Engineers.

To the Editor of Metallurgical and Chemical Engineering.

Sir: The American Institute of Mining Engineers has labored for some years under three separate difficulties.

1. Ill-defined division of responsibility, in the dual control of its activities, between the Board of Directors and the Council.

2. The independence of the Secretary of the Council, because of his election by the Institute at large, of the body he is supposed to serve; an illogical situation.

3. The possibility afforded, by the present form of Constitution and By-Laws of placing the management of the entire affairs of the Institute in the hands of a single individual.

The directors are made solely responsible for the funds and property of the Institute by the incorporation laws of the State of New York. The Constitution places the management of all its professional and social affairs in the hands of the Council who may, and who have in the past, in arranging them incurred indebtedness for which the directors are responsible; but in which they have frequently had no voice. This should be changed so that no expenditures can be incurred except on previous appropriation by the Board of Directors.

The secretary has been the executive officer and has the power, under the Constitution, of incurring debts in the name of the Institute, auditing the bills and paying them without consulting either of the governing bodies.

As shown in the report of the committee of five, the Institute has for some years been short of funds. Its annual income has not sufficed to meet all of its financial obligations.

The main reasons for this condition are:

1. The expense incurred by the interest in the United Engineering Society Building.

2. High salaries and inefficiency in the office work.

3. The large proportion of life members whose commutation of dues has been spent for current expenses as fast as received, while the obligations of the Institute to them are continuous.

4. The large number of delinquent members carried on the books and supplied with publications.

Together the life members and delinquents are about one-fourth of the total, so that the entire expenses are paid by about three-fourths of the membership.

It is generally admitted the Constitution should be amended, and in so doing we believe the difficulties mentioned above should be borne in mind and every effort made to remove them.

It is hardly possible to do away with the dual control of directors and council without putting the control entirely in the hands of the New York members, which they do not desire, and which would not be for the good of the Institute. The incorporation laws place the responsibility so entirely in the hands of the directors that in order to have meetings most of them must be residents of New York or vicinity, or the power be delegated to an executive committee of such residents which amounts to the same thing.

For this reason the dual control will have to be continued.

The undue influence of the secretary of the council should, and can be, obviated by abolishing his election by the membership at the annual meeting and by letting the council elect their own secretary subject to their own pleasure. A one-man management can be prevented by changes in the Constitution and by-laws precluding the occupancy of certain offices by the same individual.

Two policies have been in mind for the future management of the Institute. One is a continuance of the present predominating influence on the part of a single individual; the other a practical divorce of the business management and the professional activities so that they will not come in contact except at a single point.

In the past the Institute has had an especially versatile and energetic secretary; but even in this case the number of those who have not agreed with his policy has increased until they now probably constitute a considerable majority of the Institute. Even if it were desired to continue what is practically a one-man management, and if an individual combining all of the necessary qualifications could be found it is doubtful whether the Institute, with its present obligations and comparatively small membership could afford to pay sufficient to obtain him.

We believe it would be better, at least for the moment, to have a business manager selected by and responsible to the directors and have the editorial work, so far at least as the selection of material goes, performed by a committee on papers and publications, as is done by most similar societies who attempt to manage their affairs economically; the papers so selected to be turned over to an editor and the business manager, who would attend to the details of publication and distribution.

The expenses of the United Engineering Society Building have been incurred and must be provided for. It is therefore either necessary to increase the income of the Institute, decrease its expenditures, or both.

The former result can be obtained by making the Institute of greater value to its members which would probably result in increasing the membership, the latter result by more efficient management at the head office and by eliminating various subsidiary activities not strictly a part of the Institute's business.

We believe that the membership can be largely increased, as other societies of similar aims and scope have grown largely in the past few years, while the Institute has stood still. An increase in the membership beyond the present number will increase the income much more rapidly than the expense, so that a comparatively small number of additional members would place the Institute in an easy financial position.

We believe this to be a better and surer way of providing the needed funds than to increase the dues, which would undoubtedly cause enough resignations to make the financial result uncertain.

When a large proportion of the members are dissatisfied and are asking themselves whether they are getting a proper return for their money it is a bad time to ask them to pay more unless they can be clearly shown that they are to receive an adequate return.

We believe that by lopping off some unnecessary expenditures, by still closer supervision on the part of the Board of Directors considerable economies can be effected without in any way curtailing the work which the Institute was called into existence to do.

The Eve of the Eighth International Congress of Applied Chemistry

An American Welcome

Reminiscences of the Congresses of Berlin and London.

To the Editor of Metallurgical and Chemical Engineering.

Sir:—When I think of it I feel astonished that almost ten years have elapsed since that sunny morning when we all gathered before that imposing Reichstags Gebäude in Berlin. From our little group of about thirty American chemists arose many a "Hello old chap" interchanged with a "Wie geht's" or some other hearty exclamations, renewing friendships made long ago in German universities, until after a while all these happy exclamations catalyzed the gathering to a spreading fermentation of friendly feeling and rapidly increasing cheerfulness.

And then followed busy days in all the different sections, much engaged in their own specialties, from where we emerged now and then to meet all together at the general functions, lectures, and receptions without end. The most memorable event was undoubtedly the general meeting in the Reichstags Gebäude. That imposing building of the German Parliament by itself lent much dignity to the meeting at which were present some representatives of the imperial family; the whole session assumed the impressiveness of a function of state.

Well do I remember also how some of our Americans who stayed all at the Hotel de Rome hesitated to leave the hotel at nine o'clock in the morning, dressed up in regular evening suit to conform to the officially prescribed continental etiquette. Some of the more formal of our New Yorkers insisted that we had misread the German directions and that "frock coat" was intended. It was only after they had seen some congressionists walking happily and unconcernedly in the full sunlight of the street, with white starched shirt bosoms, white neckties and swallowtails, that they, too, pitched up their courage to don their evening suits.

The "white necktie" appeared to be a very essential thing then and the governmental usher at the door was very particular on this subject. I saw him refuse admission to a friend of mine, a well known Russian chemist, because he had a dark necktie. But this serious difficulty was soon adjusted by my resourceful Russian friend, who tore off his black necktie, and then walked in without further trouble and without a necktie, screening the front button of his collar under his beard which looked like a bunch of oakum.

Our German hosts had spared no opportunity to prepare us an elaborate program of entertainments of every kind, and on every occasion blossomed their national virtue, "Gemütlichkeit," which shall ever linger in the memory of all of us who were there. While I am scribbling this there still rings in my ears that hearty, wholesouled laugh of our Dr. William McMurtrie, at that time so brimful of interest for all that happened, and so keenly alive to all the latest chemical work which was then going on. Alas! dear Mac, we shall miss you much this time when your cruel sick-bed will keep you away from so many of your friends of all nations.

To my regret I was unable to be present at the Rome Congress, which from all reports was a worthy successor of that of Berlin; but I had the good fortune to participate at the London Congress. Never shall I forget those days of the spring of 1909 when our little band of American chemists, some with our wives, left on the steamer Kroonland, where we soon acquired the happy feeling that everything on the ship, inclusive captain, stewards, brass band, pantry and refreshments, belonged to the American Chemical Society. Brother Wiley made wit and humor so contagious that the Captain soon relinquished his presiding seat at the table to better listen to the never ending repartee and declamation of the apostle of pure food and good stories.

The inaugural meeting at the Royal Albert Hall, presided by the then Prince of Wales, now the King of England, and his wife, made a fitting counterpart of the similar function of the Berlin Congress. Sir William Ramsay as president of the Congress had arranged a program at least as imposing as that of any of the predecessors; all this was blended with the gentle, charming English hospitality displayed on so many occasions.

The official reception at the Foreign Office was a very brilliant affair. One of the most distinguished and elaborate social functions was the feast offered by the American Ambassador. This was preceded by a dinner party, where the six or seven American Government delegates were invited with their wives. After the dinner was over, we were led to the immense drawing room of the embassy, where a reception was held and which soon filled with the elite of chemical and diplomatic representatives of all countries. Dorchester House with all its sumptuous halls added to the impressively generous scale on which this reception was conducted, yet with it all there reigned a note of dignified cordiality which largely contributed to the success of the evening.

And now the time has come when we shall be able to try to reciprocate all the hospitality, all the favors which we have received abroad. I take it for granted that none of us who has been to any of the past congresses will need to be urged to do his best to keep up the reputation of American hospitality.

Men like Dr. Nichols, Dr. Hesse, have now spent more than two years of their best energies to make this Congress a success; they have been warmly seconded in their efforts by the executive committee and by many others who have often neglected their daily duties, have submitted themselves more than once to great inconvenience to be present at the numerous preparatory meetings.

But this is not enough, we need the help of all. Let every chemist of the United States, every chemical manufacturer or chemical merchant, any one who is convinced of the growing importance of chemical science, use his best efforts to make this Congress, not only an honor to our Republic, but an opportunity to show gratitude and appreciation for the inspiration and help this country has derived and is receiving daily from the able work that is carried on abroad. Every progress of chemistry involves the direct benefit, not of one nation alone, but of the world at large.

The past work of Lavoisier, Scheele, Humphrey Davy, Liebig, Pasteur and many others who have left us long ago still makes deep imprints on the welfare and the intellectual development of every nation of the earth.

The work of the chemist of today confers in no lesser degree benefits of unrestricted international magnitude. A chemical discovery made today in one part of the world finds its applications everywhere. Nay, more, it quickens the pulsations of the imagination of thousands of chemists of other nations; it induces them to follow any new path just laid bare by a pioneer; it stimulates further and more exhaustive research. This is the main reason why nowadays the development of a new conception proceeds with a rapidity never known heretofore in the intellectual development of our race.

Bear in mind, fellow Americans, this country cannot rival even with the smallest European monarchy in pomp and display of governmental functions. Neither should we have the slightest cause of regret for this; we can abundantly make up for all this if we will endeavor to display our best qualities as private

citizens come together to honor our distinguished foreign guests.

Fellow Americans, up till now your busy occupied life may have left you unaware of the event which is fast approaching. Well, just now, drop all your petty private matters, your business cares for a few days. Don't say you cannot spare the time; a few years more you will be dead and you shall have to spare everlasting eternity. If you have a wife, daughter or sister who is not hopelessly without brains, take them along; it will do them good to observe some of the real work of the world and they will later on take more interest in your own work. Mingle with your fellow chemists of many nations, listen to them, let them be your teachers, measure your own work, your own thoughts by theirs. Do not limit yourself in your hospitality to the sheer display of expensive entertainments—any nobody with more money than you can outdo you in this. But offer your fellow chemists the very best you have in you, something money cannot purchase—a high thinking mind and a cheerful brotherly heart.

And then, after the Congress is over, be thankful to have received this splendid opportunity for renewed inspiration in witnessing the brilliant results of the efforts of others. This is the most powerful way to make the Congress an immense success and to honor our guests.

LEO H. BAEKELAND.

Yonkers-on-Hudson, N. Y.

Influence of Paris Congresses.

To the Editor of Metallurgical and Chemical Engineering

Sir:—You have asked me to pen a welcome to our French confrères. Though using English they will easily interpret the cordiality and sincerity of my greeting.

As our friends approach this city they will surely be delighted at the sight of that idealistic tribute of friendship which their compatriots have erected as an expression not only of amity between the two nations but as symbolical of Liberty. It would be quite appropriate for Bartholdi's masterpiece to salute them as they pass through waters where Fulton made steam navigation real and where now the hydroaeroplane rises bird-like from the surface to circle about the statue and soar over and under the many bridges.

On the reverse of the medal struck in honor of Berthelot's semi-centenary of research is the inscription:

"Pour la Patrie et la Verite."

Let us imagine the goddess of Liberty, her torch aflame, transformed into the goddess of Truth, mirror in hand, and that the first President of the American Chemical Society, John W. Draper, is closing his inaugural address:

"Nature, the mother of us all, has inscribed her unfading, her eternal record on the canopy of the skies, she has put it all around us on the platform of the earth!" * * * To those who in purity of spirit worship in her heaven-pavilioned temple, she offers her guidance to that cloudy shrine in which Truth sits enthroned, "dark with the excess of light?" Thither are repairing, not driven by tyranny, but of their own accord, increasing crowds from all countries of the earth, conscious that whatever their dissensions of opinion may heretofore have been, in her presence they will find intellectual concord and amity."

May the love of Liberty and Truth guide the deliberations of the Eighth International Congress of Applied Chemistry and cement the bonds of the brotherhood of Nations.

While ancestor worship is preeminently an attribute of Orientals hero worship is common to Occidentals. But the heroism of deeds of War is giving place to the heroism of deeds of Peace.

Pasteur was by popular vote of the nation acknowledged as the greatest of Frenchmen. The beneficient results of his researches have been felt throughout the world.

It was appropriate for the members of the Second International Congress, held in Paris, in 1896, to place a commemorative wreath upon his casket, then resting in the great cathedral of Nôtre Dame.

The visits afterwards made to the Pasteur Institute, where patients were seen receiving the treatment for rabies, and to the suburban laboratory where the anti-toxins, especially that of diptheria, were prepared, demonstrated most forcibly that he had created a new era in medicine. Having been able to assist Dr. Valentine Mott to make the first inoculations of rabies in this country, from virus obtained from rabbits brought from Paris, at a time when medical men held aloof and made disparaging comment on the treatment, it is most gratifying to know that it is now not only recognized as the sole and proper treatment for hydrophobia, but is officially endorsed.

Such topics interested Pasteur in his last days, but how wonderfully successful were his researches in fermentation, in silkworm disease, in chicken cholera, and his earliest work on the tartrates, initiating new conceptions in theoretical chemistry.

The Second Congress had for its president the renouned Berthelot. He too was a master in many fields. Synthetical

MARCELIN BERTHELOT.

chemistry; the direct union of hydrogen with carbon to form acetylene; the preparation of compounds representing almost every group in organic chemistry. Researches in thermochemistry typified on the medal by the bomb calorimeter, the simple apparatus now so extensively used to determine the heating value of fuels and to disclose many important truths in general chemistry. Investigations on explosives; on the influence of electricity on the growth of plants; encyclopedist; Senator; Minister of Public Instruction; Perpetual Secretary of the Académie des Sciences; a man whose activities were so broad, so beneficial to the nation that its gratitude found expression in public obsequies and burial, his devoted wife beside him, in the Pantheon.

You have suggested, Mr. Editor, that personal reminiscences be given illustrating the influence of international intercourse in promoting the progress of chemical and metallurgical professions and industries.

It was my very good fortune to meet Henri Moissan during the sessions of the Second Congress. Two of his masterly re-

searches interested me intensely—the isolation of fluorine and his work with the electric furnace incidental to the making of diamonds. What bold investigations! The evidence of the existence of the element fluorine was so conclusive, yet the element so elusive! But Moissan was determined. He says in his monograph on his subject after noticing the charring of the cork closing the arm of the apparatus carrying the positive electrode; "Evidently a gaseous body, possessing active properties had been produced at the positive pole. I thus got, after three years of research, the first important clue in the isolation of fluorine."

The costly platinum apparatus, with its platinum-iridium electrodes, was supplanted later by one with a copper container, and thus simplified led to the production of ozone by the action of fluorine on water vapor.

While this research made him famous among scientists, that on producing diamond gave him a world-wide reputation. That by dissolving carbon in molten iron at high temperature in an electric furnace and then plunging the molten metal into water

By courtesy of Berlin Photographic Co.
PASTEUR.

where under great pressure the carbon crystallized as it segregated on cooling he actually obtained diamond, was to me convincingly shown by the microscopic specimen of the crystals bearing the characteristic markings of natural diamond.

Later in a lecture delivered in New York at the College of Physicians and Surgeons on invitation of the American Chemical Society, the American Institute of Electrical Engineers, the New York Acadamy of Sciences, and the New York College of Pharmacy, he showed this experiment to the delight of scientists and experts who had followed his words in eager interest. His perfect clarity and diction, his direct and forceful logic captivated his auditors. Among my scientific treasures is the major portion of that ingot.

His work on the carbides followed naturally from this investigation at high temperature. To these must be added that on the borides, silicides and other compounds, as well as the making of purer metals and the properties of those metals having high boiling points, the results of which last research he placed before the Congress at Rome.

He made a visit to Edison at his laboratory. The men were in remarkable contrast. Pioneers both, though each with different methods and with different objective points. The one primarily the scientist, the other the utilitarian, yet each over-

HENRI MOISSAN.

lapping their self-selected bounds and each leaving an impress beyond by reason of their digression. Marvelous advances since then. Our foreign friends will perhaps be snapped by the moving camera men; what they say in meeting will certainly be recorded by the phonograph.

A reflex of what was witnessed in Paris was the organization in this country of the Ampère Electrochemical Company for carrying out important experimental work. The development of the alundum industry, the barium process, making of cyanides, and incidentally the making of barium and calcium cyanamides; the production of silicides, which when acted on by water evolve hydrogen; and as an independent investigation the first commercial production of nitric acid from atmospheric nitrogen.

While C. S. Bradley, C. B. Jacobs, and D. R. Lovejoy were instrumental in bringing about these advances, perhaps what was of greater importance was the enlisting of a corps of young men in electrochemistry, for they all became keen in the pursuit of the discovery of new facts and in the development of new industries.

That the scientific side might likewise be advanced the writer, then Asst. Professor, utilized the information thus gained in designing electrochemical and electric furnace laboratories for the new Chemical Laboratory of the College of the City of New York. The furnace used by Moissan at his lecture was constructed in the workshop of the Department of Chemistry, and afterwards became a highly prized piece of apparatus often used in lecture demonstration and research.

The labor of many other French chemists present at the various congresses is not forgotten, especially not those of M. François Dupont, who acted as Secretary of the Second and Fourth Congresses, whom we have to thank for the compilation of the volumes representing the work of each Congress.

In the early days of the American Chemical Society several Frenchmen, then resident in New York, were welcome members. Tessié du Motay, chemical engineer and inventor, whose oxygen and water gas processes were commercially developed in New York; M. Alexandre Bourgougnon, one time assistant to the great Chevreul at the Gobelin Tapestry Works, analyst, author, and later instructor at the College of the City of New York, and M. Auguste J. Rossi, who on coming to this country was affiliated with refrigeration processes and who has now, through amazing perseverance in the electrometallurgy of titanium and its alloys made railroad transportation safer through the addition of these alloys to steel in the process of steel rail manufacture. Numerous papers from these men are to be found in the early volumes of the Society.

To-day Héroult, not content with his splendid pioneer work on the winning of aluminium, has also turned his attention to the manufacture of steel and is longing for other worlds to conquer. He is a familiar and welcome member of our scientific and engineering societies. His electric furnaces in use in the refining of molten steel will no doubt be seen by our visitors.

And reciprocally American chemists have received particular recognition in France, as Robert Hare, inventor of the oxy-hydrogen blow-pipe, and member of the earliest chemical society, the Chemical Society of Philadelphia; as R. Ogden Doremus, who made a protracted investigation on explosives under the auspices of and with the aid of the Government; as J. Lawrence Smith, T. Sterry Hunt, George F. Barker, William McMurtrie, and Harvey W. Wiley, all past presidents of the American Chemical Society.

The deliberations of this International Congress of Applied Chemistry will be an epitome of the World's Work of to-day. Engineering enterprises like the linking of two oceans at Panama, or the construction of dams and water ways to impound and distribute water to this Metropolis or to irrigate arid lands, or to harness it for power, all feats which have been made possible by the discoveries in the cement industry; the smelting of ores of iron, copper, lead, zinc, aluminium, silver, gold and other metals; the recovery of precious metals by the cyanide process from waste; obtaining metals and chemical products by electrochemical processes; vast improvements in the use of fuel through increased knowledge on the subject of combustion, and consequently increased facility in transportation, whether on land, or water or through the air; innumerable products utilized in telegraphy, the telephone, and wireless; the manufacture of materials useful in the printers art, in photography, and for the phonograph, whereby our thoughts and actions are recorded and preserved; discoveries in textile manufactures for the preparation of the fibres not only like cotton, linen, wool and silk, but artificial substitutes for some rivalling the natural products in lustre and durability; numberless dyes with which to ornament fabrics; artificial perfumes making voyages to the Indies futile; remedies to mitigate suffering, widen the field of operative surgery, to antidote some diseases, to eradicate others; chemicals to be applied as disinfectants, or be useful in sanitation; the manufacture of explosives achieving more in peace than in war; countless products which make for greater comfort, greater enjoyment of life; everything that pertains to agriculture, whether for the fertilization of the soil, the preservation of life, vegetable or animal, the conservation of not only the land but the rational preservation of its food products so that they may be kept, transported and used with safety. The twenty-six volumes of the Congress—each Section having one to represent its activities—will attest its comprehensiveness.

But beyond these evidences of the onward march of mankind in material things comes the intellectual stimulus of such a gathering. Lavoisier, who laid the foundations of the science will seem alive; we shall listen to Bertrand discourse on the "infinitely small in biology," await the disclosure of new facts in the realm of radio-activity, a department of chemistry in which Becquerel and the Curies blazed new trails, and having run the gamut of all that pertains to realism and idealism find, no doubt, our chief enjoyment in the human side of it all, in meeting old and in making new friends.

New York City. CHARLES A. DOREMUS.

Early History of Chemistry at Columbia University and Some Early Relations Between German and American Chemists.

To the Editor of Metallurgical and Chemical Engineering

Sir: Most of the chief functions of the coming International Congress of Applied Chemistry will be held at Columbia University. It seems fitting then to call back to our mind at this moment the early history of chemistry at Columbia University. It will also be particularly interesting to note the close intimate relation which in those days already existed between German and American chemists and which has never been disturbed ever since.

Previous to 1857 there was no institution of learning in New York which provided for instruction in practical chemistry.

At Columbia College, the New York University, and the Free Academy, lectures on chemistry of a more or less popular character were delivered to the senior classes. If a man wanted to go into the practice his only resource was to go to some of the New England or Pennsylvania colleges—or to Germany or France.

In 1857 Columbia College was transferred to Forty-ninth Street. This was the beginning of a new and greatly expanded life, embracing courses in physics, higher mathematics, astronomy, mineralogy, chemical lectures and laboratory practice.

In the Chemical Department the College was fortunate in securing the services of Charles A. Joy, Ph.D. of Göttingen, who had been trained by the great chemist and ideal instructor, Hofrath Wöhler. At that time Joy was professor of Chemistry at Union College, Schenectady. In addition to the equipment of a lecture room for class instruction he stipulated for a working laboratory. The location of the lecture room and laboratory was on the top floor of the large building in the College group. Six working tables, together with a sand bath, sink and some glass cases, practically filled the room.

Chas. A. Stetefeldt, the eminent German metallurgist, who had been Bruno Kerl's chief assistant at Clausthal, and subsequently Charles Martini were his assistants.

The following statement is abstracted from the official College catalogue.

"Chemistry.

"Charles A. Joy, Ph.D., Professor.

"Instruction in this department is given by lectures fully illustrated by experiments and alternated with thorough reviews and examinations. The classes frequently accompany the professor to the various manufacturing establishments of the city, where the applications of Science to the Arts can be witnessed to the best advantage.

"Practical Exercise in the Laboratory.—The laboratory is furnished with the best modern appliances for acquiring a thorough knowledge of chemistry and the applications of this science to agriculture and the arts. It will be open to its special students from the first of November to the first of June, every week day except Saturday, from 9 a. m. until dusk at a charge of $250 a year, payable semi-annually in advance. It is designed in this school to give a complete professional education in chemistry to such as may desire it. A limited number of the most distinguished students attending the chemical lectures are admitted free of charge as working pupils into the laboratory.

"For the purpose of selecting these students, a special examination is held soon after the commencement of the second session. Students in this department have access to the College Library, to the private library of the professor, and to the scientific collection of the college.

"A prize of $100 is annually paid to the most faithful and deserving student in the laboratory."

The laboratory students during 1860 were Anson P. Stephens, Julius Henry Tiemann, Joseph W. Alsop, Jr., Clarence Brown, Emory McClintock, Geo. M. Miller, Samuel B. Ward, Geo. W. Maynard.

But as the facilities were not adequate for rounding out a full chemical course, on the advice of Prof. Joy, Tiemann, Stephens, McClintock, and Maynard went to Göttingen, where they were so fortunate as to have as their personal instructors those two great men Hofrath Wöhler and Dr. Beilstein. Maynard subsequently went to the Royal School of Mines at Clausthal, where that prince of teachers, Bruno Kerl, became his guide and friend.

CLASS OF 1860, DEPARTMENT OF CHEMISTRY, COLUMBIA COLLEGE.
From left to right: G. W. Maynard, G. M. Miller, Clarence Brown, J. W. Alsop, Jr., S. B. Ward, and Professor Joy.

On the return of the writer to New York at Christmas, 1863, the Columbia School of Mines was in the process of organization through the indomitable energy of Thomas Egleston, who in face of opposition finally triumphed. There was never a more beautiful example of devotion to an educational cause than was exhibited by the men who volunteered their services without pay.

It is due to Prof. Joy that Charles F. Chandler, who had succeeded Joy at Union, was induced to cast in his lot in the new venture.

Every Columbia man, in fact every chemist in the United States, knows the result, and even Göttingen has recognized his wonderful work by making him a *double* Ph.D. Can greater honor be imagined? In his bigness of heart he has recognized the small beginnings in the six-table laboratory of 1857 in the garret of the Forty-ninth Street building by showing to every new class the photograph of the students in that laboratory.

After all the great educational triumphs have been achieved through individual effort.

New York City. GEO. W. MAYNARD.

* * *

Since no complete final program is yet available while this journal is going to press, no list of papers is given here at all, since this is obviously safer than to give an incorrect list which may be misleading. A complete program of the Congress may be obtained after August 30th from the secretary of the Congress, Dr. B. C. Hesse, 25 Broad Street, New York City.

In the following we give a concise summary of the chief features of the Congress:

Washington.

The inaugural meeting of the Congress will be held on September 4th at Washington, D. C., and presided over by the President of the United States and will be followed by excursions and a reception.

New York.

General Lectures.—Four general public lectures will be held by representatives of different nations in the great hall of the College of the City of New York in the afternoons of the following days:

Friday, September 6, 4 p. m.: GABRIEL BERTRAND, of Paris, France: "Du rôle des infiniment petits chimiques en chimie biologique."

Monday, September 9th, 4 p. m.: CARL DUISBERG, of Elberfeld, Germany: "Die neuesten Arbeiten und Probleme der Chemischen Industrie."

Tuesday, September 10th, 4 p. m.: WILLIAM HENRY PERKIN, of Manchester, England: "The Permanent Fireproofing of Cotton Goods."

Wednesday, September 11th, 4 p. m.: GIACOMO CIAMICIAN, of Bologna, Italy: "La Foto Chimica dell' Avvenire."

These four lectures will be preceded by an organ recital at 3:15 and followed by an informal tea at 5 o'clock.

Two other public lectures of great general interest will be presented before several joint sections as follows:

Saturday, September 7th, 2 p. m., in the American Museum of Natural History: SAMUEL EYDE, of Kristiania, Norway: "Oxidation of atmospheric nitrogen and development of resulting industries in Norway" in a joint session of sections II, VII, Xa and Xb.

Wednesday, September 11th, 10:30 a. m., at the College of

the City of New York: H. A. Bernhisen, of Ludwigshaten on-the-Rhine, Germany: "Synthetic Ammonia."

Professional Meetings of Sections.—The work of the Congress will be chiefly done in the meetings of the twenty four sections. These sessions will be held on Friday, September 6, Saturday, September 7, Monday, September 9, Tuesday, September 10, Wednesday, September 11, and Thursday, September 12, in the morning from 10 to 12 and in the afternoon from 1 to 3 every day with the exception of Saturday, September 7, on which only a morning session from 10 to 12 will be held. All these sessions will be held at Columbia University.

Members attending the Congress should register at the Central Registration Bureau as soon as possible after arrival in New York, and should indicate the sections or subsections in whose deliberations they intend to take part. Each member has the right to vote upon all nominations and resolutions at the general sessions of the Congress, but he is entitled to participation in the debates and conferences of only those sections or subsections for which he has registered.

* * *

The **American Institute of Mining Engineers** will hold joint meetings with Congress section IIIa (Metallurgy and Mining) on Friday, September 6, at 10 a. m. and 1 p. m. at Columbia University and will hold a further joint meeting with Congress sections IIIa (Metallurgy and Mining), Xa (Electrochemistry) and the American Electrochemical Society on Saturday, September 7, 10 a. m. at Columbia University. The program for the joint session of Saturday is a symposium of papers on electrometallurgy.

* * *

The **American Electrochemical Society** will hold sessions on Saturday, September 7, 10 a. m. and 2 p. m., on Monday, 10 a. m. and 1 p. m., on Tuesday at 10 a. m. and 1 p. m. The session of Saturday, September 7, 10 a. m., at Columbia, will be devoted to a symposium of papers on electrometallurgy and Congress section IIIa and the American Institute of Mining Engineers will join in this session. The meeting of Saturday, September 7, at 2 p. m. will be devoted entirely to an address by Mr. Samuel Eyde on the Fixation of Atmospheric Nitrogen in Norway, and will be held in the American Museum of Natural History, jointly with Congress sections Xa, Xb, II and VII.

The meeting of the American Electrochemical Society on Monday, September 9, 10 a. m. at Columbia University will be a joint session with Xa, Xb and II and papers relating to physical chemistry will be chiefly discussed. This will be continued at the afternoon session at 1 p. m., which will be concluded by an experimental lecture by Dr. E. Weintraub on Boron.

The meeting of the American Electrochemical Society on Tuesday, September 10, 10 a. m., at Columbia, will be in conjunction with Congress section Xa (Electrochemistry) and VI (Paper) and will be devoted to a symposium of papers on the electrolysis of alkali chlorides. In the afternoon the American Electrochemical Society will hold a joint session at Columbia University with sections IIIa (Metallurgy), Xa (Electrochemistry) and XIb (Conservation).

In order to take care of the very full program, the American Electrochemical Society may find it necessary to hold some extra session, but this question has not yet been settled.

* * *

Entertainments.

In advance of the official beginning of the Congress the following informal entertainments will be held.

A reception of the Society of Chemical Industry will be held on *Saturday,* August 31, at 8:30 p. m., at the Chemists' Club. On the same evening members of the Verein Deutscher Chemiker will gather informally on the roof garden of the Hotel Astor.

For *Sunday,* September 1, the Verein Deutscher Chemiker has arranged an automobile trip to Coney Island and in the evening a concert on the roof of the New Century Theater.

On *Monday,* September 2, 10 a. m., the Verein Deutscher Chemiker will hold a business and professional meeting at Havemeyer Hall, Columbia University, where Dr. F. Raschig will speak on the scientific and technical importance of tarphenols and Dr. F. W. Frerichs on 32 years in the United States as a chemist and manufacturer. For the evening the Verein has arranged a Kommers and for the ladies a theater party.

On the same evening the Chemists' Club will give a reception at its Club House to members of the Congress speaking the Latin tongues.

On *Tuesday,* September 3, the Society of Chemical Industry will hold its business and annual meeting at the Chemists' Club. An address of welcome by the Mayor of the City of New York and the address of the retiring president, Dr. Rudolph Messel, are scheduled for this occasion.

Wednesday and Thursday are the Washington days, as noted above.

On the evening of *Thursday,* September 5, the American Institute of Chemical Engineers will hold a banquet at the Chemists' Club.

The program of entertainments during the New York days of the Congress is as follows:

Friday, September 6, 8 p. m.: Kommers to Section VIIIb by the Apotheker Verein, of New York City, 9 p. m.: Reception to Japanese delegates by Dr. and Mrs. Takamine.

Saturday, September 7, 8:30 p. m.: Reception at the Metropolitan Museum of Art in Central Park, given by the American Chemical Society to the members of the Congress.

Sunday, September 8, 10 a. m.: Boat excursion up the Hudson to Newburgh.

Monday, September 9, 7 p. m.: Garden party at Bronx Park.

Tuesday, September 10, 8:30 p. m.: Reception by the Chemists' Club to all members of the Congress at the Club House.

Wednesday, September 11, 8 p. m.: Entertainment at the Hippodrome.

Thursday, September 11, 7 p. m.: Grand banquet at the Waldorf-Astoria.

Friday, September 13, 3 p. m.: Baseball game, New York vs. St. Louis at Polo Grounds. 7 p. m.: Subscription dinner of Society of Chemical industry at the Waldorf-Astoria.

For *Saturday,* September 14, visits to the Consolidated Gas Company and the Nichols Copper Company have been arranged for the forenoon, and a visit to the Corn Products Company, the Standard Oil Company, and the Bush Terminal Company for the afternoon.

Members of the Congress are urged to register as soon as they can, beginning Tuesday morning, September 3, at Columbia University gymnasium and to receive their twenty-four volumes of the Proceedings right after registration. For this purpose they must present their membership card. To ship their twenty-four volumes of Transactions to their house or office address, messenger service and express service will be available at the gymnasium of Columbia University (messenger and express charges to be paid, of course, by the members).

If any member prefers not to make the trip to the gymnasium of Columbia University personally, he can send a messenger for registration. But in order to enable the messenger to receive the volumes of the Transactions he must present a duly signed receipt for the Transactions, since no set of the Transactions will be delivered except against a receipt duly signed by the member himself.

The first complete sets of the Transactions have now arrived from the printer and it is a pleasure to state that the twenty-four volumes are not only most interesting in their contents but are beautifully printed. Every member will, of course, be anxious to have his set of the Transactions before the Congress begins and for this reason it is important that as many members as possible should take out their sets at their earliest convenience on or after Tuesday, September 3.

Crystolon—Silicon Carbide.

The Plant of the Norton Company at Chippawa, Ontario.

By Francis A. J. FitzGerald.

In many ways the manufacture of silicon carbide is unique, the reason being that the properties of the substance itself are peculiar. If a piece of silicon carbide, consisting of an agglomeration of crystals just as they come from the furnace, is submitted to a sufficiently high temperature in an oxidizing atmosphere slow oxidation occurs, the silicon forming silica and the carbon burning to carbon monoxide gas. This may readily be shown by means of an oxy-hydrogen blow-pipe flame. If the flame is turned on the crystals for a short time and these are then examined they will be seen to be covered with minute globules of silica produced by the oxidation of the silicon carbide.

On the other hand, if the crystals of silicon carbide are heated to a sufficiently high temperature in a reducing or neutral atmosphere decomposition occurs without fusion, the silicon vaporizes and the carbon remains behind preserving the original form of the silicon carbide crystals. There is no evidence of fusion. Such an experiment may be performed in a carbon tube, which, of course, is heated electrically.

It is this peculiar property of silicon carbide which makes the conditions of manufacture unique and has thus led to the development of a furnace which to many appears at first sight rather a crude and inefficient apparatus. In most processes for the manufacture of carbides or other compounds which involve the reduction of an oxide, the resulting product is fusible and this simplifies in many ways the manufacturing process as compared with that of silicon carbide where the resulting product is infusible. In the production of a fusible material a moderately careful mixture of the reacting raw materials is satisfactory since slight inequalities or lack of homogeneity in the mixture will not cause trouble provided the proportions of the constituents are correct. The conditions of silicon carbide manufacture, however, are different.

The mixture used in the production of silicon carbide should contain theoretically 60 parts of pure silica sand and 36 parts of pure carbon. When these are thoroughly mixed and heated to a sufficiently high temperature a portion of the carbon combines with the oxygen of the silica forming carbon monoxide gas, and the silicon thus set free combines with the remainder of the carbon to form silicon carbide. During this process, however, the mixture as a whole is not fused. Certainly the sand fuses, but the volume of carbon mixed with the sand is sufficiently great to prevent the particles of silica from running together, but instead of that they react with the carbon in their neighborhood to form, first of all, a greenish-colored substance which shows no crystalline structure, and as the temperature is carried higher this is converted into the crystalline silicon carbide. There is naturally a considerable shrinkage of the mixture, for from a theoretical charge weighing 96 kg only 40 kg of silicon carbide are obtained, the remaining 56 kg disappearing as carbon monoxide gas. The mixture then shrinks, but preserves generally its original form. If the heating is continued so that the temperature is raised still further the silicon carbide is decomposed, as already described, but still there is no fusion and ultimately the carbon which was in combination with the silicon is obtained as graphite.

If a mixture containing an excess of silica is heated a reaction occurs between the silica and the silicon carbide which results in the production of silicon, and this is just what happens in those parts of a silicon carbide furnace charge where there is an excess of silica, due to lack of homogeneity in the mixture.

A consideration of these facts leads to the conclusion that it would be difficult to manufacture silicon carbide in a furnace different in general principles from the well-known form that has been used for the purpose during the past 20 years. Moreover, it is not difficult to understand that the manufacture is one requiring very considerable care in order to obtain a satisfactory product and at the same time to get as large an output as possible.

In the design of the Norton company's plant for the manufacture of "crystolon," the name given to its silicon carbide, the first consideration was the quality of product, the efficiency of the furnaces, by which is meant the output per kw-hour, the labor cost and the cost of raw materials being deemed secondary matters. This must be remembered in considering the plant in order to appreciate it fairly.

The Norton company's crystolon plant is in Chippawa, Ont., about 2 miles above the falls of Niagara. The current is supplied by the Ontario Power Company at 12,000 volts, three-phase. Since it was decided to use furnaces having a capacity of 740 kw and to install only two units, it was necessary to use transformers with suitable taps for the Scott connection so that the three-phase current is transformed to two-phase. The transformers step down the voltage to 145. The secondary busbars then go to induction regulators by means of which the e.m.f. at the furnaces may be raised to 215 volts or lowered to 75 volts.

The arrangement of the electrical apparatus is shown in part in Fig. 1. The current enters the building in a room next the transformer room where it goes to the main circuit breaker and where the lightning arresters are set up. The cables from the

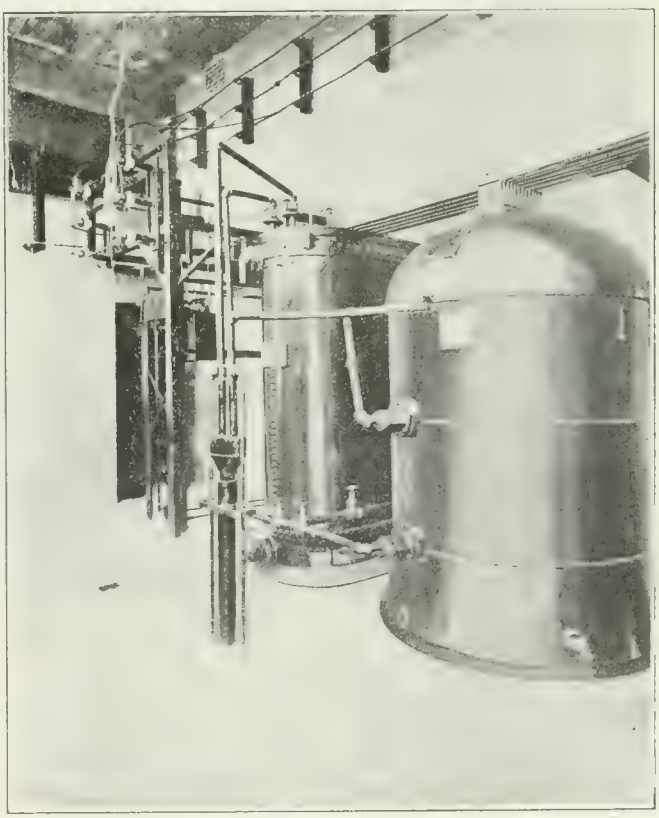

FIG. 1.—ARRANGEMENT OF ELECTRICAL APPARATUS IN CRYSTOLON PLANT OF NORTON CO.

main circuit breaker are then brought into the transformer room on brackets near the ceiling, as shown in the figure. A frame work, shown at the left, carries two single-pole double-throw switches so that the transformer, seen in the center, can be connected to any one of the three-phases. The frame work also carries circuit breakers, of which one is connected in parallel with a water rheostat and can be tripped by hand, while the other is provided with an automatic tripping device. The reason for using the water rheostat is that it is frequently necessary to throw the current on at full load and this might cause dangerous surging if the circuit was closed by means of the oil circuit breaker.

To the right of the transformer in the figure is the induction regulator by means of which the voltage of the current is raised or lowered. The induction regulator is built like an induction motor and the secondary voltage varies with the position of the rotor. Its great advantage lies in the fact that there are no contacts as in other kinds of voltage regulators and the change of voltage is perfectly continuous. The disadvantage is that on account of the air gaps between the primary and secondary there is considerable magnetic leakage, and, consequently, the power factor of the circuit is apt to be low. This, however, is more than compensated for by the advantages which make a break-down of the system highly improbable.

The busbars coming from the transformer and regulator are interlaced and pass through the wall of the transformer room to the furnace room, which they cross transversely. On either side of the busbar line are three furnaces, these forming one unit, Fig. 2. Between the terminals of each pair of furnaces on opposite sides of the busbar line bars are brought down,

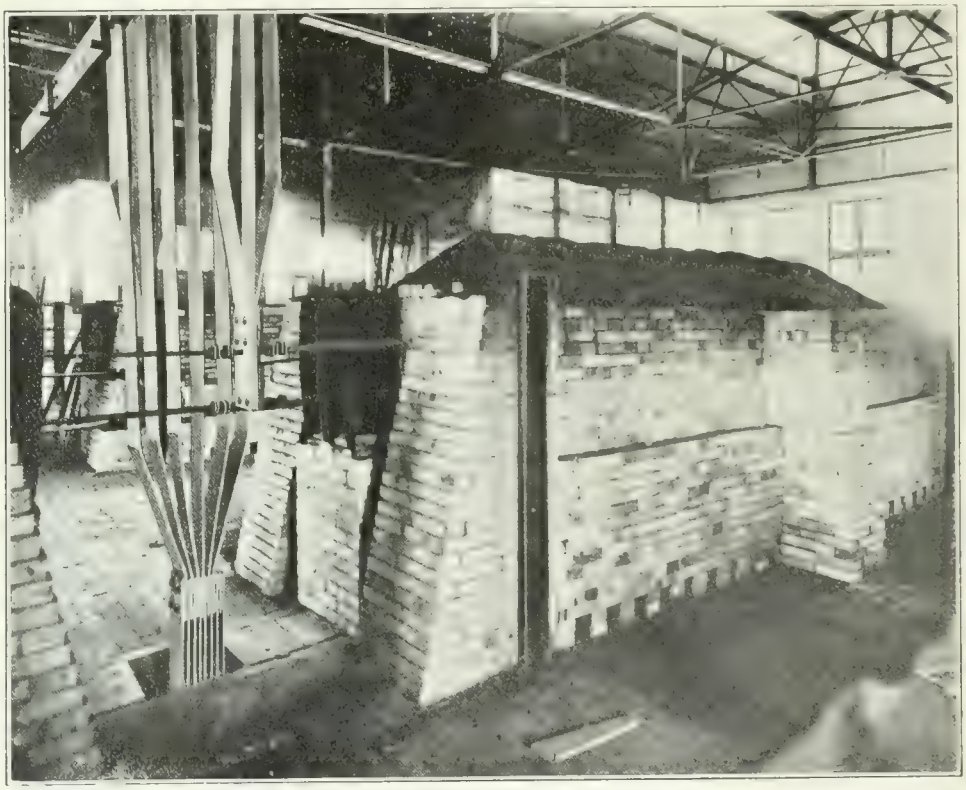

FIG. 2.—ELECTRIC FURNACES FOR MANUFACTURING CRYSTOLON

those of one polarity going down into a concrete trough which passes under the foundations of the furnaces, the other bars terminating on a level with the furnace terminals. The bars going into the trough come out at the other ends of the furnaces and can there be connected by means of cables to the terminals as shown in Fig. 3.

The grounded ends of the furnaces, that is the terminals connected to the busbars passing through the trough, are kept permanently connected, but the other terminal is only connected to the busbars when the furnace is running. In starting a furnace the regulator is adjusted so as to have the maximum voltage at the furnace terminals and this brings the furnace to load, 700 kw, in a few minutes. The resistance still keeps dropping rapidly as the temperature rises, but by means of the regulator the rate of generation of energy is kept constant. Finally the resistance becomes very nearly constant and there is only a gradual fall to the end of the run. Although it is possible to decrease the e.m.f. at the terminals to 75 volts it is customary so to construct the furnace that the resistance at the end of the run requires an e.m.f. of about 80 volts.

It has been pointed out that an objection to the use of an induction regulator is its influence on the power factor of the circuit. It is found, however, that even with the large current of 9000 amp used at the end of the run the power factor is about 0.9.

The raw materials for the manufacture are brought in on a switch at the side of the building opposite to the transformer room. The sand and sawdust are taken from the cars and conveyed to large concrete storage bins by means of elevators. The coke is thrown directly into a crusher, and when the granular carbon for making the resistor used in the furnace is required the coke coming from the crusher is passed over screens which separates particles of the required size. The under size and over size particles of coke are carried to a buhr mill where they are finely ground and thence conveyed to a concrete storage bin.

In making the charge for the furnace a mechanical mixer is used and the mixture is emptied at once into the hand cars which convey it to the furnaces. These are built in the usual way with the mixture surrounding the granular coke resistor. The furnaces have an electrical capacity of about 700 kw.

This question is sometimes asked: "Would not larger furnaces result in more economical working?" It is a fact that the consumption of energy in a small silicon carbide furnace, say of 75 kw, is very large, about 10 kw-hours per pound, and that in going to a larger sized furnace, for example 200 kw, the reduction in energy consumption is very marked. Again increasing the size of the furnace to 700 or 800 kw makes the working still more economical, but about here a point is reached where still further increase in size is of doubtful advantage. This is easily explained when certain of the peculiarities of silicon carbide are considered.

It has already been pointed out that the substance is infusible and that it must be formed between certain temperature limits. The result of this is that when a charge has been partially converted into silicon carbide, the heating resistor is surrounded with a cylinder of the carbide and, consequently, the heat which is supplied to the charge must be conducted through this cylinder to the surrounding mixture. It is obvious that there is a limit to the thickness through which it is economical to transmit heat and that very large furnaces would demand such a great increase in the thickness of the silicon carbide cylinder that they would not be practicable. On the other hand, if the thickness of the silicon carbide cylinder is kept the same and the length of the furnace increased so as to accommodate the increased rate of generation, there is nothing gained in heat economy, since the radiating surface of the furnace is increased in proportion to the rate of generation of energy.

Another objection to very large furnaces is the increased difficulty in building with the care necessary to obtain a product of the highest quality possible. Lack of uniformity in the charge or irregularities in the resistor all tend to bring about the production of an inferior abrasive. It is for this reason that the most elaborate care is taken in the mixing of the charge and the construction of the furnaces at the "Crystolon" plant. Analyses of all the raw materials are made as soon as these are

received at the plant, then in the Chippawa factory analyses of the raw materials are made twice a day and the mixture adjusted accordingly.

The equipment of the plant is very complete both as regards apparatus and personnel for carrying on research work on the working of the furnaces and methods of manufacture. This research not only covers chemical and electrical studies but also important thermal experiments. Some of the results of this work have been published by Saunders in an interesting paper read at the last meeting of American Electrochemical Society[1] in Boston.

The temperature measurements of the crystolon furnace are of great interest in many ways. They show what exaggerated notions of the temperature of the furnace have been formerly entertained and also the comparatively small range of temperature which can be utilized in making silicon carbide. As determined by Saunders the temperature at which silicon carbide crystals begin to form is only 400 degrees below that of de-

FIG. 3.—ELECTRIC FURNACE FOR MANUFACTURING CRYSTOLON

composition. There is no doubt that for some processes 400 deg. would be a large range of temperature, but for a substance like silicon carbide, on account of its other peculiarities, outlined before in this article, it is not.

The Norton company's crystolon plant is used simply for the manufacture of silicon carbide, the material as it comes from the furnace being shipped to Worcester, where the crushing, grading and further manufacture is carried on. At first sight it might appear that the separation of the plant where the crude abrasive is manufactured from that in which it is made up into marketable form is not efficient, but experience seems to show that this view is not correct. The separating by no means interferes with active co-operation and at the same time permits of undivided attention to the production of a raw material of the highest quality without which the manufacture of a satisfactory finished article is impossible.

By-Product Coke Ovens in America

The Koppers Oven and the U. S. Steel Corporation.

A very interesting paper on recent progress in by-product coke ovens in this country was presented before the Engineers' Society of Western Pennsylvania on May 21, by Mr. **William E. Hartman,** managing engineer of the H. Koppers Company, at Chicago. The paper is printed in full in the May issue of the *Proceedings* of the Society.

Mr. Hartman emphasized the rapidity of the by-product coke oven development, due to a large extent to the progressive action of the U. S. Steel Corporation, which, four years ago, built a plant of 280 Koppers ovens in Joliet, Ill., and has since invested about $10,000,000 more in the construction of its Gary, Indiana, and its Corey, Alabama, coke plants.

Use of Silica Material.—The technical advance in the industry is largely due to the use of silica material (with about 95 per cent SiO_2) in oven construction. This has made possible a considerable reduction in coking time. That **quick coking** time is an advantage in by-product coke oven practice, is evidenced by the experience of the last few years. It has been found that reducing the coke time from 24 hours to 16 hours for the charge results in a considerable improvement in the coke, this result being testified to by the blast furnace departments. Shortening the coking time increases the porosity of the coke without decreasing its crushing strength. The product is, therefore, better adapted for furnace use. The Koppers company has recently contracted with the Woodward Iron Company for eighty 13¼-ton ovens, with a guarantee of 15 hours' coking time, and Mr. Hartman confidently believes that there will be before long by-product coke ovens operated on 12 hours' coking time.

In connection with this reduction of the coking time, one feature, which may be regarded as the prime requisite in by-product oven coking, must not be lost sight of, that is, **absolute uniformity of heating** throughout the length of an oven, thus producing coke uniformly coked in a minimum length of time. Without this uniformity of heating, it is impossible to make any decided reduction in coking time, because of the danger of either over-coking or under-coking some of the charge, both of which faults are detrimental to the quality of the coke.

This necessity of absolute uniformity of heating throughout the length of an oven is also of especial importance with the tendency of increasing the size of the ovens. The ovens built at Joliet in 1907-1908, were designed with a capacity of 10½ tons per charge, and these were then considered large ovens. The ovens of the same type, built since this, have been 12¾ or 13¼ tons capacity per charge. The standard Koppers oven at this date is 15 tons per charge. This 15-ton oven referred to is 40 ft. long between doors, 11 ft. high, and has an average width of 19 in. This increase in oven size has an important bearing on the operating cost.

There is a similar tendency to increase the size of batteries, that is, the number of ovens built to a battery. Formerly a 50-oven battery was considered a maximum. The Steel Cor-

poration started out in its first plant at Joliet with four 70-oven batteries, and they have followed this arrangement in their Gary, Ind., and Corey, Ala., plants. However, it is worthy of notice that their Duluth, Minn., plants contemplate a battery of 92 ovens. The largest number of ovens that has ever been built in one battery is a recent installation of Koppers oven at Kaiser-Friedrich Colliery, near Dortmund, Germany. Here they have 120 ovens in one battery and they experienced no expansion difficulties in heating up the installation. It is evident that increasing the size of the battery decreases the construction cost, as well as the operating cost. There is no reason why those longer batteries cannot be successful in every way, provided proper construction precautions are taken for the expansion of the material.

First Cost.—Bee-hive ovens can be built for $700 to $800 per oven, including all machinery, while a by-product oven plant costs $12,000 to $18,000 per oven, and the oven battery itself costs about half of this. But the bee-hive oven receives a charge of perhaps 6 tons of coal every 48 hours, while the up-to-date by-product coke oven cokes its charge of 15 tons in from 15 to 18 hours. "With this sized by-product oven and this coking time, it has been found that the cost of construction of a by-product oven is about the same, or a little less than the cost of the bee-hive oven, figured on the basis of coke production. By this we mean that the cost of the by-product oven battery, including all of its machinery, piping, etc., but excluding that part of the plant for handling and recovering the by-products, compares favorably with the total cost of a battery of bee-hive ovens when figured per ton of coke produced. This may be surprising to many, but it is one of the results of the recent rapid progress in the industry, and it is only possible with a large oven coking its charge in the short time mentioned.

As to the life of by-product ovens no definite statement can be made. There are batteries that have been in operation ten years without any oven wall repairs (the walls receiving the most severe treatment). On the other hand, at a plant in England it is necessary to rebuild the oven walls about every two years, but this is an exceptional case, the coal used being high in alkaline salts which react chemically with the silica of the wall brick. For this reason a preliminary laboratory examination of coal samples is important.

Most American coals are low in alkaline salts and a reasonably long life can be assumed for oven walls. The battery of silica material at Joliet has been in operation now for about 3½ years, and to all appearances it is good for at least 3½ years more without repairs: and in this conenction it may be said that this plant in three years produced as much coke as was guaranteed and expected to be made in five years.

Kind of Coal Used and Preliminary Treatment.—Due to the Steel Corporation's experience with low volatile coal at Joliet, it has come to be generally believed that the best quality of blast furnace coke could only be made by using a low volatile coal, or mixture of coals. The coal used at Joliet was for a long time 80 per cent Pocahontas and 20 per cent Romeo, making the volatile content of the mixture about 20 per cent. More recently Illinois coal was substituted for the Ronco, and more recently still, they had a month's run of 60 per cent Pocahontas and 40 per cent Klondike. This mixture had a volatile content of about 25 per cent, and it is interesting to note that this coal mixture produced coke far superior to that formerly made. The porosity was higher and the blast furnace results were decidedly improved.

There is a by-product coke oven plant at Duluth, using in the ovens ¾-in. screenings from Pittsburgh coal. This has a volatile content of 34 or 35 per cent, and the coke gives very good results in their blast furnaces, the blast furnaces being relatively small. In Germany there are a large number of plants operating with washed coal containing from 10 to 12 per cent moisture, and from 14 to 16 per cent volatile matter. It is not generally known that coal of this kind can be used without having trouble from expansion during coking, but the Koppers Company has no such difficulties, and this is attributed largely to the fact that the coking processes take place uniformly throughout the length of the oven so that no part of the charge is over-coked. This over-coking would result in excessive formation of breeze, which would interfere with pushing the charge.

The specific gravity of the coal has an important bearing on the subject. The Koppers Company have several plants operating in England using very light coal and the volatile content is about 30 per cent. In order to make metallurgical coke from this light coal, it is necessary to compress the coal by stamping it into a cake before charging; while in this country there are a number of plants making good metallurgical coke from 30 per cent volatile coal without any such troublesome treatment of the coal before charging.

Another important characteristic of coals is the oxygen content. A coal that is high in oxygen requires a relatively high temperature and longer time for coking, and gives trouble through an excessive formation of carbon in the oven and pipes. Also, the gas yield is lower and the quality of the gas is poorer, so that all things considered it has been found that high oxygen in coal is much more objectionable than high ash content.

This country is as yet rich in coals of the first quality, requiring no washing to make them suitable for the manufacture of high-grade coke, but there are, nevertheless, a number of coals relatively high in ash and sulphur, which coals are decidedly improved by washing, and again there are coals high in ash and sulphur with these objectionable elements in such a condition that their percentage cannot be materially lowered by washing. If coals are washed they should be well drained so as to bring the percentage of water down to 7 or 8 per cent. This is not essential, but it is desirable. In many cases it is unnecessary to crush the coal very fine before washing, and in such cases the draining of the water is facilitated by the size of the coal.

In cases where it is desirable to mix two kinds of coal it is advisable to crush the coals very fine in order to get an intimate mixture of the two kinds. This crushing is usually done with hammer mill crushers, to a degree of fineness of 85 per cent through an ⅛-in. mesh screen. Also, if a coal is used containing small pieces of slate this degree of fine crushing will grind up the slate with the coal, producing a homogeneous mixture and avoiding cross fractures in the coke, which otherwise might be caused by the slate. When the coal is to be pulverized a Bradford breaker is usually installed to break up the lumps to about 1¼ in. size and to remove refuse. Following the Bradford breaker, in some instances, a magnetic separator is used to remove small iron refuse and thus protect the hammer mill crusher following next in series.

However, it is worthy of note that the largest by-product oven plant in the world, that is the Gary, Ind., plant, is preparing its coal successfully without the use of magnetic separators. In place of this they have each of the hammer mill crushers provided with a pocket which catches iron refuse and which can be dumped at intervals. The mixing of coals is most efficiently done after crushing, and usually a plant is provided with two mixing bins from which the crushed coal is fed onto belts, which belts discharge into one chute, provided with paddle-wheel mixers. The mixed coal is then elevated to a storage bin, located above and to one end of the oven battery. From this bin the charging larry is supplied.

Quenching of the coke is done in this country with the greatest amount of success in a quenching car. The coke is pushed directly from the ovens into a large open car, preferably lined with cast iron. The coke is quenched by a large overhead stream immediately after the coke falls into the car. It is advantageous to quench the coke as soon as possible after pushing in order that its heat may be sufficient to drive off excessive moisture, and experience shows that if the coke is quenched immediately after pushing it will not retain an ex-

cessive amount of moisture, no matter how large a stream of water is used. It has been found, however, that quenching the coke right at the ovens is open to objections, because of the large amount of steam produced, this steam having an injurious action on the oven steel work and brick work, as well as being disagreeable to the operators, so that the tendency now is to push the coke into such an open quenching car and immediately take this car away to be quenched at a quenching station slightly removed from the battery. In either case it is essential that the quenching steam be large in volume and quickly and thoroughly applied. By this method coke may be quenched so as to have not over 2 to 4 per cent moisture.

It has been recently suggested that quenching can be still more efficiently accomplished with lower resulting moisture if hot water is used, and the Koppers Company are experimenting along this line. The necessity for further improvement in our quenching methods is evident from the fact that one by-product coke oven plant has recently contracted for a part of its output on a moisture specification of 1 per cent.

It has only recently been demonstrated that it is poor policy to use run-of-oven coke in blast furnaces. Plants are now being equipped with facilities for screening, and in some cases for crushing and screening their product. For screening revolving screens are most efficient. The Steel Corporation's coke plant at Joliet and their blast furnaces have demonstrated to their satisfaction that it is exceedingly advantageous to use only thoroughly cleaned coke, reduced in size to 2 in. or less. This plant is not equipped with crushers, but the coke receives severe dropping treatment before it is screened, and is thus broken up just as effectively as though crushers were used. Other furnace plants around the country have arrived at the same conclusion, and are equipping themselves to reduce the size of their product for blast furnace purposes. In some cases coke is elevated for this treatment by means of belts, but the heavy maintenance incidental to this method of elevation is leading to the use of skip hoists for this purpose.

One of the great advantages of the by-product coke oven over the beehive is the **increase in coke yield.** This amounts to 5 to 10 per cent of the coal carbonized, and is due not only to the fact that there is no combustion in the coke in the by-product oven, but also to the fact that part of the heavy volatile matter in the by-product oven is converted into coke.

By-products.—The apparatus for winning and handling the by-products has been so perfected now that when a plant is started up with inexperienced men and with only one man to give them proper instructions the operation is perfectly smooth and the best quality of by-product is turned out from the start. It had been predicted that with the increasing introduction of by-product ovens the market prices of tar and ammonium sulphate would be rapidly lowered. People have been predicting this for the last ten years, and yet the fact is that prices for these products have been steadily increasing. This is explained by the rapid development of the market, due to the increasing uses for the products.

One of the recently developed fields for coke-oven tar is the use of the same in Diesel engines, and it may be interesting to some to know that engines of this type, of a capacity of 5000 hp and over, are in successful use on tar. Tar is previously treated only for the removal of water. Regarding the surplus gas it has been found that this can be advantageously used wherever gaseous fuel, either producer gas, blast-furnace gas or natural gas has found application.

Combination Ovens.—Mr. Hartman finally mentioned the adoption of "gas ovens" or "combination ovens" by a number of steel plants in Germany, the ovens being heated with blast-furnace gas, and all of the gas from the coal being used in the various departments of their steel plants. Among these applications is its use as open-hearth fuel. Germany has made more progress in this direction than this country, and has demonstrated clearly that coke-oven gas is well adapted for this purpose. In some cases they use coke-oven gas alone and in others they mix coke-oven gas with blast-furnace gas, both methods resulting in higher furnace temperatures, thus increasing the open-hearth output. It has been found that after the workmen become used to the new fuel the life of the furnace is as long with coke-oven gas as with producer gas. Among the advantages given are the following: Higher furnace temperatures, resulting in greater output; more uniform combustion resulting in greater fuel economy; elimination of the gas chambers, resulting in cheaper furnace construction; smaller repair costs; cheaper operating costs.

Discussion.

There were a number of communicated discussions. **Mr. F. F. Marquard,** superintendent of the coke works department of the South Sharon Steel Works of the Carnegie Steel Works, gave some information on their **Otto-Hofman ovens,** installed ten years ago. They are now operating their ovens on a mixture of 65 per cent Klondike and 35 per cent Pocahontas coal, having an average of 25.5 per cent volatile matter. They have steadily maintained a coking time of 24 hours, but within the past month they have reduced the coking time to 20½ hours with very encouraging results in the action of the coke on the blast furnaces. The blast furnaces, which are operating on all-Sharon by-product coke, responded immediately by increased iron yield and smoother working. The coke is slightly larger, more porous, and tougher.

The coke quality to-day is of prime importance. Thus the by-product coke of to-day, where it is made for metallurgical fuel, is far superior to the by-product coke made ten years ago; first, because the coal for making this coke has been thoroughly studied; second, the heating conditions are very much higher and uniform.

The oxygen in coal has a most deleterious effect on the quality of coke; for this reason coals which have been subjected to weathering, such as coal carried on stock piles even for as short a period as four or five weeks, have a pronounced effect upon both the quality of the gas and coke produced. The shorter the interval of time from the mines to the ovens the better the coking results will be.

The reduction of the coking time from 24 to 20½ hours has improved the quality of coke for use in the blast furnace. But at the same time the tar yield was reduced from 7 gal. per net ton of coal to 5¾ gal., and they had an increased amount of naphthalene to contend with in the house. The ammonia yield decreased with 4.75 lb. NH_3 per net ton of coal to 4.4 lb. The surplus gas yield increased from 3000 cu. ft. per net ton coal to 4600 cu. ft. The total gas was about the same, 12,000 cu. ft. per net ton. Thus it took no more gas per hour to heat the ovens on a 20½-hour coking time than it took on a 24-hour coking time. However, the higher heated walls enabled them to burn this quantity of gas more efficiently in the oven flues rather than allow same to be carried down to the regenerator below.

At South Sharon they get a yield of 76 per cent dry furnace coke and 3 per cent dry breeze from a coal mixture having 25.5 per cent volatile matter, which shows that 4.5 per cent of the volatile matter driven off in the laboratory test is converted into coke in the by-product oven, while, on the other hand, in the beehive ovens the coke yield is 3 to 6 per cent less than the results, as shown by laboratory analysis of the coals carbonized, which makes a saving in the coke yield from by-product ovens of from 7 to 10 per cent more than the coke yield from beehive ovens coking from the same coal.

Dr. Richard Moldenke, the well-known secretary of the American Foundrymen's Association, discussed briefly the **requirements of the foundrymen** as distinguished from those of the blast-furnace men as follows: "Shortening the coking time increases the porosity of the coke" is undoubtedly correct, "without decreasing its crushing strength" is open for discussion, as quite the opposite has been observed on occasion. Increasing the porosity of the coke is what the blast-

furnaceman wants, as he wishes to make all the gas he can (carbon monoxide). The foundryman, on the other hand, wants to get a coke with a minimum of cell-space as he wishes to produce complete combustion and keep it that way (carbon dioxide, with the consequent very much higher temperatures). Hence the foundry trade, with an annual consumption of possibly 1,250,000 tons of coke, will not welcome a reduction in the coking time either in the by-product or the beehive oven.

As to low or high volatile coals Dr. Moldenke said that every by-product plant has its own experience and consequent standard for volatile. One plant he knows of holds to 29 per cent, while another wants 25 per cent, and still another 30 per cent. One great advantage of the by-product system, due to the localities so far selected for business reasons, is the ability to mix the coals. In this way ideal coke conditions are obtainable, as a variety of coal markets can usually be drawn upon. At the beehive plants this is impossible. They serve only the coal mines of the region.

Mr. J. L. Haehnlen, superintendent of the By-Product Coke Oven Department of the Woodward Iron Company, Woodward, Ala., said that the further reduction of the coking time would depend on two points: first, more exact knowledge of the thermal conditions existing in the coking mass itself, at all points, during the complete cycle of coking, and, second, a better knowledge of the physical properties of the refractory materials entering into the construction of oven walls, etc.

Mr. W. O. White, of Uniontown, Pa., considered the situation from the standpoint of the individual or corporation which intends to operate a large tract of coking coal as a coke operation pure and simple (not in connection with a large steel plant). Then the question which presents itself is this: Will the return on the investment warrant by-product coke oven construction? His opinion is that the smoke which now goes to waste and denudes the country surrounding our coke regions of vegetation can be more profitably used in a regenerative type of coke oven than in a by-product oven. A plant constructed along this line would be one in which the coking period would be greatly shortened, while also there would be a very considerable excess of heat which can in many localities be converted into electrical power at a comparatively small additional cost of investment.

Dr. E. W. Parker, of the U. S. Geological Survey referred to the factors which had retarded the development of by-product coke ovens in this country—namely, first, the high cost of installation and, second, the fear that the markets for the by-products with exception of gas would be demoralized. This was feared especially in regard to tar. But there is now a large and growing demand for creosoting oil. To show that by-product coke ovens are a real success in this country he gives some figures on the gradual extensions of the Ott-Hoffman ovens at the Cambria Iron Company's plant and of the Semet-Solway Company's plant at Syracuse, N. Y.

Chemistry of Ammonia Recovery.

Mr. J. R. Campbell, chief chemist of the H. C. Frick Coke Company, of Scottdale, Pa., then presented a paper on the chemical aspects of the problem confining himself to the NH_3 yield and its various aspects.

Table No. 1.

	Lb. $(NH_4)_2SO_4$ per ton coal.	
Coal, 1.3 per cent nitrogen figured to sulphate		122.6
Ammonia yield, actual sulphate	25.0	
Nitrogen left in coke, as sulphate	78.2	
Nitrogen left in 10,000 cu. ft. gas as sulphate	12.0	
Nitrogen in tar (90 lb. per ton) as sulphate	3.5	
Nitrogen in pyridine	0.3	
Nitrogen in cyanides	0.4	119.4
Unaccounted for		3.2

Table No. 2.

	Per cent
Recovered as ammonia	20.3
Remaining in the coke	63.7
As elementary nitrogen in gas	8.1
In tar	2.9
As pyridine	0.25
As cyanide	0.3

Table No. 1 and No. 2 are taken from a paper of Mr. J. D. Pennock, chief chemist of the Semet Solvay Plants. It will be noted that the total recovery of ammonia as sulphate is only about 20 per cent. Even at its best the present practice shows considerable losses in nitrogen. On the other hand, it is stated that it is possible to recover 75 to 80 per cent of the nitrogen as NH_3 in producer gas plants where the total destruction of the coal is effected. Apparently, there is also some discrepancy between the laboratory recovery of NH_3 from destructive distillation tests and the practical yield, which has been accounted for by several hypotheses.

Mr. Campbell described how the laboratory results on destructive distillation are reported. Table 3 is a standard form and the results are on a high volatile coal with high sulphate yield.

Table No. 3

	Per cent
Sulphur:	
(a) In coal	2.05
(b) In coke	1.53
(c) In gas	0.760
Phos	0.004

American method	54.17
Cu. ft. gas per net ton of coal:	
(a) O deg. C. and 30 in. mercury	9760
(b) 15 deg. C. and 30 in. mercury	10,370
(c) 15 deg. C. and 30 in mercury, Inc CO_2 and H_2S	11,010
Composition of gas:	Per cent
(a) N_2	4.70
(b) H_2	53.60
(c) CH_4	27.40
(d) Ill.	3.30
(e) CO.	11.00
Sp. gr of gas	0.34
Calorific value of gas:	
(a) B.t.u. per cu. ft. of gas, min.	516
B.t.u. per cu. ft. of gas, max.	583
(b) B.t.u. of gas per lb. of coal, min.	2517
B.t.u. of gas per lb. of coal, max.	2843
$(NH_4)_2SO_4$:	Per cent
(a) Free	1.33
(b) Combined	0.45
(c) Total	1.78
Practical Yield.	
(a) Coke	69.00

(b) Tar 3.70
(c) Sulphate 1.67

Equivalents per net ton of coal.

(a) lb. of $(NH_4)_2SO_4$ 33.4
(b) lb. of benzol 25.1
(c) Gallons of tar 7.4

Mr. Campbell then commented on the different forms of NH_3 and its recovery by the Koppers direct process. It will be noted that the NH_3 is both fixed and free. Their experience on the ordinary mixture for the coking charge is that about 80 per cent of the NH_3 is free and 20 per cent combined. From a practical standpoint the free NH_3 is that which is found in the condensed form, or what is called the weak liquor. The free NH_3 is in the form of ammonium carbonate, ammonium sulphate and free NH_3, and the fixed NH_3 is in the form of ammonium sulphate, ammonium chloride, and ammonium sulphocyanide. It is upon this principle that Koppers has devised his direct process for the plants of the U. S. Steel Corporation. By this arrangement it will be seen that only a small part of the NH_3 has to be distilled with lime in the regular way. They believe that the technical distinction between the free and fixed NH_3 is that the one is distilled over with steam without the use of lime and similar compounds added for its liberation.

In other direct processes an effort has been made to pass the gases only slightly condensed directly into the sulphuric acid saturators. This probably is the ideal direct process if it could be worked out in practice since the stills could be dispensed with altogether. There are some objections to this process as pointed out by Koppers himself and others, chief of which is the formation of HCl in the bath from the action of sulphuric acid on NH_4Cl, which acts deleteriously upon the iron piping, blowers, etc., and Koppers points out that the undecomposed NH_4Cl remaining in the ammonium sulphate may later act upon the phosphates in making fertilizers, causing the formation of HCl which attacks the sacks in which the sulphate is shipped. Further, the presence of ammonium sulpho-cyanide in the ammonium sulphate acts delerteriously upon vegetation when the sulphate is used for the manufacture of fertilizers.

Briefly the process of recovering the ammonia in the Koppers direct process is this: The gas from the ovens is delivered to the by-product building and passed through the primary water-tube coolers; here it is cooled down to approximately 25 deg. Cent.

This cooling process condenses most of the tar vapors, together with such water vapor as is driven off from the coal as charged to the ovens.

The gas is then passed through the gas exhausters to the secondary tar scrubbers; then through the reheater, in which the temperature of the gas is rinsed to about 60 deg. Cent. The gas is then passed through a sulphuric acid bath in the saturators, in which the reaction takes place between the ammonia and sulphuric acid, recovering the ammonia as ammonium sulphate.

The gas is then passed out of the saturators to the fuel gas holders and delivered from them directly to the ovens or mills for heating purposes.

The tar and water condensed out of the gas in the primary coolers is passed to separating tanks where the tar and water in the form of weak ammonia liquor is separated by the difference in their specific gravities. The weak liquor containing most of the fixed ammonia is then pumped to the stills and the ammonia vapor driven off and condensed to strong ammoniacal liquor, when it is desired to manufacture this product. However, should it be desired to recover all of the NH_3 as ammonium sulphate, the ammonium vapor from the stills is returned to the gas ahead of the primary coolers and carried with it into the sulphate saturators. It is understood that lime is added in the stills for the liberation of the fixed ammonia compounds.

The sulphate is recovered and dried in the usual way, *i.e.*, by the use of centrifuges.

TABLE 4.—CATALYTIC EFFECT OF IRON AND IRON COMPOUNDS ON THE NH_3 YIELD.

	$(NH_4)_2SO_4$ per net ton
Test No. 1—Standard sample	22.4 lb.
Test No. 2—Standard sample with 10 per cent Fe drillings.....	16.0 lb.
Test No. 3—Standard sample with 10 per cent flue dust	11.8 lb.
Test No. 4—Standard sample with 10 per cent FeS_2	22.6 lb.
Test No. 5—Standard sample with 10 per cent FeS	20.8 lb.

TABLE 5.—CATALYTIC EFFECT OF CALCIUM COMPOUNDS ON THE NH_3 YIELD.

	Per cent increase in $(NH_4)_2SO_4$
Test No. 1—Standard sample with 2 per cent CaO.....	10 to 15
Test No. 2—Standard sample with 12½ per cent $CaCO_3$.	12.5
Test No. 3—Standard sample with 3 per cent $CaCl_2$.....	11.4

Tables 4 and 5 show the catalytic effect of certain compounds on the NH_3 yield. That on the effect of iron and iron compounds is still the subject of investigation in their research laboratory, though there apparently is not much question but that iron and its oxides exert quite an adverse effect on the NH_3 yield. It will be noted that exposing hot gases to metallic iron reduces the ammonia yield about 28½ per cent, to iron oxide, about 47 per cent and to FeS about 8 per cent. This is supposed to be brought about by the catalytic action of iron and its compounds at about 870 deg. Cent., at which the NH_3 is dissociated into its elements.

On the other hand, calcium compounds exert a catalytic effect quite to the contrary of iron compounds, having a tendency to unite H and N into NH_3. Lime itself will increase the ammonia yield as shown by Table 5, but the objection to it is that it absorbs some of the otherwise volatile sulphur in the coal, thus causing a high sulphur coke, which is not permissible for blast-furnace purposes. If enough lime is used all of the sulphur found in the coal will be retained in the coke. The objection to lime is in a measure offset by the use of limestone, since the volatile sulphur for the most part is driven off at or before the decomposition of the limestone takes place.

By the use of lime and limestone the combined ammonia is pretty well destroyed, as it is natural to suppose, tests showing a reduction of 60 per cent in the combined ammonia. The lime apparently does the same work in the mixture of coal as it does in the stills.

The increase in the ammonia yield by the use of calcium chloride is accompanied by phenomena not found in the other experiments. The free and combined ammonia practically change places, *i.e.*, there is only 20 per cent free ammonia and 80 per cent combined ammonia. Thus not only does the calcium chloride have a catalytic effect, but it also converts the free ammonia to a monium chloride, the handling of which interjects some new problems into its recovery as ammonium sulphate, which will not be discussed here.

The object of emphasizing the catalytic effect of iron on the ammonia yield causing in every instance a decrease is that it may account for the low practical yield of ammonia compared with the regular tube test in the laboratory on destructive distillation. It is readily seen that this could be brought about on account of so much iron piping around by-product coke ovens to which the hot gases are exposed.

The present ammonia yield obviously can be increased by the use of chemicals in the coking charge, as lime compounds before noted, which have a tendency to combine the elemental H and N into NH_3 instead of dissociating it. Also, it is pointed out at this time that the construction of future by-product plants may be modified in such a manner that the iron piping will not have such a catalytic effect. All these

phenomena are now being investigated carefully by the United States Steel Corporation, and if it is found that there is any weight to the hypotheses advanced advantage will be taken thereof and the desired improvements in the practice and changes in the equipment will be made.

Further Discussion.

Dr. F. Schniewind, president of the United Coke and Gas Company, of New York City, gave various data on United-Otto coke ovens in this country and the Cambria Steel Company's pioneer plant using this type of oven. He emphasized that the ideas of blast-furnace superintendents in regard to the quality of coke required have undergone material changes. For instance, the coke is now being broken before it is charged into the furnace. He also stated that if the short coking time were actually a standard of uniformity of heating, it was a fact that batteries have operated in 14 hours, not for a day but for months. This naturally greatly increases the daily capacity of a plant; but that it will also decrease the cost per ton of coke to a minimum is still to be proven. The destruction of by-product is enormous when the temperature of the ovens is carried above a certain point, and therefore the craze for big capacities may not always be conducive to highest economy. The market for the by-products has been very rapidly developed within the past few years, especially for tar products and for ammonium sulphate, and for by-product coke-oven gas He referred to the gas distributed by the by-product coke-oven plant in Camden, N. J., through the northern part of the State of New Jersey and the gas made by the plant of the Citizens' Gas Company at Indianapolis.

Mr. R. D. Hapgood, chief chemist of the Gulick-Henderson Company, of Pittsburgh, referred to tests made by him to determine the relative strength of beehive coke and by-product coke when subjected to physical tests intended to duplicate as nearly as possible the handling of coke between the time it leaves the oven and its final consumption in the furnace. After the coke has been subjected to these crushing tests it was screened and the various sizes weighed. All coke remaining on the 1-in. screen or larger was considered furnace coke. From these tests approximately 66 to 68 per cent of furnace coke was obtained from the beehive coke, and 76 to 78 per cent from the by-product coke.

Mr. J. W. Dougherty, president of the Pittsburgh Crucible Steel Company, asked whether it would be possible in a by-product coke oven, properly designed, to make a satisfactory furnace coke from Pittsburgh vein of coal carrying 34 per cent volatile matter, assuming the coke was to be used in a furnace originally designed to produce at least 500 tons a day from Old Basin Connellsville or a good Klondike coke.

Mr. E. A. Moore, president of the American Coke and Gas Construction Company, of Camden, replied that Pittsburgh vein coal 34 per cent volatile will not make a suitable blast-furnace coke for a 500-ton furnace.

Mr. W. E. Hartman confirmed this from the past experience of the Koppers people, but stated that lately experiments indicate that high heats and short coking time are going to enlarge the possibilities of the by-product ovens very decidedly. We find that shortening the coking time improves the coke for blast furnace use and we expect within the next few weeks to make some experiments on Pittsburgh coal with short coking time. As far as we know up to date we would not say absolutely that you can use Pittsburgh coal to make coke for a 500-ton furnace, but we think there are possibilities of being worked out.

Mr. F. C. Keighley said that the installation of by-product coke ovens is almost wholly a question of time, place, and condition. There must be a market for the by-products. He thinks that the building of by-product ovens will preceed with great despatch, not so much from a coke standpoint as the seemingly great demand there is likely to be for the by-products. It is possible to coke inferior coals in by-product ovens which could not be treated profitably in beehive ovens; however, the time has not yet arrived in this country when coke manufacturers have to resort to the employment of inferior coal for coking purposes.

He also gave some data on beehive oven practice and stated that the average yield of coke from coal in the beehive oven probably runs from 64 to 66 per cent, although he has obtained a yield of 70 per cent of coke in an experimental beehive oven.

Mr. W. L. Affelder, general manager of Bulger Block Coal Company, of Bulger, Pa., emphasized the magnitude of the possibilities of the by-product coke oven by stating that at present there are about 45,000 tons of volatile matter discharged into the atmosphere every day from the coke ovens in the Connellsville coke region. As the very high first cost of the by-product coke oven often proves a prohibitive factor, reference was made to the arrangements between the Bethlehem Steel Company and a German syndicate which is putting in a by-product plant at Bethlehem; the Bethlehem Steel Company furnishes the coal and takes the coke and the gas at a price and the Germans get the balance.

Mr. J. W. Dougherty emphasized that some day natural gas will be exhausted and that unless some other gas is forced into the pipes now laid in the ground for natural gas purposes, millions of dollars of property will become worthless. With natural gas selling at 30 cents per 1000 cu. ft. for domestic purposes, it seems that the gases from which the tar and sulphate of ammonia have been extracted will become, also, a very valuable product. He ridiculed the present cry of the high cost of living while there is so much waste in the coke industry. Mr. Dougherty said that the solution would be very simple in the Pittsburgh district if satisfactory blast-furnace coke could be made from Pittsburgh coal carrying 34 per cent volatile, but since this is not yet possible, as stated above, he thinks a remedy would be to ship some low volatile coal into the Pittsburgh district so as to get a mixture containing 25 to 28 per cent volatile matter from which good furnace coke can be produced.

Mr. A. W. Belden, of the U. S. Bureau of Mines Testing Station in Pittsburgh, remarked in regard to the Bethlehem Steel Company's arrangement that the Tennessee Coal & Iron Company, of Birmingham, Ala., made that same arrangement with the Semet-Solvay Company in 1898 and the Semet-Solvay people got their money out of the by-products.

Dr. H. C. Porter, of the U. S. Bureau of Mines Testing Station of Pittsburgh, criticised Mr. Campbell's experiments in so far as they were made on a laboratory scale and, therefore, might give an exaggerated idea on the effect of iron in reducing the yield of ammonia in practice and also on the effect of lime in increasing the ammonia yield. The latter fact was discovered some years ago and in practice it has been discarded after trial on account of the slagging of the lime with the silica brick for one thing, and possibly also on account of the effect on the coke.

Mr. Irving C. Allen, of the United States Bureau of Mines Testing Station, emphasized the great possibilities of a ready market for the tar products from by-product ovens as a result of the successful experiments made in recent years with the use of heavy tar oils in Diesel engines.

Mr. W. L. Affelder asked why Pittsburgh coal contained ing 35 per cent volatile matter would not give suitable coke in a by-product oven. He acknowledged the fact, but wanted to know the reason. Is it that it will not coke in a by-product oven because the coal shrinks too much, whereas a low volatile coal expands?

Mr. E. A. Moore replied that Pittsburgh high volatile coal volatilizes so rapidly that it expands and makes a cellular structure so large and with walls so weak that when it is put into the furnace the coke is so fragile as to break down and make it very difficult to operate in driving the blast. That is the principal feature, aside from the usual high sulphur con-

tent. As a matter of fact, different coals require different heating treatments in by-product coke ovens.

In his final reply, the author, **Mr. W. E. Hartman,** stated with reference to Mr. Campbell's remarks on the lowering of ammonia yield with increased temperature and reduced coking time, that they are working on that subject and "are improving the conditions over present construction; not only attempting to keep the ascension pipe cool by water-cooling it, but we are also lowering the horizontal flue to keep the products of combustion below the gas space so that the gas space above the coal is not exposed to so much heat."

As to the statement which had been made that the Koppers ovens makes small coke and therefore Koppers says small coke is the best kind of coke to use in the blast furnace, Mr. Hartman replied that "in some cases we are putting crushers in to break the coke. I think that is all that is necessary to answer that point.

"At Joliet the coke under 1 in. is 2¾ to 3 per cent."

Mr. Hartman confirmed a statement by Mr. E. A. Moore as to the effect of wet coal on the coking time, that this "depends altogether on the moisture and the fineness of the coal when it is put into the oven and the rapidity with which you raise the heat. You can coke it just as rapidly as dry coal, but you are liable to do more or less damage to the coke if the nature of the coal is such as to enlarge the cellular structure. You are liable to produce water gas and increase the volume but reduce the heat value. Ordinarily we say it takes about three hours longer with 10 to 12 per cent moisture under normal heat conditions as compared with dry coal."

As to whether crushing coal is always an advantage Mr. Hartman said that they have lately come to the opinion which is to be proven to a greater or less extent by experience, that if the coal is clean, without slate, and is only one kind of coal and not a mixed coal, it is not so necessary to crush it fine.

Mr. J. R. Campbell in reply to Dr. Porter said that he did not wish to convey the impression that the catalytic effect of iron and certain iron compounds on the NH_3 yield accounted entirely for the low practical yield or losses of NH_3. He merely mentioned it as one of the contributing causes, and the fact that both Mr. Hartman and Mr. Koppers realize this and are endeavoring to overcome it by certain modifications in the Koppers oven is a very good proof that there is something in the claim even though all our data must necessarily be based on laboratory experiments.

Also, he did not intend to convey the impression that he had made a discovery in the use of lime to increase the NH_3 yield. He simply brought that point in to show the catalytic effect of certain elements on the NH_3 yield. However, with reference to Dr. Porter's objection to the use of lime, Mr. Campbell had never seen any ill effects from the use of crushed limestone with the coking charge either upon the oven walls or the coke itself where the limestone is judiciously used and in accordance with the laws of chemical combination. "Dr. Diehl has made a very valuable contribution to the literature on the subject in which he points out that no ill effects can take place if a mono-silicate is formed during the coking process. As it seems to me he shows conclusively that there is no danger from the slagging action upon the brick."

Several speakers in the discussion referred to the introduction of silica brick into beehive and by-product coke-oven practice and to early work done by Bradley and Kier in this direction. Mr. Campbell said that a first-class lime bond brick nowadays will not run over ¼ per cent breakage and contains usually less than 2 per cent lime. The proper designation of this class of refractories is lime-bond silica brick in distinction from clay-bond silica brick and straight fire-clay brick. There is no question but what the lime-bond brick is rapidly supplanting other kinds of refractory material where high temperatures must be maintained continuously.

In Mr. Campbell's estimation it is the only kind of material for this construction.

Zinc Ore-Dressing in Colorado.

By H. C. Parmelee.

Magnetic Separation at the Wellington Mill.

In a series of notes on this subject published in Metallurgical and Chemical Engineering in October, November and December, 1910, and February, 1911, reference was made (November, 1910, p. 620) to the proposed addition of a magnetic-separating unit at the mill of the Wellington Mines Company, Breckenridge. At that time a low-grade zinc-lead-iron middling was being stored with the expectation of treating it by magnetic separation as soon as a sufficient tonnage had been accumulated to warrant the purchase and erection of the necessary machinery. About 20,000 tons of middling was accumulated, and a magnetic-separating plant erected, which has been in operation for several months.

Herreshoff Furnace Used as Dryer.

The middling contains from 18 to 19 per cent zinc, 4 to 5 per cent lead, about 30 per cent iron, 2 per cent insoluble, and from 43 to 44 per cent sulphur. It carries, also, about 6 per cent moisture. In size it ranges from ⅜ in. to fine as delivered to the dryer, which is a five-hearth Herreshoff furnace. Originally it was planned to dry the ore by passing the hot gases from the roaster through the dryer and thus avoid the cost of fuel for this operation. Unexpected difficulties were encountered, however, which caused the plan to be abandoned. The sulphurous gases attacked the iron rabbles, especially on the two upper hearths where the ore was moist, forming iron sulphite which rapidly wore away. No doubt some sulphuric acid also was formed by catalytic action, and this added to the rapid destruction of the iron rabbles. Another bad effect noticed was that the ore on the top hearth gradually packed and formed a solid bed which could not be removed by the rabbles. As the latter wore, the bed gradually increased in thickness, and had to be barred from the hearth before new rabbles could be substituted for the old; otherwise the new rabbles would break. A set of rabbles wore out in three weeks on the upper two hearths, whereas the rabbles on the lower hearths were still in service after three months' operation, and were still good for further use. The plan of utilizing the heat of the roaster gases might prove feasible in some other form of dryer, such as an open shaft with baffles, but it is certain that the idea is not feasible where there is a possibility of chemical reaction between the sulphurous gases and metallic parts.

After abandoning the above plan, the ordinary firebox was used, burning Crested Butte (Colorado) semi-anthracite coal. This has proved to be an economical method of drying. The dryer is charged with about 32 tons of ore per day, containing 6 per cent moisture. Five hundred pounds of coal is sufficient to dry this quantity of ore, evaporating from 7½ to 8 lb. water per pound of coal. After drying the ore is ground to 14 mesh.

Effect of Roasting at High Temperature.

The roasting furnace is of the usual multiple-hearth type, but has seven hearths instead of six, the latter being more common. A peculiar feature of the roast at this mill is the unusually high temperature required. At other similar plants roasting is carried on at a temperature of from 550 to 600 deg. C., but here it has been found necessary to roast at a minimum temperature of 650 deg. C. Attempts have been made to reduce this temperature, but on each occasion the subsequent magnetic separation has been affected adversely. The high temperature is detrimental to the furnace, increasing the cost of maintenance. The rabble-arms on the lower hearths, where the heat is most intense, are rapidly attacked by sulphur. The formation of iron sulphide continues until the strength of the rabble-arm is so reduced that it has to be removed. A section of such a rabble-arm shows that the iron has been converted into iron sulphide for about half its thickness.

The roasted ore is cooled and screened. Screening is advisable for removing foreign substances and small masses of ore which may have become sintered or agglomerated in the furnace. The quantity thus removed is small, but its elimination results in uniformity in the feed to the magnetic separators and in the later classification prior to wet concentration. The cooler is a hollow cylinder, 6 ft. diameter and 16 ft. long, with a spiral vane on its inner surface. The major portion of its weight is borne by the water in which it rotates, although it has roller supports at the ends. A spray of water plays on the cooler from above to keep the surface always wet and prevent the accumulation of steam in the mill building. The machine requires but little power, as it can be turned by hand. At its present capacity of 35 tons per twenty-four hours, the ore is colled sufficiently in half the length of the cylinder, and is discharged at a temperature of about 100 deg. Fahr. This type of cooler is in use at the works of the United States Zinc Company, Pueblo, Col., and was also used in the old Economic mill at Florence during the days when chlorination of Cripple Creek ore was practised.

Magnetic Separation and Wet Concentration.

The two magnetic separators are of the Ball-Norton type, with twelve magnets of alternating polarity arranged in three sets of four magnets each. The magnets have a core of soft iron, 1 in. x 8 in. x 12 in., and are wound with 600 turns of No. 13 asbestos-covered copper wire. Each separator takes a current of 16 amp at 75 volts. The first and third sets of magnets carry 4 amps each, and the second 8 amps. The feed and separating belts travel in the same direction, the latter running between the former and the magnets, but at a higher rate of speed than the feed belt. The space between the two belts is about ½ in., and as the magnetic particles are attracted to the upper belt, they are caused to shift their position each time they pass under the magnets which are of alternating polarity. This action is supposed to be beneficial in liberating non-magnetic particles which may have become mechanically entangled in the magnetic mass. These machines have a capacity of from 25 to 30 tons each in twenty-four hours.

The magnetic-iron tailing is without present value. It contains 55 per cent iron, 1.5 per cent lead, 4 per cent zinc, 1.5 per cent insoluble, and 3 oz. silver per ton. The zinc-lead mixture is classified in a four-compartment Henderson classifier,* and concentrated on one Card and four Wilfley tables. Zinc recovery averages 65 per cent at the grade of concentrate now made. The concentrate contains 48 to 49 per cent zinc, 7 per cent iron, 2½ per cent lead, 3 per cent insoluble and 2 oz. silver per ton. The lead recovery is lower, ranging from 45 to 50 per cent, on account of the losses in the zinc and iron products. The lead concentrate contains 70 per cent lead, 7 per cent zinc, 1½ per cent iron and 14 oz. silver per ton. The figures for percentage of recovery can be regarded only as close estimates, as the plant has been in operation but a short time and no opportunity has been afforded to check the results.

A dust-collecting system prevents serious dust losses and keeps the mill clean. A No. 8 Buffalo fan draws the dust through a Cyclone collector, and all sources of dust are either connected with this system or provided with pipes leading out of the building. The collected dust is delivered to the feeder of the roaster.

We acknowledge the courtesy of Mr. R. M. Henderson, manager for the Wellington Mines Company, in furnishing the data here given.

The Eagle Mining & Milling Company.

The Battle Mountain mining district embraces a small mineralized area in the southwestern part of Eagle County, Colorado, lying north of Leadville and easterly from Kokomo and Breckenridge. This district was the scene of considerable activity in mining during the early days of Leadville's history and produced ores similar to those which characterized the Leadville district at that time. The old mining town of Gilman, high on the cliffs of Eagle River Canyon, was a mining center in those days, but at present Red Cliff is the principal town in the district.

Gold, silver and lead were the valuable metals mined in the early days of this district. Some copper was also produced. Smelting was the metallurgical process most relied on, and only high-grade ore could be mined at a profit. With the gradual exhaustion of these ores, mining suffered a decline, which was more pronounced by the fact that zinc ores were encountered in increasing quantity. Zinc was not only without value at that time, but its presence in otherwise valuable ore was a detriment to profitable mining on account of the penalty imposed by the lead smelters.

With changing industrial and metallurgical conditions zinc ore has become more and more valuable, and to-day it constitutes the principal mineral production of this district. The Iron Mask mine, formerly famous as a producer of silver-bearing lead carbonate ore, is now one of the largest zinc mines in the state of Colorado. It is located near the old town of Gilman, and controlled by the Eagle Mining & Milling Company, which also operates an 80-ton concentrating mill for the treatment of Iron Mask ore. The mill was built at Belden, in Eagle River Canyon below the mine, and is connected with it by a Bleichert tramway 1100 ft. long.

Minerals in the Crude Ore.

Iron Mask zinc ore is a mixture of the sulphides of zinc, lead and iron, with some carbonate of iron and very little silicious gangue. These minerals usually occur finely crystalline, with occasional masses of coarser crystals ⅛ in. to ¼ in in diameter; but the latter is exceptional, and it is necessary to grind the ore to 16 mesh to separate the minerals from each other. The iron carbonate sometimes occurs in large masses of botryoidal form crystals, but is usually finely distributed. Following is the average composition of the ore as sent to the mill: Zinc, 17 per cent; iron, 30 to 32 per cent; lead, 2 to per 5 cent; sulphur, 28 to 30 per cent; insoluble, 1.5 to 2 per cent; silver, 1 to 3 oz. per ton, and gold, 0.05 oz. per ton.

The zinc mineral in this ore is marmatite, or ferriferous blende, which is a variety of sphalerite containing the combination ZnS and FeS in ratios varying from 2:1 to 5:1, the latter being more common. Analysis of a clean crystal of Iron Mask marmatite showed only 54 per cent zinc, as compared with 67 per cent in pure sphalerite. Based on the formula ZnS.FeS this marmatite would also contain 12 per cent iron and 34 per cent sulphur. It is obviously impossible to produce from this ore a zinc concentrate as free from iron as could be made from pure sphalerite associated with iron as pyrite.

The other minerals in Iron Mask ore are pyrite, siderite and galena. The precious metals occur mainly in the galena, but also in the marmatite and pyrite. The siderite occurs in varying proportions, and in sending ore to the mill care has to be taken to keep the proportion of this mineral as low as possible on account of its effect on the operation of the roasting furnaces.

Preparation of the Ore.

The coarse crushing plant is built at the loading station of the aerial tramway, near the mouth of the incline through which the ore is raised. Here the ore is crushed to ¾ in. size and transported to the mill in buckets holding 1200 lb. The tramway is operated wholly by gravity, the descending loaded bucket pulling the empty up from the unloading station at the mill. One man attends to loading the bucket and operating the brakes, the loads being dumped automatically at the lower station. Coarse crushing on one shift supplies ample ore for twenty-four hours' operation of the mill.

Fine grinding is finished at the mill. The following table gives a screen analysis of the ore as delivered to the mill, and

*Described in this Journal, Nov., 1910, p. 621, and June, 1912, p. 343.

the tonnage of the various grades, based on a total of 80 tons per day:

On ⅛-in mesh	83.2 per cent	66.5 tons.
Through ⅛-in. and on 16 mesh	6.5 per cent	5.2 tons.
Through 16 mesh	10.3 per cent	8.3 tons.
	100.0 per cent	80.0 tons.

The ore is first screened into three sizes: (1) a finished product passing 16-mesh screen; (2) a size between 16-mesh and ⅛ in., which is reground in the fine rolls, and (3) the oversize of ⅛ in. which goes to the coarse rolls. All roll products are elevated and again passed over the screen. Midvale steel roll-shells on both coarse and fine rolls have given service for about two years, the former wearing a little longer than the latter.

The screen is stationary and inclined at an angle of 42 deg. It is built of removable sections, 22 in. by 20 in., after the manner of the Edison and Rowand types. Each section has an available screen area of 18 in. by 18 in. They are arranged in seven rows of three sections each, giving a screen frame about 5 ft. wide and 13 ft. long in the direction of inclination. The first five rows are 16 mesh and the last two are ⅛-in. mesh. This gives an available area of 33.75 sq. ft. of 16-mesh screen and 13.5 sq. ft. of ⅛-in. screen. Both ton-cap and punched-slot screen have been used. The former show slightly greater capacity, but the latter have given longer service and more accurate grading.

Roasting and Magnetic Separation.

As the ore contains only 1½ per cent moisture it is not dried before roasting. Two six-hearth roasters have a capacity of 40 tons per day each. The temperature of the roast is kept quite uniform at a maximum of 550 to 560 deg. C. on the third hearth from the bottom, and 525 to 535 deg. C. on the bottom hearth. Three forms of rabble blades are used: in-throwing, out-throwing and mixing. The two latter are used on those hearths having a peripheral discharge, one out-throwing blade being hung on each arm next to the vertical shaft, with mixing blades on the remainder of the arm. The single out-throwing blade is necessary to prevent the ore from piling up around the central ring as it falls from the hearth above, but the centrifugal force of the mixing blades is sufficient to move the ore over the remainder of the hearth. The siderite in the ore has a tendency to reduce the temperature of the roast, and if too much of that mineral is present the temperature is lowered to a degree at which the iron minerals are not rendered sufficiently magnetic to be removed later by the magnetic separators. For this reason care is exercised to keep the proportion of siderite in the ore as low as possible. Following is a comparative analysis of a lot of crude ore and the same ore after roasting:

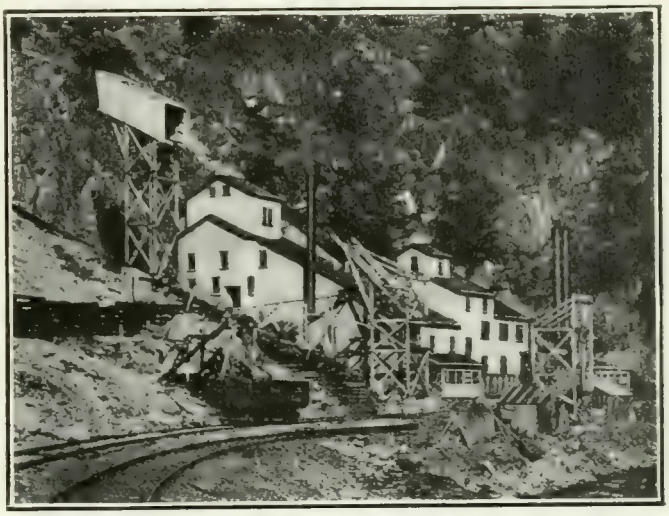
	Crude.	Roasted.
Zinc, per cent	16.9	21.3
Iron, per cent	31.7	33.2
Sulphur, per cent	26.6	22.2

The roasted ore is cooled in a revolving iron cylinder fitted with tires running on rollers. A series of blades in the form of an interrupted helix on its inner surfaces moves the ore gradually from feed to discharge end. Water is distributed over the outer surface of the cylinder from launders supported above it.

Two Cleveland-Knowles magnetic separators formerly were used, but have been superseded by one separator of the Ball-Norton type, similar to those in the Wellington mill. This machine is run at much greater capacity than those at the Wellington mill, for it treats the entire roasted product from 75 or 80 tons of crude ore daily. Probably better work could be done if two machines were used, but even with one the grade of zinc concentrate has been raised several per cent above that obtained with the old machines. This has been due to a cleaner magnetic separation of the iron, which is ascribed to the better facilities afforded in the Ball-Norton machine for the release of non-magnetic particles which have become mechanically entrained in the magnetic mass.

The magnetic-iron tailing from the Ball-Norton machine is reground in a sample-grinder and run through one of the Cleveland-Knowles machines to make a further separation of any zinc-lead mineral which may have escaped separation in the first operation. The iron product is practically without value. Occasionally a lot of ore will have sufficient silver in the pyrite to make it worth smelting, but generally it is stacked on the tailing pile. It contains, on an average, 45 per cent iron, 20 per cent sulphur, 6 to 8 per cent zinc, 1 per cent lead, 1½ per cent insoluble, 0.07 oz. gold, and 1½ oz. silver per ton.

The zinc-lead concentrates from the two magnetic separators are combined, mixed with water and screened through a 30-mesh Bunker Hill screen. Sizing was substituted for classification in this case because the material was almost wholly



80-TON CONCENTRATING MILL OF THE EAGLE MINING AND MILLING COMPANY, NEAR RED CLIFF, COLO.

composed of two minerals, with practically no gangue. It is possible, however, that the use of the launder system of classification with a jig compartment, proposed by Mr. Frank E. Shepard in this journal (April, 1912, p. 218), would increase the saving of galena and improve the work of the tables. At present, however, the two screen sizes are distributed to Card tables, where the zinc and lead concentrates are separated. There is no regrinding or re-treatment of middlings, and practically no silicious tailing to be separated.

Zinc recovery averages 70 per cent, and the concentrate contains an average of 47 to 48 per cent zinc. A recent shipment analyzed as follows: 49.3 per cent zinc, 13.1 per cent iron, 0.07 per cent manganese, 1.9 per cent lead, 0.08 per cent lime (CaO), 2.0 per cent insoluble.

The lead concentrate contains, on an average, 70 per cent lead, 6½ per cent zinc, 2 per cent iron, 0.20 oz. gold and 20 oz. silver per ton.

The daily production of the mill averages 20 tons of zinc concentrate and 3 tons of lead concentrate, showing a concentration ratio of 3½ to 1.

Labor and Power.

The labor regularly required is distributed as follows: Coarse crushing and aerial transportation, one shift, two men; milling, three shifts, one general superintendent, three foremen, three tablemen, one engineer, one repairman and two loaders.

The entire mill, coarse crushing machinery and one air compressor are operated by water-power developed by a 24-in. Pelton wheel. Water is brought to the mill through a 3200-ft. pipeline under a head of 600 ft., corresponding to a pressure

of 250 lb. per square inch at the wheel. Water-power is available throughout the year, but an auxiliary steam-power equipment is at hand ready for immediate use in case the water fails.

Sampling.

The work of the mill is checked by daily assays of samples of the crude ore and products. A Scobey sampler is placed over the roaster hoppers, and a hand sample taken from each bucket of ore sent over the tramway. Half-hourly samples are taken of the iron and zinc products of the magnetic separators, and of the zinc and lead concentrates from the Card tables.

Cleanliness and order mark the work at this mill. There is little dust, considering that the ore is handled dry through the various steps to the final wet dressing. The design has been adapted to a mill site that presented some unusual difficulties, and all the machines are readily accessible and easily inspected. For over two years the results have shown a degree of regularity in tonnage and grade of products that indicates careful handling.

To Mr. S. N. Hicks and Mr. C. H. Hanington, of Denver, who control the Eagle Mining & Milling Company, our thanks are due for the information here given.

Table of Melting Points of Chemical Elements

In Circular No. 35 of June 15, 1912, of the Bureau of Standards of Washington, D. C., a table of the melting points of chemical elements is given.

The values of the melting points used by the Bureau of Standards as standard temperatures for the calibration of thermometers and pyrometers are indicated by *italics*. The other values have been assigned after a careful survey of all the available data.

As nearly as may be, all values, in particular the standard points have been reduced to a common scale, the thermodynamic scale. For high temperatures, and for use with optical pyrometers, this scale is satisfied very exactly by taking $c_2 = 14{,}500$ in the formula for Wien's law connecting I, monochromatic luminous intensity of wave length λ and T, absolute temperature: $\log I/I_1 = c_2\lambda \log e\ (I/T_1 - I/T)$. For all purposes, except the most accurate investigations, the thermodynamic scale is identical with any of the gas scales.

Element	Deg. F.	Deg. C

Brittleness in gold-bullion bars, which is caused by the presence of small quanities of sulphur, may be entirely removed by re-melting the bullion bars and stirring with an iron rod until the rod ceases to be thinned at the end which is immersed in the molten bullion.

The percentage of bullion (sponge gold) in well squeezed or pressed amalgam depends principally on the state of division of the gold before it was amalgamated. Where the gold is coarse, and when ordinary amalgamating tables are used, the mercury does not penetrate far into the gold. Well cleaned and pressed amalgam sometimes yields well under 18 per cent sponge gold where the gold exists naturally in a very fine state of division, or when hard and granular amalgam has been subjected to prolonged grinding with more mercury. Under these conditions the freshly cleaned and pressed amalgam is soft and buttery.

The Modern Dry Cell, Its Development, Construction and Manufacture

BY H. K. RICHARDSON.

The common dry cell, while a small thing in itself, is the basis of a very large industry, and thus has many points of interest for the electrochemist.

The magnitude of the industry is little appreciated by those not familiar with it. At the present time it is probable that 50,000,000 of the standard 2½ x 6 in. size; 5,000,000 of the complete flashlight batteries, consisting of about 15,000,000 single cells, mostly 2 5/16 in. high by 13/16 in. in diameter; and a large number (approximately 2,000,000) of special sizes and shapes are made in this country each year. Probably an equal number are made abroad.

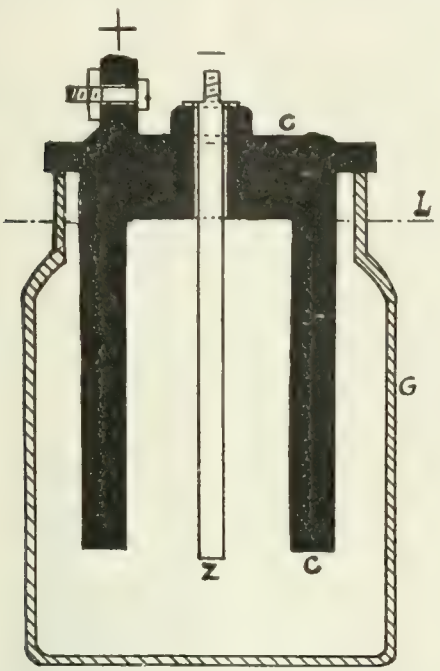

FIG. 1.—CROSS SECTION OF SALAMMONIAC PRIMARY CELL. (G, GLASS CONTAINER; C, CARBON CYLINDER; Z, ZINC POLE; L, SOLUTION LEVEL.)

The monetary value of a year's production in this country is not far from $10,000,000. The financial importance of the industry is thus considerably greater than the combined value of the four well-known electrochemical industries of carborundum, alundum, artificial graphite and aluminium manufacture. The combined value of the products of these four industries in 1909 was about $6,000,000.

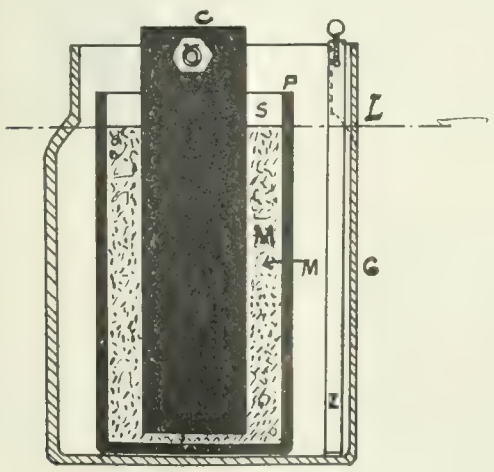

FIG. 2.—LECLANCHÉ CELL.

The production of these cells, due to the simple nature of the process of manufacture, is in the hands of forty or more separate manufacturers. The largest of these manufacturers probably makes at least one-third of the total production.

The development of the present type of cell is easily traced from the record of primary cell patents. In the description which follows only those changes will be described that have contributed materially to the improvement of cell construction.

The modern dry cell is an outgrowth of the familiar zinc-sal ammoniac-carbon ($Zn - NH_4Cl - C$) cell.

A cross section of this cell is given in Fig. 1.

The distinguishing feature of this cell is the large carbon pole and the small zinc pole.

To increase the holding-up power of this type of cell, Le clanché brought out in 1868 a cell using manganese dioxide as depolarizer. The so-called Disque Leclanché is the best representative of this kind of cell. A cross section of one of these cells is given in Fig. 2.

The noticeable features of this cell are the reduction in size of the carbon pole; the use of manganese dioxide as depolarizer; and the use of a porous porcelain cup as the container for the depolarizing mixture of manganese dioxide and ground carbon or coke.

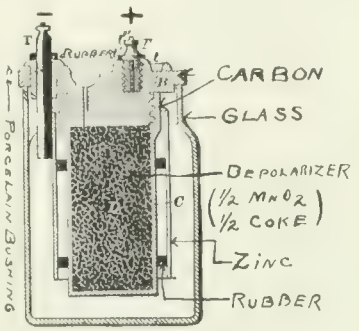

FIG. 3.—HAYDEN CUP CELL.

The next important improvement in cell construction was the introduction of the Hayden cup cell. Fig. 3 shows a cross section of this type of cell.

The improvements to be noted in this cell are the substitution of a porous carbon cup (C) for the porous porcelain cup of the Leclanché cell as the container for the depolarizing mixture of manganese dioxide and carbon, and the use of a large circular zinc closely surrounding the hollow carbon cup as the negative pole. The small distance between the carbon and zinc poles gives a cell with a smaller internal resistance than any previously made.

After the introduction of the above mentioned cell inventors busied themselves with schemes to render the cell electrolyte unspillable. From the experience gained by many fanciful and dubious experiments the first successful dry cell resulted. This cell was brought out by Gassner about 1883. Fig 4 is a cross section of one of these cells.

The features to be noted in these cells are the use of the zinc pole as the container; the use of the cheese cloth as the container for the depolarizing mixture, and the use of the plaster of paris mixture to render the electrolyte unspillable.

These cells were high in internal resistance, they seldom gave over six (6) amperes on short circuit, and were low in voltage, about 1.3 volts. To improve both of these qualities the present type of cell was developed. To-day the majority of dry cells are made according to the cross section of the cell shown in Fig. 5.

This cell consists essentially of three parts:

(1) The negative pole or zinc container,

(2) The paper or porous partition between the positive and negative poles.

(3) The positive pole of two components.

(a)—a *carbon rod* surrounded by

(b)—a *mix* of manganese dioxide, ground carbon, and electrolyte.

The details of construction of these various parts follows.

Negative Pole—Zinc Container

The zinc container is made of sheet zinc; for the ordinary size (2½ x 6") cell, No. 10 rolled zinc 0.020" thick is commonly used.

This zinc is tested for lead and iron. One brand in common use tests as follows:

Lead	0.16 to 0.37%	Average	0.27%
Iron	0.003 to 0.022%	Average	0.013%

The presence of lead in the zinc is not as serious an objection as is commonly supposed, for its overvoltage is enough to prevent local action. In fact lead if present to less than a certain percentage seems to benefit the shelf life of the cells. By shelf life is meant the length of time that the short-circuit amperage of the cells is over ten (10). The percentage of iron must, however, be kept low.

Paper.—The kind of paper in use varies considerably with the manufacturer, some preferring three layers of thin blotting paper while others use a single layer of heavy pulpboard. The paper mostly used is a forty point (0.040 inch thick) pulpboard made up of approximately 75% ground wood and 25% sulphite fibre.

The function of the paper is twofold; a reservoir for the electrolyte, and a means of separating the positive and negative poles. Thus a paper to be satisfactory for dry-cell work must be capable of absorbing many times its own weight of liquid (the ordinary paper absorbs about 150% of its own weight of water) and the pores be so small that the finest particles of the ground carbon will not be drawn through it by colloidal migration or capillary attraction to the zinc pole. If this latter point is not taken care of, a high-resistance short-circuit is formed between the carbon and zinc poles which results in the cell slowly running down even while on open circuit.

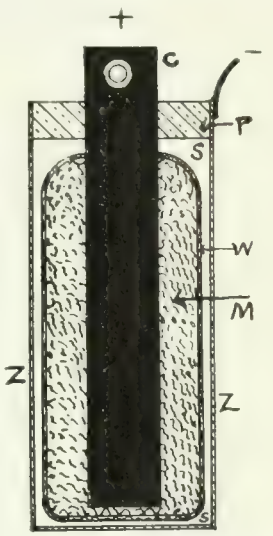

FIG. 4.—CROSS SECTION OF GASSNER CELL.

Positive Pole.

The positive pole, contrary to the usual idea, is not the piece of carbon that holds the connector, but is all the material that is contained within the paper partition, that is, it consists of

A—A mix of ground carbon, manganese dioxide, and electrolyte.

B—A carbon plug (a plate or rod).

A—The Mix.—The composition of the "mix" as used in the majority of the factories probably does not vary much from the following formula:

Pyrolusite—85% manganese dioxide	100 parts
Ground coke	80 "
Artificial graphite	20 "
Salammoniac—NH_4Cl	20 "
Zinc chloride—10 to 12 qts. 30° Be'	7 " approx.

The usual grade of pyrolusite tests over 85% MnO_2 and less than 1% Fe. The most commonly used grades are the Caucasian from the Caucasian Mountains, Russia, and the Japanese from Japan. In the factory parlance these are called Caucasian or Japanese "manganese."

The ground carbon used is obtained by grinding up the so-called retort coke, *i.e.*, the carbon deposited at the top of the retort in gas manufacture by the "cracking up" of the hydrocarbons. Carbon scrap free from copper is also used. In either case the material is freed from iron particles by a magnetic separator. The fineness of the grinding depends upon many factors and is usually different in different factories.

The graphite in use is mostly Acheson graphite Ba2. A few manufacturers use natural flake graphite.

The best of salammoniac is used and usually tests over 99% NH_4Cl and is free from sodium chloride and sulphate.

The zinc chloride used is that grade employed for the preserving of wood. A sample of this material analyzed:

Zinc chloride	91.6%
Manganese "	1.9
Magnesium "	1.2
Calcium "	1.1
Sodium "	0.1
Zinc oxide	2.0
Insoluble	1.5
	99.4%

The function of the various materials of the mix are as follows: The manganese dioxide is, of course, the depolarizer. The ground carbon next to the paper lining collects the current at the periphery of the "mix" and conducts it by means of the other carbon particles to the center carbon plug. The plug thus serves only to connect the mix to the outside circuit. The graphite is used to reduce the internal resistance. The salammoniac is the electrolyte while the zinc chloride is used only to improve the shelf life, *i.e.*, to reduce the local action.

B—Carbon Plug.—The carbon plug varies in shape according to the fancy of the manufacturer, the various shapes being designed to prevent the plug working loose in the mix. A few of the different shapes in use to-day are sketched below.

There are various means used to connect to the carbon plug. With plugs of the shape of numbers 1, 2, 4 and 7 in Fig. 6 the connection is usually a brass bolt, nut and knurl. In the case of number 3 the connection is made by drilling a vertical hole in the carbon, filling it with hot solder (*S*) and inserting therein a brass screw (*B*), and allowing all to cool. The solder then anchors the screw; a nut and knurl completes the connector. Numbers 5 and 6 have brass cap connectors which are forced onto the top of the carbon by hammering. Number 6 with a knurl is a common type found on the market. Number 5 is used with the so-called wireless battery box or in any case where a soldered connection is needed. The tops of all carbon plugs are soaked in paraffin to prevent the electrolyte from being sucked up to and corroding the brass connector.

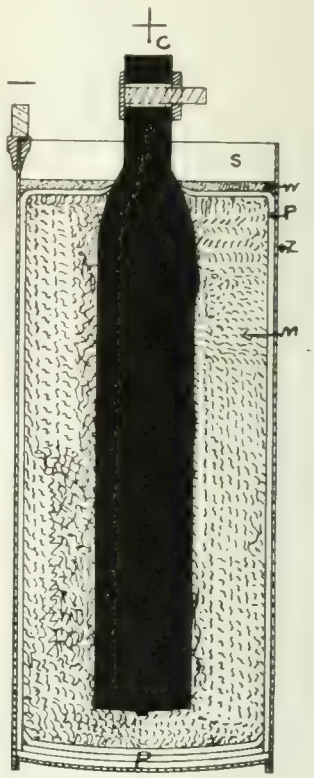

FIG. 5.—PRESENT TYPE OF DRY CELL.

Most all cells use a simple brass post and knurl to make connection to the zinc container. Cells made for the wireless battery box have the upper third of the zinc container formed into threads that screw into the box receptacle.

During the process of manufacture there are a few precautions that need to be taken. No large pieces of metal can be allowed to get into the mix or short circuits will result from torn linings. A small amount of finely divided copper is the worst enemy of the dry cell manufacturer as only 0.02% copper to carbon has been known to ruin a cell in two months. It was at one time supposed that if any solder got inside of the zinc can local action would result. Experiments have proven that there is no such effect. This is explained by the fact that the overvoltage of the tin of the solder is so high that

Process of Manufacture of a 2½ by 6″ Cell
Outline of Operations

MIX

Pyrolusite — ground to size
Carbon — ground to size
Graphite — Weighed out according to formula
Sal-Ammoniac — Weighed out according to formula
Zinc Chloride — made up to a 30° Baume Solution

(*) Mixed thoroughly DRY

Zinc chloride solution added

Mixed thoroughly WET

CAN MANUFACTURE

Sheet Zinc
Rolled to cylinder
Side lap seam soldered
Cupped bottom inserted and soldered
Can (Z) tested for leaks

ASSEMBLY

Paper lining (P) inserted in can
Carbon plug (C) centered to can
Mix (M) tamped around the plug
Paper lining turned down over mix at (W)
Brass connector soldered to zinc can
Cell allowed to stand 24 hours
Tested for current and voltage
Sand (W) sprinkled over the turned down paper
Pitch seal (S) poured over sand
Connections applied to carbon plug
Cell dipped into insulating paint
Allowed to stand two weeks
Inspected for all defects and tested for current and voltage
Put into paper jacket
Packed for market

(*) Some manufacturers prefer to saturate hot zinc chloride solution with the sal ammoniac and add the same to the dry mix.
All references in ( ) are to Fig. 5.

no hydrogen can be liberated on open circuit. Zinc chloride is so deliquescent that on very humid days the mix will take up

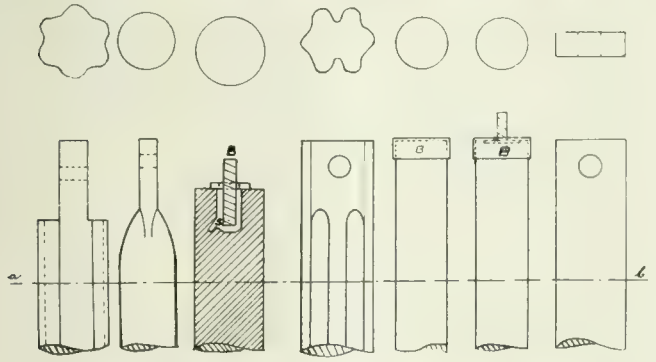

FIG. 6.—DIFFERENT SHAPES OF CARBON PLUGS. ALL VERTICAL VIEWS WITH EXCOPTION OF NO. 3, WHICH IS A CROSS SECTION, THE UPPER DIAGRAMS ARE SECTIONS OF THE PLUGS IN THE MIX, ALONG LINE A-B IN THE LOWER DIAGRAM.

water and the cells go "wet." If the trouble gets too bad the surplus water must be absorbed with sawdust before sealing the cell or the cell is likely to ooze out when put on service.

From the above table it is seen that the greatest item of expense is the zinc container, a reduction in the thickness of which would reduce the service obtainable from the cell.

The total cost as given above is probably the lowest limit to which the cost of manufacture can be pushed under present conditions. It probably represents the cost of about one-third of the present yearly production.

As very little machinery is needed for the manufacture of a dry cell and the cost of the materials per cell is so low, approximately six and one-half cents, relatively little capital is necessary for a small plant. Thus the reason for the existence of

Analysis of Cost of Manufacture

Materials	Costs Per Pound Cents	Cost Per Cell Cents	Percentage %	
Manganese Dioxide	2.00	1.00	15.8	
Ground Coke	0.75	0.30	4.7	
Graphite	2.00	0.20	3.2	Per Cent. of Material Cost
Sal ammoniac	6.63	0.66	10.4	
Zinc Chloride	5.00	0.30	4.7	
Zinc (Sheet)	7.50	2.07	32.7	
Pulpboard	3.00	0.15	2.4

Melting Points of Fire Bricks.—In the *Journal* of the Franklin Institute of August on account is given of an investigation carried out at the Bureau of Standards by C. W. Kanolt on the melting points of fire bricks. The melting point is designed for this purpose as the lowest temperature at which a small piece of the brick can be seen to change from a rigid to a fluid state. The experiments were made in a resistance vacuum furnace. The samples, which were from one to two centimeters in diameter, were heated at the rate of about 10 deg. per minute when near the melting point. It was found that in the case of certain bricks made of heterogeneous material of relatively low melting point the melting points were slightly higher after six hours' heating to 1550 deg., apparently as the result of the gradual running together of dissimilar particles to form a mixture having a higher melting point that the most fusible of the original materials.

The results are summarized in the following table:

Material.	Number of Sample.	Melting point, Centigrade.
Fire Clay brick	41	1555 deg. to 1725 deg. mean 1649 deg.
Bauxite brick	8	1565 deg. to 1785 deg.
Silica brick	3	1700 deg. to 1705 deg.
Chromite brick	1	2050 deg.
Magnesia brick	1	2165 deg.
Kaolin	3	1735 deg. to 1740 deg.
Bauxite	1	1820 deg.
Bauxite clay	1	1795 deg.
Chromite	1	2180 deg.
Pure alumina		2010 deg.
Pure Silica		1750 deg.

The value 1750 deg. given for silica is not the true melting point, but represents approximately the temperature at which the silica flows distinctly. It was found that silicon carbide does not melt below 2700 deg.; it becomes unstable at much lower temperatures.

Gold and silver of good fineness may be recovered from matte by melting the roughly broken matte, then adding iron, the quantity of which should be deduced from a preliminary trial.

Graphite crucibles, if free from slag, can be assayed very accurately by roasting the crushed sample in a roasting dish with a little copper oxide, stirring well during the roasting operation In this way all graphite is burnt away. The copper is then dissolved out from the roasted sample, and the material remaining, now only fireclay and precious metals, is fire-assayed in the usual way.

Radiation Pyrometry—V.

By G. A. Shook.

Relation Between Black Body Temperature and True Temperature.— In the preceding articles of this series the laws of "black body radiation" have been developed and have been applied to practical pyrometry. It has been shown that the "temperature" of an incandescent object, as determined by means of a radiation pyrometer calibrated against a black body, is not the *true* temperature of the object, but the so-called *black body temperature* unless the object is itself a black body.

Thus when a temperature observation is made on a stream of flowing iron or on a sheet of incandescent iron the value of the temperature thus obtained is always somewhat *lower* than the true or thermo dynamic temperature. If, however, the metal is in the interior of a uniformly heated furnace, the pyrometer then indicates the true temperature of the metal.

At first sight it might seem that this is a formidable objection to all radiation methods. Fortunately, however, in industrial practice, black body conditions are not difficult to realize so that the errors caused by this lowering of the true temperature are not significant.

Again it is apparent that if the radiation pyrometer is always used under the same conditions the scale will still be consistent. For example, in giving the temperature of an ingot of iron, it should be expressed in *black body degrees centigrade* and not merely *degrees centigrade*. If, however, we are considering the temperature of iron in an open-hearth furnace, it can be expressed on the centigrade scale. Obviously, the two temperatures obtained under the two conditions could not be used interchangeably in any calculation involving an accurate determination of the temperature.

Under certain conditions of observations it is possible to determine the true temperature of a body even though the latter is not within a uniformly heated enclosure.

Consider a shell of any material whatever, maintained at a constant uniform temperature throughout (Fig. 1.). Let us

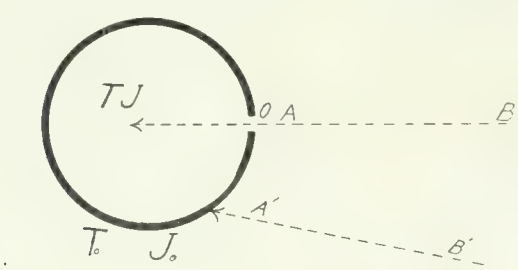

FIG. 1.—UNIFORMILY HEATED ENCLOSURE.

suppose that a small hole O, is made in one side of the shell so that a temperature observation can be made of the interior by means of an optical pyrometer. If a pyrometer is sighted in the direction AB, the true temperature of the shell can be determined. If it is sighted on the outside of the shell as in the direction A^1B^1, the black body temperature can be determined.

Let J be the intensity of the radiation emanating from the interior and T the corresponding temperature of the interior. Also let J_0 represent the intensity of the radiation from the exterior and T_0 the corresponding temperature. T is the true temperature and T_0 the corresponding black body temperature. If one should look in the direction AB, the area of the incandescant surface outlined by the contour of the hole would appear much brighter than the surrounding area.

Applying Wien's distribution law to the two cases of observation, we have

$$\log J_0 = K_1 - (K_2/T_0) \qquad (1)$$

and

$$\log J = K_1 - (K_2/T) \qquad (2)$$

Subtracting (2) from (1)

$$\log (J_0/J) = K_2 [(1/T) - (1/T_0)] \qquad (3)$$

But J_0/J, the ratio of the energy emitted by any body to the energy emitted by a black body at the same temperature is, by definition, the *emissive power* of the body.

If the emissive power of a black body is taken as unity, then the emissive power is equal to the *absorptive power*. Since most all of the bodies dealt with in pyrometry are opaque,

$a = e = 1 - r.$

Where

a = the absorptive power,

e = the emissive power,

r = the reflective power.

Equation (3) may now be written

$$\frac{1}{T} - \frac{1}{T_0} = \frac{\log a}{K_2} = \frac{\log a}{14{,}500 \times 0.4343} \qquad (4)$$

The absorptive power varies markedly with the wave-length, but only slightly with temperature. Hence, if the absorptive power, a, is known for any substance at the particular wave-length used, the true temperature, T, may be determined.

Suppose, for example, that an optical pyrometer indicates a temperature of 1300 deg. when sighted upon a stripe of incandescant iron and let us suppose further that the pyrometer utilizes a wave-length of 0.65μ. The absorptive power, a, for iron at 0.65μ is about 0.415. Substituting in equation (4)

$$\frac{1}{T} - \frac{1}{1300 + 273} = \frac{0.65 \log 0.415}{14{,}500 \times 0.4343}$$

whence

$t = 1405$ deg. C.

The following tables, I and II, may be used to determine the true temperature of a body composed of these metals. The tables are made out for a wave-length of 0.65μ. This is approximately the wave-length used by most optical pyrometers.

Table I.

University of Illinois, Urbana, Illinois

The FitzGerald and Bennie Laboratories in Niagara Falls

In the following article an attempt will be made to give some notion of the work of the FitzGerald and Bennie Laboratories, at Niagara Falls, as they should be a matter of general interest on account of their somewhat unique nature. However, some of the most interesting work cannot be described on account of its confidential nature.

The plan of organizing such laboratories occurred to the founders while they were working for the Carborundum Company and the Acheson Graphite Company, because it seemed that not only these companies, but many others, had all sorts of problems which for their solution needed merely some systematic work in the laboratory. No doubt some large manufacturers would have a research laboratory of their own, and might not require outside assistance, but many people engaged in engineering and manufacturing work would not have enough research work to keep a laboratory of their own busy.

As an example of such work people would frequently inquire about methods of melting in electric furnace, so as to form alloys which could not be fused in fuel-fired furnaces, and such has proved to be the case. Problems would also arise in relation to the power developments at Niagara Falls. For example, Mr. FitzGerald made a study of transformer oils and an investigation which showed the error of using iron pipes for

FIG. 1.—CORNER OF FURNACE ROOM.

carrying cooling water used in transformers. Trouble was experienced with marble panels used in high-tension switch boards, which was found to be due to the formation of calcium chloride on the surface. A study of the deterioration of wooden insulator pins showed that this was due probably in part to ozone, and certainly in part to nitric acid formed by electrical discharges.

It did not appear advisable at first to attempt the construction of an elaborate experimental works, because it was uncertain in just what direction work would chiefly develop and, moreover, it seemed probable that much work, at least that proposed on a large scale, would have to be carried on at the plants of clients, or would necessitate the actual building of apparatus and plants specially for carrying on the experimental work. Experience has shown that this judgment was correct, for while a research laboratory of this kind may well be equipped with the necessary apparatus and materials for carrying on preliminary experiments on a small scale, or even in some cases semi-commercially, it is not feasible to attempt work on such a large scale as a commercial undertaking would demand.

An obvious objection to a lack of elaborate experimental facilities was that much work had to be turned away in the case of prospective clients who had no facilities of their own for experimental work, and did not feel inclined to equip their plants with the necessary apparatus. This led to the installation of a laboratory plant where experimental work on electric furnaces could be conducted. A 25-kw transformer which would give secondary emf's of 110 or 55 volts according to the connections was installed. Small as it was this greatly increased the field of the laboratories work.

Several important investigations on electric furnace construction and metallurgical problems of various kinds were carried to a successful conclusion. Hopeless as it might seem with such a small equipment a study of the graphitization of electrodes by the process patented in England in 1893 by Castner was undertaken, and led finally to the development of a com-

Switching Directions For 5-KW Furnace Set

Switch Combination	Secondary Volts	Maximum Current	Maximum KW
1-3-5-8-10-12	40	125	5
1-3-5-8-9-12	20	250	5
1-3-5-7-9-11	10	500	5
2-3-6-7-9-11	5	500	2.5
2-4-6-7-9-11	2.5	500	1.25

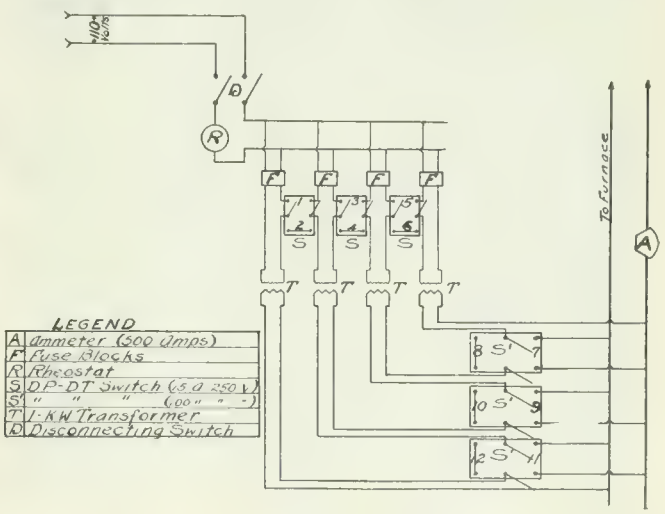

FIG. 2.—WIRING DIAGRAM.

mercial furnace for the purpose. Much experimental work was also done on the heat treatment of carbon, the production of carbides of various metals, and several special alloys. A furnace was also developed by data established with this small unit employing combined gas and electric heating. That this combined method is of value is shown by the fact that five such furnaces are now running for heating certain materials, the electrical energy being used to reach the higher temperatures only.

Meanwhile, owing to the liberal policy of local power companies, facilities could be had as to buildings and power permitting work on a much larger scale. For experimental and demonstration purposes a local building was remodeled and equipped with one Kjellin and two Colby induction furnaces. At another location in the vicinity a furnace of the Héroult type was installed in order to study the Lash Process of making steel. For this purpose a 750-kw transformer was installed, as well as a complete crane and ladle equipment, the whole comprising a miniature steel making plant.

An interesting problem undertaken by the laboratories was the development of a furnace for working the Imbert Process.

This process is for the production of zinc from sulphide ores, using iron to combine with the sulphur. Many experiments had been carried on in Europe with this process, but the furnaces had not proved satisfactory.

The problem presented was the construction of a furnace in which it was possible to form a molten bath of iron, and feed into this the zinc ore. It was further required that the furnace should be gas-tight, and that accurate temperature regulation should be possible. In conjunction with Mr. John Thomson a furnace was designed with a capacity of 600 lb. of iron, and

FIG. 3.—DRAFTING ROOM AND LIBRARY

using 50 kw as the maximum. A place was found at Niagara Falls where this furnace could be built and tested, and experiments made which gave all the necessary data for the design of a 150-kw furnace.

With this latter furnace experimental work in Europe was to be carried on at the works of the Hohenlohehütte, Upper Silesia, and it was thought desirable to ship the whole electrical equipment, as well as the furnace parts, from the United States.

The laboratories then installed the whole electrical equipment in Hohenlohehütte, and during a period of three months operated the electrical plant and the furnaces. From the data obtained as the result of these preliminary experiments a very complete experimental plant was designed which would permit of working on the commercial scale.

Another instance in which the work of the laboratories has been carried into actual commercial practice is shown in the case of the plant designed and operated for some time for the Norton Company, at Chippawa, Ont., where is made the Crystolon (silicon carbide) used by that company as an abrasive. The first unit, consisting of 750 kw electrical output and six furnaces, has since been greatly enlarged. (An illustrated description of this interesting plant, by Mr. FitzGerald, will be found elsewhere in this issue.—Ed.)

The result of several years' experience in work of this kind resulted finally in the present equipment of the laboratories. This apparently was the best design which would at the same time permit of experimental work on a sufficiently large scale to determine whether or not there was a reasonable chance of commercial success in any new process, and to work out details for commercial plants.

The office building has the offices, library, and drafting rooms on the second floor, while the first floor is devoted to a chemical and physical laboratory. The building connects by a covered passage with the furnace room. This is an "L" shaped building, 100 ft. long, 60 ft. wide for rather more than half its length, and 80 ft. wide for the remaining 42 ft. The furnace room is 15 ft. high to the eaves, and the roof has a lantern for its whole length to provide thorough ventilation. One corner is partitioned off for a transformer room.

The electric current is supplied at 2200 volts, and is stepped down by a 150 kva. transformer, which has twenty-two taps in the primary coil, and two secondary coils which can be connected in series or parallel by means of a switch. This arrangement permits of delivering current to the secondary busbars at voltages ranging from 50 to 100 volts in 2.5-volt steps, and from 100 to 200 volts in 5-volt steps.

This apparatus is used for the larger experiments with electric furnaces. For smaller work not requiring more than 4 or 5 kw a simple and convenient equipment is used which may be worth describing. It consists of four 1-kw. transformers, 100 volts primary, 10 volts secondary, connected up as shown in the wiring diagram.

As might be expected there are few permanent furnaces at the laboratory, since on account of the great variety required it is better to build furnaces specially for the purpose. In experimental work the construction of temporary furnaces which lend themselves readily to modifications are desirable. One permanent furnace is a two-electrode arc furnace of the Héroult design, which has been used for a great variety of experiments, making special steels, various alloys, and trying out metallurgical processes.

This furnace is arranged with a readily removable roof, which when in place is less than 2 ft. from the molten bath of metal.

This method provides a severe test for refractory materials, and some interesting work has been done in the development of new refractories, as well as the study of heat insulation.

Another furnace of more or less permanent nature is of the ordinary Siemens type, and is used for testing electrodes in an investigation on methods of manufacture.

A very useful apparatus is the large tube furnace, which can be usefully employed in various ways, but especially in making melting point determinations. The tube is of carbon, and is

FIG. 4.—CHEMICAL LABORATORY.

heated by means of a granular carbon resistor. The inside diameter of the tube is 4 in. A furnace of this kind is also very useful for submitting materials when heated to the action of various gases.

Of importance equal to the equipment is the staff of trained electric furnace workers. Skilled in the construction and operation of all sorts of electric furnaces these men contribute not a little towards the successful conduct of an experiment. Experimental research is essentially costly, but not necessarily expensive. Only highly paid men are worth having in a research laboratory, as efficiency is of prime importance. This has been the policy of the FitzGerald & Bennie Laboratories.

Notes on Electric Zinc Smelting.

By WOOLSEY MCA. JOHNSON

Electric zinc smelting for some years has been the subject of much criticism both public and private. This criticism has been of all kinds, sincere and insincere, fair and unfair, sensible and senseless, and has come from all sorts and conditions of people. I, myself, have given the subject, I believe, a severe analysis as to its limitations and whatever success I may attain has been due in no small measure to this course of action.

But much of the criticism is due to a general intellectual myopia and a fixed mental astigmatism on the part of the critics. Such has seemed to me to be in the main elementally humorous and to fit precisely some of the categories of the ridiculous found in Henri Bergson's "Le rire."

It is the obviousness of the central conception that causes this attitude on my part. For all that is needed is to compare the action of an electric zinc furnace which smelts continuously in

FIG. 1.—FURNACE BUILDING AND LABORATORY OF THE CONTINUOUS ZINC FURNACE CO. AT HARTFORD, CONN.

a reducing atmosphere, saving by-products and susceptible of expansion to large-sized units, with the operation of the 50-lb retort where the action is intermittent and as inefficient from modern industry's standpoint as is the feeding of a sick calf with a spoon. Other attempts to solve the zinc problem like wet processes and blast furnace methods have usually seemed of little commercial promise and all have proved abortive.

Now, while the central idea of electric zinc smelting is obvious and simple, its practicalization and its commercialization are neither obvious nor simple. On the other hand, people have erred in magnifying the intrinsically great difficulties to such an extent that these clouds have distorted the view of a real and great mountain. The point of view of such critics is perfectly natural and when rightly interpreted, their criticisms are of great value to the pioneer.

Pressure of work now prevents me from writing at length on either the possibilities and probabilities of our enterprise or giving much data on the Hartford actualities. An article in the METALLURGICAL AND CHEMICAL ENGINEERING for May, 1912 and in *Iron Age* of May 2, 1912, gave some of our experimental facts and an outline of the philosophy of the subject or, we might say with more definite expression, a sketch of its architectonics.

I give merely herewith a short summary of a test that to me is the most interesting test that I have ever made, and a few personal comments.

Metallurgical Balance Sheet of Run 4 E. F. 10.

Ore, 2840 lb. dry at 39.0 per cent	1108	lb. zinc
Flue-dust, 300 lb. dry at 56.7 per cent	170	" "
Total zinc delivered to pre-heater	1278	" "
Zinc in spelter, 691 lb. at 97.1 per cent	670.	lb. zinc
" blue-powder, 32 lb. at 96.0 per cent	30.8	" "
" flue-dust, 280 lb. at 68.6 per cent	192.0	" "
" slag, 1359 lb. at 2.49 per cent	34.0	" "
" charge not smelted and found in furnace, 81 lb. at 50.5 per cent	20.7	" "
Total zinc accounted for	947.5	" "
Unaccounted for, lost in "dusting," in charging pre-heater, and electric furnace, and in soakage of furnace	330.5	lb. zinc
	1278.	" "

As on next run, furnace gave a "plus recovery," soakage was largest item.

As good a metallurgical "cut-off" as possible was made. Loss by volatilization was practically nil.

Slag analyzed:

	SiO_2	FeO	Zn	ZnO
	per cent	per cent	per cent	per cent
No. 1	39.2	15.5	1.90	2.38
No. 2	39.0	14.3	2.04	2.51
No. 3	32.2	23.3	2.50	3.13
No. 4	27.5	27.0	3.50	4.31

Slags contained less than 0.05 per cent Pb, 0.05 per cent Cu.

The ore analyzed approximately, 39.0 per cent Zn, 8.7 Pb

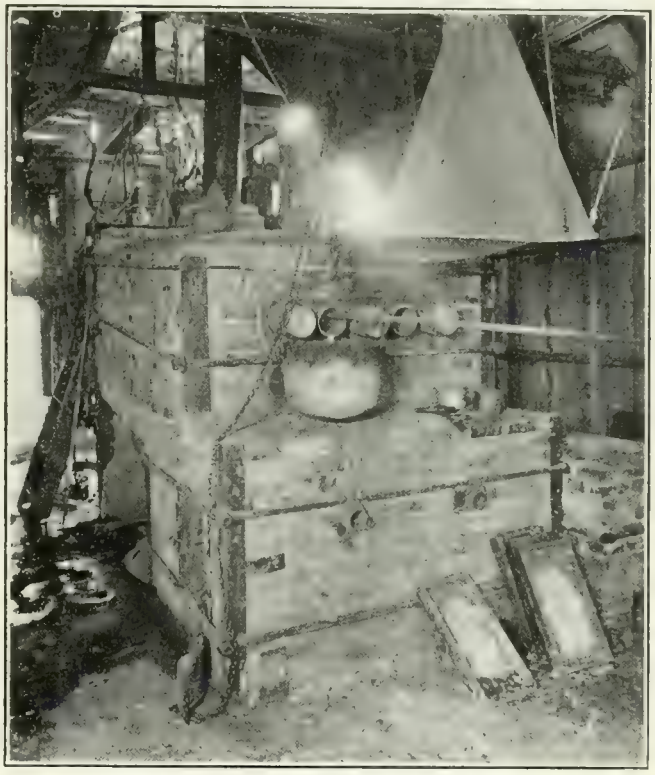

FIG. 2.—TAPPING ELECTROTHERMIC ZINC.

12.0 Fe, 5.2 CaO, 1.0 MgO, 8.0 SiO_2, 3.0 Na_2O and K_2O, 0.59 Cu, 3.70 S.

Most of analyses were made in duplicate and by two different chemists:

Time of smelting		48 hr.	
Kilowatt-hours on phase A		1754	
" " B		586	
Both		2340	
	Phase A.	Phase B.	
Av. volts	41.3	19.0	
Av. amp.	1200.	440.	
Av. kilowatts	36.	12.2	

Av. power on both phases 48.8 kilowatt.

$$\text{Kilowatt-hours per lb. spelter} = \frac{2340}{691} = 3.39$$

$$\text{Kilowatt-hours per ton pay charge} = \frac{2340}{3140} \times 2000 = 1490$$

Lead and matte were not tapped out. I have made runs giving much better results than this, but this run is different in that we then operated on conditions to make a new slag high in FeO and relatively low in silica.

The slags are higher in FeO and lower in ZnO than any I have ever made either in a smelting furnace or in a research furnace.

It would appear that this test has little or no metallurgical promise. For considered from the standpoint of productive results, it is the poorest long test that has ever been made at Hartford in a twelvemonth. We have made runs making considerably less flue-dust and blue-powder with slags lower in zinc and having a lower power consumption per ton charge smelter and per lb. spelter made. Its results are not decisive.

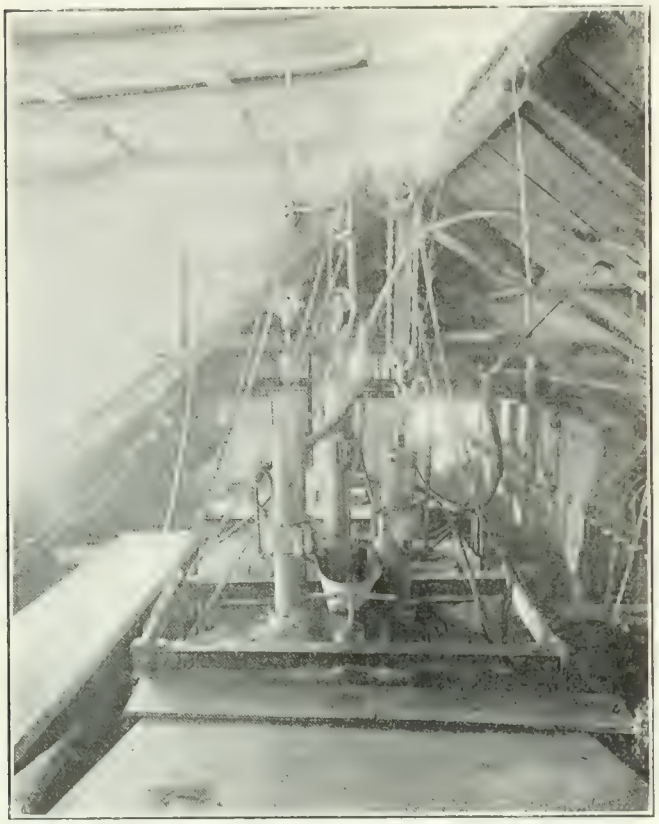

FIG. 3.—ELECTRIC ZINC FURNACE FROM CHARGING FLOOR

But looking at things in a broad way, this run with its slags high in iron oxide and comparatively low in zinc oxide shows "what a wonderful metallurgical agent is the electric current, when its use is understood." It was in the year 1905 that I conducted some experiments on the relative reducibility by coke of iron oxide and zinc oxide dissolved in slag, at temperatures from 1100 deg. C. to 1300 deg. C. The purpose of these were to find upper limits in FeO possible with a slag low enough in ZnO to be commercial, and they were predicative of our present successes.

It was found that the affinities—to use a good old-fashioned term of chemistry—between the carbon, oxygen, iron and zinc molecules and atoms change with the conditions much in the same manner that the affinities between iron, C, Si and O change in the blowing of a Bessemer converter with varying physico-chemical conditions.

Since that time these tests which were the precursors of our present achievements have been studied in the course of all our work both in the light of metallurgical and commercial probabilities and also in the light of the phase-rule.

As the successful electric zinc furnace will create a new metallurgy as distinct from the present metallurgy as that of the Bessemer converter is from the metallurgy of a puddling furnace, it is hoped that this test will prove of some technical interest to metallurgists. I therefore take pleasure in publishing an account of it in the columns of METALLURGICAL AND CHEMICAL ENGINEERING—a journal that expounds the modern principles of physical chemistry and commercial science to a profession that is absorbing them quickly and gladly.

It is a peculiar fact that most of the zinc made in this country has come "from Missouri." The photographs of our Yankee zinc furnace reproduced with this article will "show" some people a few things. At least it would seem probable that they will be "shown." At any rate, it is necessary "to show them."

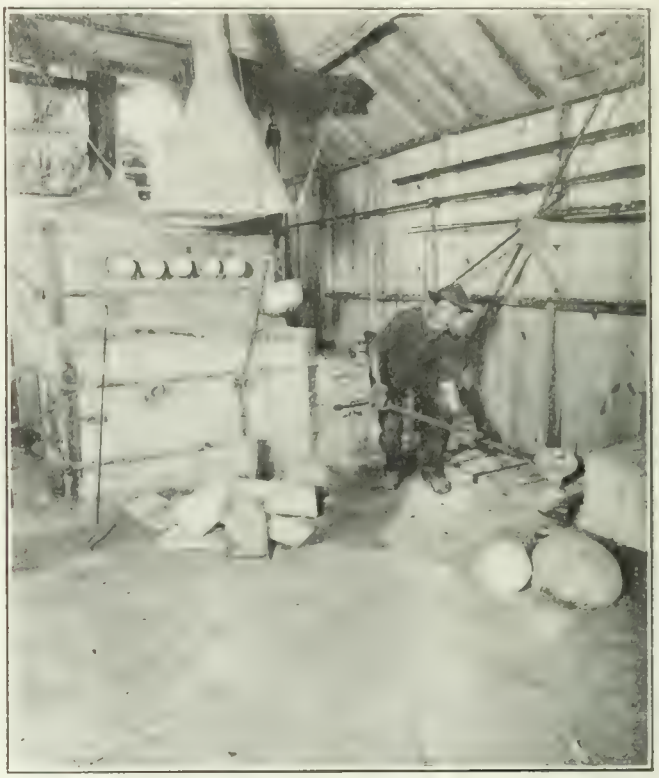

FIG. 4.—CASTING ELECTRIC FINE SPELTER.

Hartford, Conn.

Mechanical Agitators.

In designing the details for *mechanical agitators,* sufficient provision generally is not made for break-downs and replacements. Attention to the following points will be appreciated during working by the engineer in charge:

(1) The pinion wheel on the line shaft should be made "split."

(2) The same applies also to the bevelled crown wheel on the vertical agitator shaft.

(3) The vertical agitator shaft can be arranged, either by coupling or other means, so that the step-bearing on the tank bottom can be entirely removed without removing the crown wheel above it, and without having to take out a length of the line shaft.

(4) In order to have all the pinion wheels on the line shaft interchangeable, in many cases it will be found a subsequent economy to keep the line shafting the same size for its whole length, and not, as is usual, to decrease the diameter of the line shaft as one gets farther away from the driven end.

In smelting gold slimes with an oxidizing flux, if the oxidizing agent be manganese dioxide and used in excess, the slag produced may carry an excessive quantity of gold which does not show in the "pan."

The Use of Electric Furnace Pig Iron in the Open Hearth Furnace.

By D. A. Lyon.

In a paper recently presented by Prof. Richards at a meeting of the Engineers' Society of Western Pennsylvania (an abstract of which appeared in the July number of this Journal, page 397), he pointed out the fact that a metal may be obtained from the electric reduction furnace which is much better suited to steel making than is the product of the blast furnace. In this connection it may be interesting to note that the advantages gained in the use of this metal were not at first appreciated by the Swedish steel makers.

The first metal produced at Trollhättan did not look very much like pig iron and moreover, as its analysis was different from that of the metal which they had been using, they were doubtful as to being able to use it in the production of steel, and even hesitated about attempting to do so.

The first attempt at using this iron in the production of steel was made at Degerfors. A basic furnace was used. The iron of the electric furnace was mixed with ordinary gray iron and a smaller quantity of scrap than usual. This mixture was made so as to insure a hot metal upon melting down. The results exceeded their expectations, and on the third trial the charge was made up only of the electric furnace metal and scrap. Much to the surprise of those operating the furnace, it was observed that the usual boil did not occur immediately after the metal was melted.

Tests were then made on the electric furnace metal in an acid furnace. Although small quantities of this metal were at first used, it was soon ascertained that the charge could be made up of the ordinary proportions of 64 per cent pig iron and 36 per cent scrap.

Pig iron of normal composition was finally obtained as a product of the Trollhättan furnace, and when this iron was used for steel melting in the open-hearth, together with the same proportion of scrap as had been used in the previous tests, it was found that a longer time was required in which to complete the refining of the metal, and that it was necessary to add more ore than in the previous tests.

As a result of the tests at Degerfors the conclusion was reached that a metal could be produced in the electric reduction furnace which was more suitable for steel making than the ordinary pig iron which had previously been used for this purpose.

In order to understand the reason for this conclusion, it may be well to note briefly some of the reactions which take place in the open-hearth when treating pig iron of normal composition as compared to those which take place when treating pig steel.

In converting normal pig iron into steel in the open-hearth process, in order to meet the requirements of the process, the pig iron must contain enough Si to protect the iron from oxidation during the melting down, and likewise enough Si and Mn to free the iron after melting down from whatever oxides and gases that were formed and taken up during the production of the pig iron in the blast furnace, as a result of the action of the blast. Whatever Si and Mn that may be present in excess of this amount only prolongs the time required to finish the heat.

Immediately after, and even during the melting, there occurs a violent boiling of the metal. This is especially so in an acid furnace if a low silicon iron is used, even if it is not spongy. Again, there is a similar partial boil when the metal is charged into the ladle and moulds, especially in the case of hard steel. On the other hand when electric furnace "pig steel" is heated in the open-hearth furnace process this partial boil does not take place, and the regular boil commences immediately after the charge is melted and before the ore is added.

Several theories have been advanced to account for the behavior in this manner of "pig steel" upon melting. One of these is that the material is practically free from minute particles of oxides such as are generally present in ordinary pig iron, and which, as previously stated, are produced by the reoxidizing effect of the blast. Due to the absence of these oxides, practically no reaction with the Si and Mn present occurs at this time, and on this account the partial boil in the open-hearth furnace, during and after the melting, when treating electric furnace metal, does not occur, and it is possible to at once decarburize the charge by ore additions. The presence of silicon in such pig iron is therefore unnecessary during the first portion of the open-hearth process.

As above stated, in the tests at Degerfors it was found that more time and more ore was required in the treatment of normal electric furnace pig iron than was the case in the treatment of normal blast furnace pig iron. The reason for this is no doubt due to the fact that inasmuch as pig iron of normal composition contains no oxides it is not necessary that silicon and manganese be present in the iron in order to take up oxides, and hence the removal of the Si must be accomplished principally by means of ore, and as pointed out by Odelberg, only after this is accomplished can the decarburizing proper commence.

Summarized then, we may say:

1. That "pig steel" made in the electric furnace is better suited to the production of open-hearth steel than is the normal blast furnace pig iron.

2. That normal pig iron made in the electric furnace is less suited to the production of open-hearth steel than is normal blast furnace pig iron.

From what has been stated above it must not be inferred that it is not possible to produce normal pig iron in the electric furnace. As a matter of fact some hundreds of tons have been so produced in this country and in Sweden. Although the furnace at Trollhättan is so operated as to produce "pig steel," because this metal is better suited to steel making than is normal pig iron, the Noble Electric Steel Company, of California, on the other hand so operate their furnaces as to produce a soft foundry iron which is particularly suited to meet the requirements of the foundries of that section of the country. However, it has been found that a greater output may be obtained when making "pig steel" per unit of electrical energy expended than is the case when foundry pig iron is produced.

That the production of "pig steel" has met the requirements of the Swedish and Norwegian steel makers is borne out by the fact that as a result of the successful operation of the furnace at Trollhättan, and of the tests at Degerfors, the following plants have been built and are now in operation.

Place	No. of furnaces.	Rated H.P. capacity.
Domnarfvet, Sweden	1	3000
Hardanger, Norway	1	3000
Hagfors, Sweden	2	3000
The following are approaching completion:		
Hardanger, Norway	1	3000
Arendal, Norway	3	3000
Switzerland	1	2500

The Uddleholms Company are also increasing their plant at Hagfors by a third furnace, and are installing three more furnaces at their Nykroppa works. Altogether they propose to spend about $1,700,000 on these plants, and it is stated that they will probably substitute electric smelting altogether for their blast furnaces.

Pittsburgh, Pa.

Iron and Steel Institute.—The autumn meeting of the British Iron and Steel Institute will be held at Leeds from September 30th to October 4th. The professional sessions will be held at the Hall of the Philosophical and Literary Society. There will be a reception by the Lord Mayor and a garden party tendered to Lord and Lady Airedale, besides excursions to works in the neighborhood.

The Disadvantages of the New American Standard Copper Specifications.

By Ernest A. Lewis.

In June, 1911, the American Society for Testing Materials issued a proposed standard specification for copper, which, although it has met with approval by many American users and manufacturers of copper, is most unsatisfactory compared with the high-class copper which English users and makers approve. I am quite at a loss to understand why such a specification has been adopted.

America supplies the world with the largest proportion of copper of any country manufacturing this metal. The cause of the unsatisfactory nature of the new standard specification is most probably the development of the process of manufacturing modern copper. This is the adoption of electrolytic methods in conjunction with the Bessemerizing of crude mattes to 99 per cent purity and upwards, and no impurity worth mentioning, which copper is still further refined by electrolysis and the remaining small impurity is eliminated. It is then melted down into billets, wire bars and so forth.

It is most excellent copper, as a rule, for high conductivity wire and brass alloys, but for wearing properties it is inferior. I believe it is safe to say that the old Welch process of smelting is practically obsolete nowadays. The modern cupola and Bessemerizing plant has eliminated it; even in smelters where the old "Tough" and "Best Select" copper is made, the process is so altered as hardly to be recognized as the old Welch process of fifty years ago. The advance of the electrolytic refineries has altered the character of the copper, both in its properties for manufacture and wear.

To advocate the use and adoption of exceedingly pure electrolytic copper in preference to tough arsenical copper is similar to advocating the use of wrought iron for chisels and knives and the disuse of steel. What would be said of any committee which suggested such a thing? Wrought iron has its uses, so has steel. Pure copper has its uses, so has tough copper.

It is well known that all metals have definite properties, and that the presence or absence of certain elements in them makes a great difference in these properties. The most characteristic of metals to which an added element makes an enormous difference is iron when carbon is added. Take the comparatively pure metal iron as wrought iron, add to it by well-known methods 0.2 per cent carbon, 0.5 per cent carbon and 1.0 per cent carbon. We have practically four different metals or alloys of iron and carbon. There is a vast difference in their properties; each is suitable for different purposes. If the iron-carbon alloy is complicated by the addition of a few percentages of chromium or manganese we have alloys of totally different properties to the original iron.

When a small percentage of one metal is added to another it may mix with it and not alloy, the perfection of mixing depending on the rapidity of cooling, an example being bismuth in very pure copper, free from oxygen and arsenic; it may dissolve entirely in the metal like zinc will dissolve in copper; it may unite with a portion of the metal to which it is added, and on cooling separate out as a net work, such as arsenic in copper or phosphorus in copper; it may form a definite crystalline composed with a portion of the metal embedded in the alloy like cubes of Sb SN in an alloy of 10 per cent antimony and 90 per cent tin. All those various types of alloy have their uses.

Of recent years a large amount of research has been done in determining the properties of copper of various kinds. The Alloys Research Committee of the (British) Institution of Mechanical Engineers published in 1893 a valuable research by the late Professor Roberts-Austen and at the same time a valuable paper was read before the same body on "tensile" tests and a chemical analysis of copper plates from fireboxes of locomotives on the Great Western Railway by Mr. William Dean. These two papers and their discussions contain an enormous amount of valuable information. Professor Roberts-Austen's research was hardly on commercial lines, but it helps to explain many things connected with the practical metallurgy of copper. In 1903 the writer publisher a research on the effect of impurities on deoxidized commercial copper (*Engineering*, Dec. 4, 1903) and another research on "The effect of silver, bismuth and aluminium upon the mechanical properties of 'Tough Pitch' copper containing arsenic," by F. Johnson, M. Sc., was read before the Institute of Metals in September, 1910.

In the face of such papers it is difficult to understand why any committee representing makers and users of copper should recommend for all purposes a copper of 99.88 per cent purity. One of the most important uses of copper in every country, except the United States of America, is for fireboxes and tubes in locomotives. A copper which will stand this work will stand anything.

The various researches on copper have now brought forward an explanation of the properties of different varieties of the metal. It must be remembered that there is nearly as big a difference between the properties of a pure copper such as the committee recommended and a good quality of arsenical copper as there is between wrought iron and rail steel.

One thing the committee overlooked is that *it is impossible to work pure copper.* The copper they recommended is non-arsenical oxygen copper with only sufficient oxygen in it to enable it to be rolled hot, but such a copper is too soft to be of commercial value from a coppersmith's point of view. If such copper was subjected to a process for hardening it, such as the addition of phosphorus and removal of oxygen, it would pass the chemical test all right, but would fail on the electrical test.

From what I can gather from American friends the electrical test is considered of great importance in America. For electrical work this test is considered of great importance over there. For electrical work this test is, of course, important, but for copper for sheets, tubes and rods, and ingots for casting into brass for rolling, *in my opinion it is valueless and even misleading.* What is wanted is bending tests, opening tests, swaying tests, tensile tests, chemical analyses of value, *i. e.*, limiting the impurities. None of these appears in the American specification.

The metals and non-metals which may be present in refined copper or manufactured copper either as impurities or intentionally added for some purpose are lead, bismuth, tin, antimony, arsenic, zinc, manganese, nickel, phosphorus, silicon, and oxygen. Taking commercial brands of copper ingot the only brands which do not contain any of the above constituents other than in traces, except oxygen, are the various remelted electrolytic brands and native copper. These are the only brands which would pass the American specification.

If we take the metals and non-metals in order and compare their properties and effect on copper, as shown by modern research, with the opinions of experts in the manufacture and use of copper, we see the great mistake the American committee has made.

Lead.—In pure copper cast under ideal conditions with every care taken *to keep out oxygen*, this metal makes copper unworkable even in so minute a quantity as 0.1 per cent. In the Welch process of refining copper, lead is added to help to oxidize other impurities, but it must be removed from copper for sheets. For casting copper for the foundry it is immaterial if 0.1 per cent lead is left in. In an arsenical copper 0.1 per cent lead is harmless in the presence of 0.3 per cent arsenic and upwards, as will be shown below.

Bismuth.—This metal need hardly be considered in the large amounts that lead is met with, but in minute quantity it can be present in electrolytic copper. It has been proved that 0.005 per cent will make a pure copper made from electrolytic cathodes of inferior working qualities if the right adjustment

of oxygen is not correct. This condition might easily be obtained with a copper which would pass the American specifications as regards both analysis and conductivity, but such copper would be rejected by a bending test, such as is required in England. The American committee who drew up the specifications was, I understand, composed of representatives of users and makers. I do not suppose for one moment that anyone would make such a copper as I have described intentionally, as makers have a reputation to live up to. I merely mention it to show how a specification of this kind requires the greatest care in drawing up. Consider what would happen if owing to a quantity of bismuthic copper ore getting to the maker's smelter, unnoticed probably by their chemists. When the copper comes to the users it will not work hot. It is sampled as suggested, passes the analysis test and the conduc- of 0.05 per cent; this is at least five times the amount present had passed the specifications. Probably we should see a new standard specification drawn up on the lines I am suggesting. It has been proved conclusively that arsenic will neutralize the injurious properties of bismuth even when present in quantity of 0.05 per cent; this is at least five times the amount present in any commercial copper.

Tin is not present in commercial refined copper, but it has been added to copper for tubes to harden them in quantity up to 1 per cent. As far as I am aware this copper is not used now.

Antimony is not present in commercial copper except in traces, but it toughens copper and increases the tensile strength. Although it is not made commercially, I am inclined to think there is a future for this kind of copper when the right proportions of oxygen and antimony are known. It is much harder than even arsenical copper and would probably resist erosion well.

Arsenic is usually present in the English variety of copper known as "tough" copper. It is extremely beneficial in copper for coppersmith's work owing to its remarkable properties, which are dealt with below.

Zinc is never present in refined coppers, but for copper for drawing into tubes for plumbers' work and such like made by casting round sand cores and drawing direct into tubes, 1 per cent is sometimes added to non-arsenical copper to enable sound castings to be made. It is not present in any other kind of copper.

Manganese is never present in refined copper, but it has been used and recommended for use similar to zinc.

Nickel is sometimes present in refined copper; it intensifies the injurious effect of bismuth and lead. In England 1 per cent or 2 per cent nickel has been added to copper for use as loco tubes and stays.

Phosphorus is not present in refinery copper, but when casting oxygen-free copper 0.06 per cent is present, as a rule, in the finished metal. This kind of copper cast from pure electrolytic is very good quality. It can be rolled hot at a dull red heat and drawn down. It is altogether debarred from use in America if the standard specifications are acted upon.

Silicon is not present in refined copper, but for electrolytic castings the only way to make them is to add 2 per cent cuprosilicon to the molten copper (made from cathodes) before casting. This does not come under the specifications.

Oxygen is the most important element in copper. It is present in all copper. Even copper containing phosphorus contains 0.02 per cent to 0.03 per cent. In other kinds of copper *its quantity is of importance,* but the amount to be present is not even mentioned in the standard specifications.

The only metals or non-metals which interest copper refiners are lead, bismuth, arsenic, oxygen, and sometimes nickel These elements may be grouped into three groups:

1. Lead and bismuth.
2. Arsenic and oxygen.
3. Nickel.

The first group are the elements which in pure copper, free from arsenic and oxygen, render copper brittle and weaken the tensile strength, especially above the ordinary temperature. Roberts-Austen took a very pure copper and added to it 0.1 per cent bismuth, it was cast under conditions which precluded any chance of oxygen being present, and then he tested the rods as cast. The following were his results: (See *Proceedings* of the Institution of Mechanical Engineers, April, 1893, second report to the Alloys Research Committee.)

Temperature of rod.	Tensile strength per square inch.	Percentage of elongation.
15 deg. C.	18,020 lb.	20 per cent.
101 deg. C.	11,510 lb.	15 per cent.
162 deg. C.	5,620 lb.	0.0 per cent.
199 deg. C.	3,860 lb.	0.0 per cent.
274 deg. C.	4,940 lb.	0.0 per cent.
292 deg. C.	2,770 lb.	0.5 per cent.

It would be quite impossible to work this copper hot or even cold. Under conditions similar to these tests I have proved that 0.005 per cent bismuth would render copper unworkable. I have also found out experimentally that similar quantities of lead *in the complete absence of oxygen or arsenic* will make copper unworkable hot. A microscopical examination of the structure shows clearly why it will not work. Neither lead nor bismuth will alloy with copper when oxygen or arsenic are not present in certain definite quantities.

Both lead and bismuth are easily fusible metals; they surround the crystals of copper as a minute network of lead or bismuth. When they are heated they melt and the copper loses all cohesion, hence the rapid fall in tensile strength and elongation at high temperatures. Even in the cold bismuth renders copper unworkable even in minute quantity, but lead being of a plastic nature does not affect the copper in the cold.

The second group are the elements which not only toughen copper, but also render inert the ill effect of the metals bismuth and lead. *It is an impossibility for any refinery to supply billets for rolling purposes which do not contain one or other of the elements in quantity sufficient to effect working properties.* Roberts-Austen in his classical research took several percentages of arsenic and added to it pure copper under the same conditions as the bismuth tests described above and the following results are taken from his tests:

Temperature of rod.	Tensile strength per square inch.	Elongation per cent.
COPPER CONTAINING 1.5 PER CENT ARSENIC (AS CAST).		
15 deg. C.	26,460 lb.	20.0 per cent.
215 deg. C.	19,450 lb.	37.0 per cent.
COPPER CONTAINING 1.2 PER CENT ARSENIC (AS CAST).		
20 deg. C.	24,840 lb.	20.0 per cent.
224 deg. C.	16,460 lb.	15.0 per cent.
346 deg. C.	14,860 lb.	10.0 per cent.
COPPER CONTAINING 0.5 PER CENT ARSENIC (WORKED AND ANNEALED).		
18 deg. C.	33,420 lb.	37.0 per cent.
258 deg. C.	30,030 lb.	23.0 per cent.
446 deg. C.	20,000 lb.	13.0 per cent.
COPPER CONTAINING 0.2 PER CENT ARSENIC (WORKED AND ANNEALED.)		
18 deg. C.	30,150 lb.	30.0 per cent.
144 deg. C.	30,960 lb.	21.0 per cent.
249 deg. C.	28,730 lb.	30.0 per cent.

When arsenical copper is examined microscopically the copper crystals are seen to be surrounded with a thick network of alloy which is probably a solution of arsenide of copper in copper. This has the remarkable effect of neutralizing the injurious effect of bismuth and lead. This is well known to English refiners.

In 1903 the writer made some experiments on the effect of bismuth and arsenic on copper containing no oxygen. He found that 0.1 per cent bismuth in pure copper would not roll or bend, but when 0.6 per cent arsenic was added to the same copper it would roll fairly well and also bend. The author also

found that copper containing 0.05 per cent bismuth and 0.6 per cent arsenic would roll and bend well. Such copper without the arsenic would not roll at all.

All refined copper, whether arsenical or non-arsenical, must of necessity contain oxygen when cast from a refinery furnace as distinct from a crucible. F. Johnson in the course of his paper read before the Institute of Metals (September, 1910) shows conclusively that oxygen removes the injurious effect of bismuth. He rolled copper containing 0.052 per cent bismuth and 0.079 per cent oxygen, 0.094 per cent bismuth and 0.155 per cent oxygen and 0.124 per cent bismuth and 0.073 per cent oxygen. He remarks that the last bar "showed a bad surface appearance after the hot-rolling process, but the rolled material could then be hammered out at a red heat to a knife edge without showing any signs of cracking."

It is suggested that bismuth forms an oxide united with a portion of the cuprous oxide, which is malleable. This may be so. Of course, copper with such a high percentage of bismuth could not be rolled on a manufacturing scale, but the results are interesting as showing how the injurious effect of bismuth can be counteracted with oxygen alone without arsenic

In the same paper F. Johnson gives other results on arsenical copper of the type cast from the refinery furnace. This copper always contains oxygen in addition to arsenic. A certain proportion of oxygen is as necessary in this class of copper as in ordinary refined copper without arsenic. There is really no need for a specification of arsenical copper made from the refinery to specify the percentage of oxygen as unless the proper portion is present the metal would not pass the refiner's tests to which he subjects his metal before ladling. The following are typical results obtained by Johnson:

Mark.	Copper per cent.	Arsenic per cent.	Oxygen per cent.	Tensile strength tons per sq. inch.	Elongation per cent on 3 in.
R	99.905	nil	0.089	14.92	39 per cent
E	99.592	0.344	0.066	15.70	41 per cent
EF	99.565	0.410	0.060	15.75	51 per cent.
V[1]	99.570	0.361	0.052	15.75	38 per cent.

It will be noticed that R is the only sample which would pass the standard specification of the American Society for Testing Materials. The superiority of the arsenical copper is marked especially in the tensile strength. Further results are given of the effect of arsenic, oxygen, and bismuth in the same paper. I will quote two results:

Arsenic per cent.	Oxygen per cent.	Bismuth per cent.	Tensile strength tons per sq. in.	Elongation per cent on 3 in.
0.420	0.055	0.051	15.71	44
0.390	0.084	0.097	16.09	48

The superiority of the arsenical copper is marked even in the presence of bismuth in quantities which would never be found in practical work. In the paper of Mr. William Dean read at the same meeting of the Institution of Mechanical Engineers at which Professor Roberts-Austen's second report was presented are several examples of the superiority of arsenical copper in practical work on locomotives over non-arsenical copper. Here follows a few results of copper fireboxes:

Mileage.	Arsenic per cent	Lead per cent.	Copper per cent.
489,334	0.534	0.051	99.195
493,994	0.811	0.081	98.001
506,341	0.292	0.126	99.250
177,633	0.013	0.043	99.828
54,564	0.042	0.056	99.810

These are figures of actual working practice and are confirmed by many other large railways. The most significant figures are that the percentages of copper nearest to the American specification are the most unsatisfactory from a user's point of view.

The ratio of arsenic to lead is important in refined copper. There must be three times the quantity of arsenic present as there is lead to get a good copper. The English practice of copper refining gives far better results from a user's point of view than the American.

Having now brought forward indisputable evidence from practical men as to the utter unsuitability of such a standard specification for copper for all purposes, I will compare the American specifications with the English practice. The American specification lays great stress on the electrical conductivity test.

"All wire bars shall have a conductivity of at least 98.5 per cent (annealed) and all ingots and ingot bars shall have a conductivity of at least 97.5 per cent (annealed) excepting only arsenical copper, which shall have a conductivity of not less than 90 per cent (annealed)." It is certainly necessary to have a conductivity test for copper for electrical purposes. But for other purposes it is not only useless, but very misleading.

Of what use is an electrical conductivity test of any kind in arsenical copper? What use is such a test for billets for tubes or cakes for rolling into sheet? It would be possible, as I have shown above, to produce a copper which will pass the conductivity test but would not be satisfactory in working.

Again the standard specification says that the copper contents must be at least 99.880 per cent and to see that the parcel is of this quality it is proposed to take two pieces (probably four pieces are intended, but even this number is quite inadequate) and drill them and from the mixed drillings of these pieces the whole parcel is to be rejected or accepted in case of any dispute.

How any committee representing makers and users could suggest such a test is what I cannot understand. In the first place, even if one got a representative sample in this way, the three different analysts may not agree within 0.03 per cent, and I venture to say that if any one took an ingot of copper and drilled it in several places and mixed the drilling and sent it, as three different samples to the same analyst, even a man of high repute, his results would vary by 0.03 per cent. Another matter is that, as the author pointed out in *Metal Industry* for September, 1911, it is easy for ingots cast at the beginning of a furnace charge to vary by 0.05 per cent from those cast at the end of the ladling.

The very best recast electrolytic copper would only just pass the analytical test of 99.880 per cent purity. As it is absolutely impossible for any refiner to make such recast copper without adding to it 0.08 per cent to 0.1 per cent oxygen as cuprous oxide, it would be impossible to cast the copper as "tough pitch" without the oxygen. It would be highly improbable for such copper to contain lead owing to the property which lead has, that in an acid sulphate solution it separates out as oxide on the anode.

But this does not apply to bismuth, and as the tendency of refiners will be to get over-poled rather than "tough pitch" copper in order to pass the analytical test, bismuth might be present in such copper in minute quantity in such a form as to render it unsuitable for making brass alloys for rolling, etc. Why is not the percentage of bismuth limited to 0.005 per cent, and why is not the proportion of oxygen specified?

Putting on one side the fact that such copper would be too soft in practice for hard wear, it could not be cast from a refinery without oxygen. It is possible to cast billets from crucibles for rolling into tubes with only 0.03 per cent oxygen, by the addition of 0.05 per cent to 0.09 per cent phosphorus, but this variety of copper would not pass the conductivity test, although such copper is excellent from the point of view of hard wear and tear. This is an example of an excellent variety of copper which would pass one test in the specification and fail in another.

The only specification given for the arsenical copper is the unnecessary conductivity test. In England the percentage of arsenic is usually specified to be from 0.35 per cent to 0.6 per cent. Many users have found it necessary to limit the lead to

0.1 per cent. In many cases it is essential to have at least double the quantity of arsenic as there is lead.

In the discussion on the second report to the Alloys Research Committee the following interesting figures were given by one of the speakers, Dr. David Watson. The figures are obtained on copper locomotive fireboxes.

Lead, per cent.	Arsenic, per cent.
Three good plates.	
0.079	0.847
0.025	0.440
0.130	0.332

These figures are typical of the experience of English users and makers of arsenical copper.

Another use of arsenical tough copper is that in the brass foundry it is altogether superior to pure copper for making gun metal and alloys of that type. The arsenic acts as a toughener. In some of the largest brass foundries in England arsenical copper is always used for gun metal.

The American standard specifications are in urgent need of revision for the following reasons:

1. They do not represent the modern views of metallurgists as shown by recent researches and are not drawn up in accordance with known facts published by practical users and makers of copper.

2. They put makers of "tough" copper at a great disadvantage, although modern research shows that "tough" arsenical copper is more suitable for making into tubes, rods, and plates (other than electrical work) than the copper recommended.

3. The methods of rejection or acceptance of parcels of copper by the method of sampling an analysis as described by the specification are unfair to the maker and are against the experience of practical refiners and chemists.

4. The physical tests are quite inadequate as they contain no reference to tensile strength, elongation or bending tests.

5. Chemical tests are of no value unless the various impurities likely to be in copper are specified and limited.

6. Copper which is suitable for one purpose may be quite unsuitable for another purpose, therefore no one specification can cover copper for all purposes.

Birmingham, England.

Tanks and Pipe is the title of Catalog 10, just issued by the Pacific Tank & Pipe Company, of San Francisco, giving an illustrated description and list of sizes of the principal types of tanks built by this company. An interesting type is their patent non-shrinking water tank which is made with a deep channel or groove in the top of the staves. This groove is filled with water from pump discharge which, by absorption, passes into the pores of the wood, keeping the entire tank moist at all times and preventing shrinkage. A similar but modified principle is used in the same company's non-shrinking oil tanks. Other types, described in the catalog, are plain water and oil tanks, closed-top oil tanks, wagon tanks, fermenting tanks, wine storage tanks, brewery tanks, silos, tank towers, wooden pipe, and accessories.

Mr. William B. Ruggles, president of the Ruggles-Coles Engineering Co., 50 Church St., New York City, has just returned from England and advises that the Electro-Metals Co., Ltd., London, have been appointed their sole agents for all Europe, excepting Norway and Sweden. The Electro-Metals Co., Ltd., will appoint sub-agents on the continent.

Experiments in Oil-Smelting in British Columbia

The annual report of the Minister of Mines of British Columbia for 1911 contains some notes by Wm. Fleet Robertson, Provincial Mineralogist on attempts to smelt with oil as fuel. For the past two years the Dominion Oil Smelting Company, Ltd., in Vancouver, has been conducting a series of experiments in the old Van Anda smelter, in an attempt to perfect or render practicable an oil-fired furnace for smelting ores, and has achieved a degree of success such as to render the process worthy of serious consideration. The particular form of furnace being experimented with is covered by Canadian patents granted to J. J. Anderson, and acquired by the company. More recently, March, 1912, Mr. Anderson has taken out United States patents for a new furnace, which is a modification of the Van Anda furnace, designed along lines suggested by Mr. Thomas Kiddie after the latter had made a test at the Van Anda plant.

The Van Anda furnace, of which a rough sketch is given in Fig. 1, is essentially a shaft furnace superimposed above one end of a reverberatory furnace or combustion chamber. In operation, the ore with suitable fluxes is fed into the shaft from the charging floor, passing down onto one end of the reverberatory hearth. The shaft thus serves as a feeding hopper for the reverberatory. The latter is fired from four injectors which squirt vaporized oil into the front of the chamber, the flame impinging on the foot of the ore column in the shaft. The products of combustion pass upward through the charge, thereby heating it to near the melting point, and escape through a suitable flue and stack. The melted ore flows down over the inclined hearth of the reverberatory into a well or sump, in which the matte and slag separate by gravity, each being tapped through holes placed at suitable levels. The injectors are operated under steam pressure, and the proper amount of air is supplied by a pressure blower.

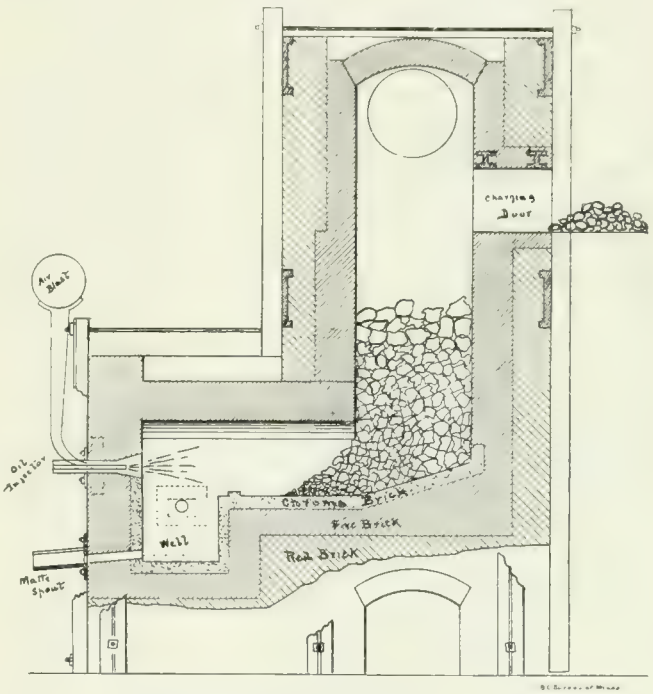

FIG. 1.—DOMINION OIL SMELTING COMPANY. OIL-FIRED BLAST-FURNACE, VAN ANDA, B. C.

The furnace undoubtedly requires and will receive considerable modification before it is commercially successful; but that a considerable advance has been made toward that goal is indicated by the results of a test made by Mr. Thomas Kiddie, a metallurgist of British Columbia, who has had previous experience with oil-fired furnaces at the works of the Orford Copper Company, New Jersey.

The ore mixture smelted consisted of ore from the Boundary district, British Columbia, iron ore as flux, and copper slag from a previous operation. Two burners were started to heat the furnace, when the other two were added. The mixture was readily smelted without trouble or interruption. Allowing one hour for heating the furnace, the oil consumption was as follows: for preliminary heating, 60 gal.; smelting for 2.33 hr., 157 gal., or a total of 217 gal. This gives 14.6 gal. of oil per ton of material smelted, equivalent to a cost of 43.8 cents per ton of ore. The rate of smelting was 110 tons per 24 hours, an increase of over 100 per cent over the best preious demonstration. It was Mr. Kiddie's conclusion that the furnace could be improved to take advantage of more complete combustion of the oil, and the cost of smelting reduced to from 30 to 35 cents per ton of ore. He estimated the saving in labor cost at the furnace at 9 cents per ton of ore.

After the furnace had been remodeled according to Mr. Kiddie's suggestions, another test was made by Mr. W. C. Thomas, who smelted 25 tons of material at the rate of 100 tons in 24 hours, and with a consumption of oil for smelting amounting to 11.2 gal. per ton of ore, costing 33.6 cents. The result was considered gratifying, as it confirmed the previous opinion of Mr. Kiddie.

An earlier instance of adapting oil to blast smelting is found in a furnace patented by the late J. W. Nesmith, of the Colorado Iron Works Company, Denver. This furnace was experimented with at the factory of the Colorado Iron Works Company, for several years. The only commercial plant ever turned out by the company is a 200-ton furnace owned by the Pioneer Smelting Company, near Tucson, Arizona. This furnace has been in operation for a short time, and the preliminary results lead to the belief that it will be successfully operated with crude oil as fuel.

Report of Bureau of Mines

The first annual report made by Dr. Joseph A. Holmes, director of the Bureau of Mines, has just been issued, covering the fiscal year ended June 30, 1911. The general aim and purpose of the inquiries and investigations made by the bureau under the terms of the organic act are to increase safety, health, economy and efficiency in the mining, quarrying, metallurgical and miscellaneous mineral industries of the country. The demands now being made on the bureau by both the government and the general public are such as might be expected in the case of a bureau of much longer activity and larger income. These demands are the more embarrassing because the funds at the disposal of the new bureau are less than they were for the technologic work under the Geological Survey.

The urgent needs of the bureau include new buildings, grounds and equipment; sufficient funds for the continuous operation of the mine-rescue and first-aid work; investigation of mine accidents; enlargement of fuel investigations, and new investigations looking to the prevention of mineral waste.

The first year's work of the bureau has been confined mainly to investigations into the causes of mine explosions, testing of mineral fuels, and studying mine accidents. Another of the investigations relates to smelter fumes, which in California and some other states have proved destructive to government forests. This investigation should be extended to include different types of smelters, and the behavior in these smelters of different varieties of ore, and to the various possibilities of preventing or lessening the escape of deleterious fumes in smelters.

Another minor investigation has been made in connection with furnace slags and the influence of different metals and other mineral substances on the character and value of slags; and also the influence of metals like titanium on the behavior of molten iron in the furnace. Data have been collected also on waste in metallurgical operations. Information in hand indicates a large extent of this kind of waste and the importance of further investigations to determine how it may be reduced

The Fractional Distillation of Wood Tar by Electrical Heat

By H. K. Benson.

Inasmuch as the wood tar industry of the Pacific Northwest finds it necessary to distil wood tar in order to successfully utilize and dispose of this product, it was thought desirable to ascertain the cost of heat from an electrical source for this purpose. In these experiments the work of Richards and Matthews,[1] Morse and Frazer,[2] and of Day and Allen,[3] suggested the means and methods used. The problem as applied to wood tar consisted in ascertaining the cost viewed relatively from the improvement in the grade of products due to absolute control of heat and the utilization of all the heat.

In the distillation of wood tar in a retort heated by gas the distribution of heat is far from uniform and satisfactory control is not obtained. Excessive local heating is produced, causing the decomposition of the heavy oils, the formation of non-condensable gases, and an increased yield of coke residue. To overcome these difficulties an apparatus was designed with the following ends in view:

1. Application of heat where most needed.
2. Uniformity of heat.
3. Absolute control.
4. Elimination of "bumping."
5. Utilization of all the heat.
6. Uniform quality of fractions.

Design of Apparatus.—Several designs were attempted but only one proved satisfactory. In this the heat was applied by passing a current through nichrome wire wound outside of a distilling flask. After a series of preliminary tests, a mixture,

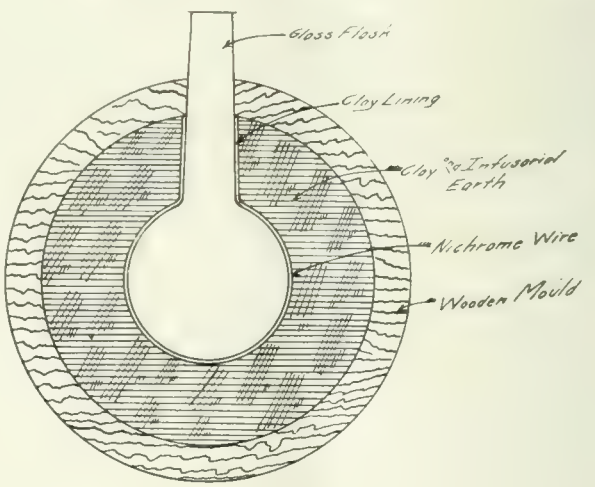

FIG. 1.—SECTION OF DISTILLING FLASK.

consisting of two parts infusorial earth and one part plastic blue clay, was selected as a desirable insulating material. Wooden moulds were made the size and shape of a distilling flask, and cut into two equal sections, lengthwise of the neck. By means of rows of pegs driven into the wood, 18 ft. of number 24 nichrome wire, having a resistance of 26½ ohms, was wound on each hemisphere. A larger hollow wooden mould (see Fig. 1) was filled with a stiff mixture of the insulating material and the hemisphere embedded. It was left to air dry over night, and put into a steam oven to bake for 24 hours. At the end of this time, a current was passed through the wire, and the wooden mould burned out, leaving the wire around the walls of the depression. After cooling, the wire was covered with a thin plastic clay, forming a smooth receptacle for the distilling flask and keeping the wire from touching the glass.

The other half was prepared in a similar manner. By placing

[1] Journal A. C. S. 30:1282 (1908).
[2] American Chemical Journal 32:93 (1904).
[3] Unpublished letters.

the two halves over the flask, it was entirely surrounded by wire and this in turn with an insulating layer 2 in. thick. The wire was wound with a view to partial concentration of the heat near the bottom of the flask, where it would be of most service.

The wires from the two sections were connected in parallel, making a combined resistance of 13 3/10 ohms at 24 deg. C. Two turns were taken about the neck of the flask to diminish the condensation in that part of the apparatus. The current used was obtained from the storage batteries in Bagley Hall, where any electromotive force from 2 to 110 volts can be obtained.

Distillation tests.—Three different tests made in the electrically heated retort show the uniformity of product obtained in this manner (see tables Test I, II, III).

4:19		41	3.2	196	42.7 gms. oil
4:28		39	3.1	212	
4:42		37	2.9	213	
4:51		39	3.1	224	25.3 gms. oil
5:15		40	3.0	230	
5:23		40	3.0	250	32.1 gms. oil
5:31	1.45	40	3.0	230	

Properties of fractions.—Below 110 deg. C. water and very small quantity of light yellow oil were given off. This oil was separated and added to the next fraction. The first oil fraction distills between 110 deg. C. to 190 deg. C. and has a light amber color which becomes clear red on standing. From 190 deg. C. to 215 deg. C. a darker amber colored oil is obtained which gradually changes to a red. Between 215 deg. C. and 230 deg. C. a thicker oil is obtained which also slowly changes to a darker color. The last fraction between 230 deg. C. to 245 deg. C. produces a rich reddish oil which in a few days, becomes almost opaque. Lastly a final residue of black brittle pitch, breaking with a conchoidal fracture and of brilliant luster, is obtained.

*Fractions obtained by distillation with gas flame.

Test with gas-heated retort.—For comparison purposes the usual gas-heated retort was used and the distillation conducted under ordinary laboratory conditions. The oils obtained in the various fractions were of a cloudy appearance, and a considerable quantity of white fume was formed. This test is designated as IV in the following tabulated summary of results:

Test	Tar Gms.	Water °C	110°C. 190°C. %	190°C. 215°C. °C	215°C. 230°C. °C	230°C. 245°C. %	Pitch %	Time H M	Watts
I.	435	3.72	12.00	7.33	6.48	8.00	62.70	2:28	370
II.	450	3.25	12.53	9.50	5.62	7.13	62.00	2:43	350
III.	430	3.72	11.74	10.30	5.39	6.30	62.55	3	370
IV.	429.5	3.33	13.00	7.07	5.14	7.70	63.60	2:15	15 cu.ft.

Cost of electricity.—The comparison of cost of electricity with gas must, of course, be considered from the standpoint of market price. The cost of gas for domestic use ranges from 80 cents to $1 per 1000 cubic feet. Using 70 cents as the cost of gas delivered would make the cost of 15 cubic feet to be 1.12 cents. To distill a like quantity of tar by electricity requires 370 watt-hours. The cost of electricity for power purposes ranges from 3 cents to as low as 6/10 of a cent per kw-hour. In view of the fact that this would be a desirable load to carry, since it could be run off peak or as a 24-hour load, a price of 1 cent per kw-hour could be realized. On this basis the use of 370 watt-hours would cost less than 4/10 of a cent.

The general conclucion reached is that distillation of wood tar by heat from electricity will yield a larger quantity and a higher grade of oils than by heat from flames. Compared with gas as a fuel, electricity is much cheaper and probably compares favorably with the cheaper fuels in economy. The ease with which distillation can be controlled, and the decrease of danger from fire are among the advantages of this method.

The experimental work, described in this article was done under the author's direction by C. E. Brown and G. B. Shadinger, forming a portion of a thesis submitted for the degree of B.L. in electrical engineering at the University of Washington.

The Relation Between Temperature and Viscosity of Lubricants.

The Ellis-Elebash Temperature—Viscosity Law.

By R. L. Ellis.

The purpose of a lubricant is to reduce, or, as nearly as possible prevent, friction. In a lubricated bearing the friction is of two kinds, viz.: that due to the attrition of the rubbing surfaces and that due to the internal friction between the molecules of the lubricant itself. The lubricant reduces the friction of attrition by interposing a film of the lubricant between the rubbing surfaces and thereby keeping them more or less perfectly separated. The relative motion of the rubbing surfaces with the film of lubricant interposed sets up internal friction in the lubricant itself.

From this it will be evident that the lubricant with the least internal friction, which will keep the rubbing surfaces separated, will reduce the total friction to a minimum. This internal friction of a lubricant is usually termed viscosity or body, so

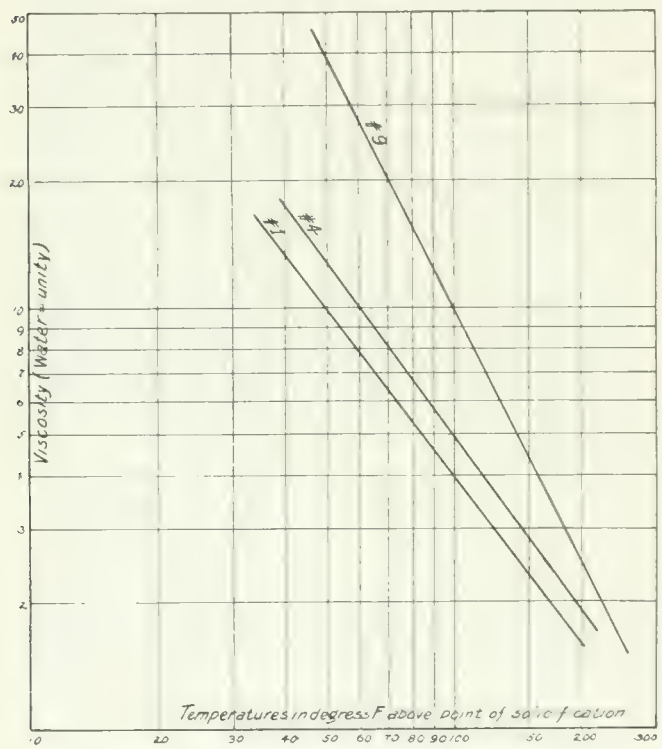

FIG. 1.—TEMPERATURE—VISCOSITY DIAGRAM.

that the above statement might be paraphrased by saying that the best lubricant for a given service is the one with the least viscosity which will produce the necessary film between the rubbing surfaces, or it is the thinnest lubricant which will stay in place and do the work.

It, therefore, follows that, broadly speaking, and within certain limits, viscosity may be taken as the measure of value of an oil for lubricating purposes. And granting this, the determination of viscosity, and the extent of its variation, is a matter of considerable importance in the proper selection of oils for lubrication. In general, viscosity is independent of specific gravity, cold test, flash point or fire test, but is a function of the kind of oil and the temperature at which determination is made. It should be stated, however, that while the viscosity is independent of the specific gravity of the oil, nevertheless, its determination by means of the pipette type of instrument is more or less affected by the specific gravity.

It is possible, moreover, to add certain ingredients to an oil which will materially affect the determination of the viscosity as made by means of the pipette type of instrument, but which do not add to its value as a lubricant. And, again, some of these artificial loadings add largely to the viscosity at low temperatures but do not sensibly affect it at the higher temperatures. From this it is apparent that it is not altogether safe to place too great confidence in the viscosity of an oil as determining its fitness for a given use without a knowledge of some of its other properties or characteristics. Nor can we confidently predict the probable lubricating value of an oil at one temperature from a knowledge of its viscosity and known lubricating value at some other temperature. For while the viscosity of an oil, in general, varies inversely with the temperature, the rate of change is not uniform as between different oils, nor is the rate of change uniform over any wide range of temperature changes in the same oil.

Although the viscosity of an oil, by and of itself, is not conclusive as affording a measure of its lubricating value, it is nevertheless probably the most important single characteristic as affecting this value. And while this fact has been generally conceded by the best informed, the application of the knowledge in determining the suitability of an oil for a specific service is a problem not unattended with considerable difficulty. The great majority of the users of lubricants have not recognized the importance of this problem, and its complexity has deterred many who have recognized its importance from seeking a solution. It is no small undertaking to determine the viscosity of any considerable number of oils over the wide range of temperatures and at the close intervals necessary to predict with any degree of certainty what the viscosity will be at any prede-

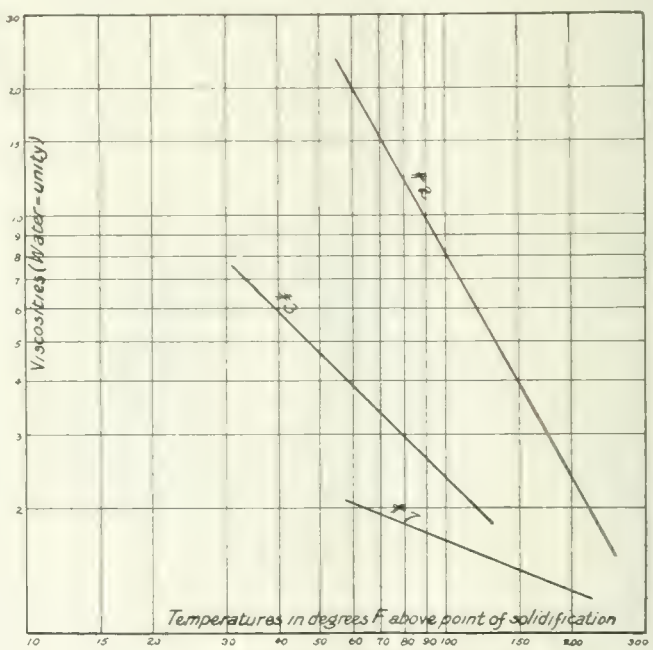

FIG. 2.—TEMPERATURE—VISCOSITY DIAGRAM.

termined temperature. And without this very intimate knowledge of the exact relationship existing between temperature change and the corresponding viscosity change for each oil proposed, the consideration of viscosity in its relation to lubricating value is of small utility.

Being confronted with the desirability of knowing the viscosity of an oil at widely differing temperatures and at frequent intervals it becomes evident that it is a matter of considerable interest and importance to ascertain if there be not some general law connecting temperature change with the corresponding viscosity change, since it is reasonably to be expected that such a law would greatly simplify the process of such viscosity determinations for a large number of temperatures. Recognizing the desirability of some simple method of predicting with reasonable certainty the viscosity of a given oil for different temperatures without the necessity for a separate determination for each, an attempt was made to ascertain

if there be not some law applying to at least some considerable number of lubricating oils likely to be met with in practice.

In making the attempt to find such a law, a large number of separate determinations were made covering oils of widely different characteristics and over a large number of temperature changes. These determinations were supplemented by data obtained from different sources covering substantially the same information. After this information was tabulated and classified curves were drawn on rectangular cross-section paper an attempt was made to recognize the shape of the curves and if possible determine the equations representing them. Or failing this, to ascertain if it were possible to approximate the curves by determining a relatively small number of points in each case.

The resulting curves appeared to be all of the same general shape and to the eye closely resembled the polytropic curve of expansion of elastic media corresponding to the general equation $PV^n = C$. The natural limitations of the human mind

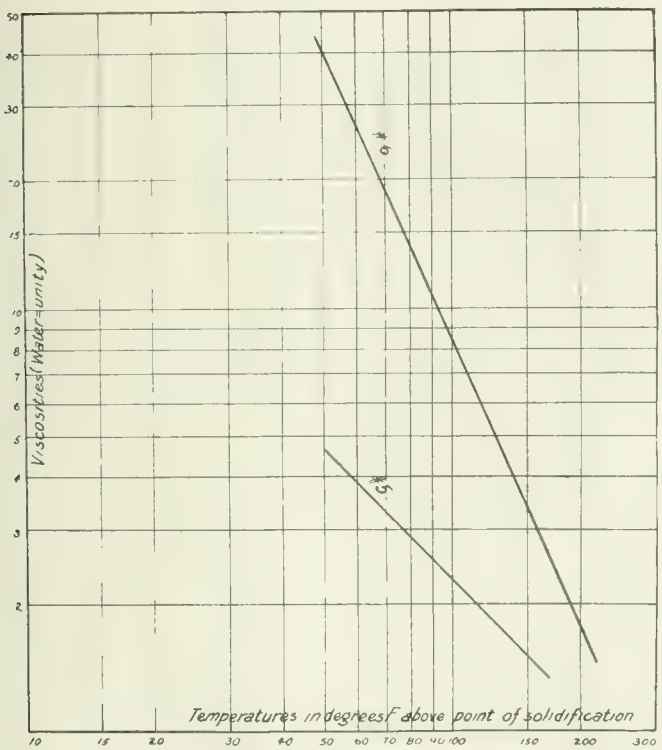

FIG. 3.—TEMPERATURE—VISCOSITY DIAGRAM.

are such, however, that we are not able in general to distinguish between curves, especially when they approximate the same general form. It is doubtful if the investigation would have gotten past this stage had it not occurred that one of the curves corresponding to the special case of the curve wherein the value of n is unity. In this case the temperatures were plotted from 0 deg. Fahr. and represented the base. The viscosities were taken with reference to water (and are therefore specific viscosities rather than absolute) and used for ordinates, being plotted from zero also. With these conditions, this curve corresponded at almost every point to the equation

$$TV = C,$$

and was consequently rather easily recognized.

This close correspondence of the curve with this equation throughout the whole part plotted, and the similar shape of the other curves led to the belief that possibly the other curves corresponded to the general equation if proper values could be found for n and C and provided the proper origin be selected for T and V. The plotting of this polytropic curve on rectangular cross-section paper gives a curve depending for its form and position on the values of T, V, n and C. When, however, this curve is plotted on logarithmic paper it becomes a straight line which depends for its position on C and for its slope on the value of n.

The relationship of the curves is as follows:

Being given

$$TV^n = C.$$

Then,

$$\log T = n \log V + \log C.$$

This assumes the same form as the equation for a straight line,

$$Y = aX + B$$

Where $Y = \log T$, $s = -n$, $X = \log V$, $B = \log C$.

And thus $s = -n$ represents the slope of the line to the axis $\log T$ and is numerically determined by taking two points on the curve and determining the value of the ratio,

$$\frac{OY}{-OX} = -n,$$

the value of the ratio being negative on account of the measurement being toward the left on OX and hence negative.

For a time we were at a loss to understand why the temperatures taken as above 0 deg. Fahr. scale should give a straight line characteristic since this point represents no very definite point as does the zero on the Centigrade scale. This

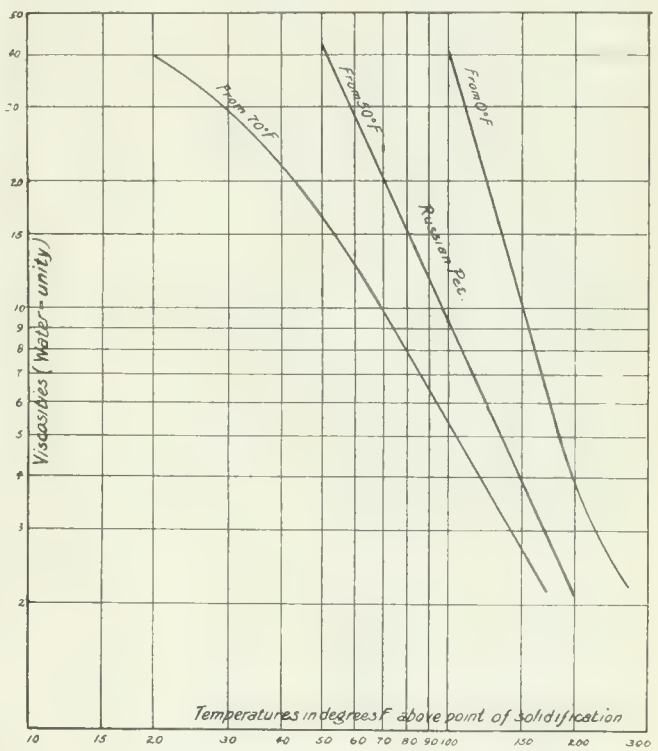

FIG. 4.—TEMPERATURE—VISCOSITY DIAGRAM.

was made clear when we discovered that some of the oils, especially the more viscous petroleum products, when plotted in temperatures above zero Fahr. did not give a straight line, and it became necessary to alter the point of origin. It was then discovered that the oils giving a straight line for which the origin was taken from zero Fahr. completely solidified at or about this point, and that the other oils if plotted with their temperatures of complete solidification as the origin gave substantially straight-line characteristics.

In few cases, if any, were we able to get all of the points exactly on a straight line, nor were we able to get two successive determinations of viscosity to agree exactly in value except in rare cases. This was especially noticeable at temperatures much above or below room temperature.

The tendency of all of the viscosities, for the different oils for which determinations were made by those conducting the investigation, was to deviate from the straight-line characteristic both at high and at low temperatures. At temperatures

greatly below that of the surrounding atmosphere the viscosities tended to run low and at high temperatures to run high. The more the oil temperatures deviated from room temperatures the more marked this tendency became. After discovering the apparent applicability of the curve $TV^n = C$ to temperature-viscosity variations a considerable number of the determinations were remade in order to determine, if possible, the reason for this discrepancy.

In remaking these determinations great care was exercised to insure uniform temperature throughout the whole mass of oil, to detect if there were any change in the temperature during the test period, and to determine if the temperature of the oil at the nozzle were the same as in the oil mass. When we were able to maintain practically uniform test conditions as above we found in each case the points fell much nearer the straight line, but in general the points at the extremes of temperatures did not fall exactly on the line. The more accurately the tests were made the more nearly the points conformed to the general law.

Plotted curves from data, obtained from our own determinations and from other sources, we would occasionally find a single point which fell entirely away from the line. In making a redetermination of our own data for the particular point, we invariably found that an accurate determination brought the point practically on the line and it is assumed that the same would be true of the data from other sources, though there was no means of checking this.

The commercial form of viscosimeter is hardly to be considered an instrument of precision, and unless all of the conditions of its use are rigidly maintained constant during a determination the aggregate of the errors are likely to be rather large. The sources of error encountered seem to have been due to the temperature not being uniform throughout the oil mass and the rapid change of temperature at the efflux nozzle, these being more noticeable where the temperatures differed greatly from that of the surrounding air. The change of specific gravity in the oil with the change in temperature, of course, has more or less influence on the determinations made on this type of instrument, but the errors due to this change are necessarily rather small.

Several curves are submitted herewith showing the characteristics of several varieties of lubricating oils. These are grouped for non-interference on the sheets rather than for any reasons of similarity of the oils, although some of the oils on the same sheet show very similar curves. On sheet 4 are shown several curves to illustrate the departure of the curve from a straight line due to taking the temperatures from different temperatures; one from the point of solidification, and one each from temperatures above and below this point.

The number of separate determinations of viscosity tabulated and studied do not cover a wide enough range either in temperatures nor in kinds of oils, nor is the accuracy of these determinations believed to be of sufficient accuracy to enable it to be said that the law holds universally. However, it is believed that the very close correspondence to the law of data obtained from widely different sources makes it more than probable that the law holds throughout the ordinary range in temperatures and for the oils likely to be met with in ordinary use, and more than possible that it holds universally.

The Ellis-Elebash law may be stated as follows: In any lubricating oil a change in its temperature is accompanied by a corresponding change in viscosity, and if T represents the temperature in degrees above its point of complete solidification, and V represents the corresponding viscosity relative to water (water being considered as unity), then the rate of change in viscosity corresponding to a change in temperature is such that it is represented by the polytropic curve corresponding to the equation

$$TV^n = C,$$

in which n is a coefficient depending upon the particular oil under test and C a constant which also depends upon the particular oil. n might be termed the modulus of viscosity.

The practical application of the law is that: Given the point of complete solidification of the oil and two determinations of viscosity (preferably at rather wide variation of temperature) it is possible by plotting the curve on logarithmic paper to determine with substantial accuracy the viscosity at any other temperature within the range over which oils are likely to be needed for lubrication. Or failing the point of solidification and given three viscosity determinations (as above) it is possible to determine the point of solidification by method of trial and error, and to determine the viscosity at other temperatures as first stated.

Consequently, since in practice an oil which has a reasonably small viscosity change with a given temperature change (above and below the working temperature) is most desirable, the law forms a simple and effective means of determining the extent of this variation by means of the inclination of the line to the axis log T.

Selma Lighting Co.,
Selma, Ala.

If working cyanide solution contains lime, or lime salts, and it is necessary to drip strong cyanide solution into the working solution just before it comes in contact with the zinc, it is inadvisable to make this strong solution from solid cyanide containing alkaline carbonates in any appreciable quantity, otherwise the resulting precipitate of calcium carbonate will be a source of loss and expense in the subsequent smelting.

Plug cocks cause trouble on high-pressure water-service pipes, especially when they are at, or near, the end of a long line. The rapidity with which such cocks can be closed causes shocks, if not bursts, on the pipe line.

Notes on Chemistry and Metallurgy in Great Britain.

(From our Special Correspondent.)

Ancient Indian Iron.

Sir ROBERT HADFIELD recently secured specimens from the noted iron pillar of Delhi which have given the following results on analysis—the iron having been actually determined: Carbon, 0.08 per cent; silicon, 0.046; sulphur, 0.006; phosphorus, 0.114; iron, 99.72; total, 99.966. Specific gravity, 7.81, It is noteworthy that manganese is absent. Sir Robert is of opinion that this is the first complete analysis of this iron which has been published. It shows that Indian metallurgists more than a thousand years ago could produce wrought iron of excellent quality; and the very low sulphur content points to their care in selecting pure fuel. In his paper on "Ancient Sinhalese Iron and Steel," read at the May meeting of the Iron and Steel Institute, Sir Robert gave interesting particulars of this remarkable pillar. It is a solid shaft of wrought iron, upwards of 16 in. in diameter and 22 ft. high, consisting of blooms of about 80 lb. weight each welded together; but the welding is not uniformly good. It probably dates from about 300 A. D. Some three years after the Iron and Steel Institute was formed, special inquiries were made by the committee concerning this pillar (1872, Vol. II, page 156); and Lieutenant Spratt, R. E., then stationed at Delhi, gave the height of the column above the ground as 24 ft., the depth underground as 3 ft., and reported that the lower end is a bulb like an onion and rests on eight short thick iron rods, the inferior extremities of which are leaded into blocks of stone.

Coal Dust Explosions.

The construction of the experimental station at Eskmeals, Cumberland, which was begun in September last, has been delayed by the coal strike and other causes, but is now approaching completion, and it is expected that in about a month experiments on a large scale will be begun under the direction of the consultative committee consisting of the members of the Royal Commission on Mines and the Coal Dust Committee of the Mining Association.

The main equipment consists of three steel galleries, the largest of which has been transferred from the old station at Altoft's colliery. It consists of old boilers, and has a length of about 800 ft. with a diameter of 7 ft. 6 in. It runs east and west, resting on sleepers laid on the shingle; and at the eastern end two turns at right angles bring a return arm, parallel with the main tube, to the fan house. By the side of the main gallery there is a smaller tube 400 ft. long constructed of flue pipes, 3 ft. in diameter, carried on concrete pillars; and by means of curved tubes at both ends this tube can be joined up to the main gallery. Provision of compartments for containing gaseous explosive mixtures will allow a gas explosion in the small tube to start a dust explosion in the main tube. Instruments for recording pressure and velocity are stationed between the two tubes in a series of huts, each of which is provided with apparatus for taking photographs of the explosions through glass-covered slits on a disk rotated at a speed greater than that of the propagation of the explosions. For preliminary experiments there is a third tube, further to the north, 150 ft. long and 1 ft. in diameter, connected with a gasometer holding 1500 cu. ft. and with a fan. The adjustment and reading of the recording instruments will be effected at the chronograph house, which will be provided with a large photographic darkroom. To the south of the main gallery there are various buildings accommodating accessory plants. Power is derived from two 25-hp Robey engines driving two dynamos, one of which generates current at 200 volts and the other at 100 volts; and the battery room contains 60 chloride cells. Gas-making and coal-crushing plant, a lamp-testing station, together with physical and chemical laboratories complete the equipment of the station. The whole of the arrangement appears to have been carried out with great care and foresight, and there is every reason to anticipate the attainment of conclusive results in the near future.

The Institute of Metals.

For the first time since the formation of the Institute the annual autumn meeting will be held in London on Sept. 25 and 26 at the Institution of Electrical Engineers. The mornings will be devoted to the reading and discussion of ten papers, and the afternoons to inspections of Messrs. Fraser & Chalmers' works at Erith, the National Physical Laboratory and Woolwich Arsenal. A visit to the Brooklands motor race course and aviation ground has also been arranged with the view of witnessing the competition for the aviation prize offered by the Institute.

Quick Combination Methods in Smelter Assays.

A paper bearing this title, recently read before the Institute of Mining and Metallurgy, has elicited the subjoined communicated remarks from Mr. J. H. LEVINGS. As chief assayer of a large customs smelter he made thousands of lead determinations by various methods, and finally exclusively adopted Alexander's method, which, after severe testing against English and German assayers, was found very accurate. The solutions were filtered hot, after the lead sulphide had subsided, and with good filter paper and re-filtration of the first portions the loss was negligible. Lime does not ordinarily interfere, but it is as well to remove the beaker from the hot plate as soon as the first fumes of sulphuric anhydride appear; and the drop of nitric acid adhering to the cover-glass will do no harm. But in the assay of flue dust containing 30 per cent lead and 10 per cent lime Alexander's method gave results about 2 per cent too high, and for such flue dust another method was adopted. The applicability of the method to ores containing over 5 per cent antimony depends upon the method of breaking up the ore. For ores containing 10 to 30 per cent antimony the author uses the same mixture as for attacking base bullion, viz., 3 parts nitric acid, 2 parts water, and 1 part tartaric acid, by weight. About 20 cc. of this mixture are used for attacking, and when the ore is broken up 7 cc. of sulphuric acid are added; the vessel is then placed on the hot plate, and when the color of the gas bubbles—which is at first brown—becomes pale it is removed from the hot plate and the action will generally go on by itself until the evolution of colorless gas shows that nitric acid has been driven off. Too prolonged heating decomposes the tartaric acid. After dilution the whole is boiled and the remaining operations are conducted in the usual way.

Another way of attacking antimonial lead ores is to first warm with hydrochloric acid for ten or fifteen minutes and then add enough nitric acid to decompose all sulphides on heating. The sulphuric acid is then added, and the whole is evaporated until sulphuric anhydride is given off, and the usual procedure is followed.

Engineering Imports and Exports.

The returns by the Board of Trade for the half year ended on June 30 are not completely satisfactory on account of decreases in exports. The imports of iron and steel, including manufactures, totalled £5,713,864, an increase of £28,298 as compared with the corresponding period of 1911, and exports were £21,550,651, a decrease of £609,990.

Imports of other metals, including manufactures, amounted to £14,516,123, an increase of £1,069,185, and exports were valued at £5,543,038, an increase of £57,275. In electrical goods the imports touched £721,821, and increased £33,301, while exports, put at £2,066,333, showed an increase of £711,900. Imports of machinery were £3,427,375, a rise of £278,727, and exports figured at £15,689,186, and showed a decrease of £40,222. Imports of new ships reached only £14,302, a decrease of £33,638, but exports went up to £2,696,590, an increase of £164,344.

Taking the month of June only the imports showed an increase of £89,260 for iron and steel; an increase of £136,314

in other metals; a decrease of £8,128 in electrical goods; an increase of £39,238 in machinery, and an increase of £612 in ships. Exports exhibited a decrease of £167,445 in iron and steel; a decrease of £75,650 in other metals; an increase of £85,292 in electrical goods; a decrease of £210,630 in machinery, and a decrease of £129,060 in ships.

Market Prices.

July.

Tin has kept within closer limits than usual, but has been down to £196 (18th) and, generally speaking, under the £200. Bettering at the close of the month it closes at £203.

Copper exhibits an upward tendency, £75.7.6 on the 17th, £76.10.0 on the 19th, and £78.15.0 by the 23rd. It closes at £78.0.0.

Iron, Hematite opened at 73/6 and has kept fairly strong. closes at 74/7½.

Iron, Cleveland has improved considerably, and even touched 58/9 during the week preceding July 28. It closes at 58/3.

Alum lump, per ton	£5.15. 0
Antimony, black sulphide powder, per ton	20. 0. 0
Borax, British refined crystal, per ton	17. 0. 0
Copper ore, 10 to 25 per cent, per unit	13/6 to 14. 6
Copper sulphate, per ton	24. 5. 0
Carbolic acid, liquid 97 99 per cent, per gal	1 6½
Creosote, ordinary good liquid, per gal	3¼
Caustic soda, Ash 48 per cent ordinary, per ton	5.10. 0
Hydrochloric acid, per cwt	5. 0
India rubber, Para fine, per lb	4.11½
Naphtha, solvent, 90 per cent, 160 deg. C., per gal	2. 9
Petroleum, Russian spot	8
Quicksilver, per bottle	8.10. 0
Sal ammoniac lump, firsts, delivered U. K., per ton.	44. 0. 0
Sulphate of ammonia, f.o.b. Liverpool, per ton	14.12. 6
Sulphur, recovered, per ton	5. 0. 0
Shellac, Standard T. N. Orange Spots, per cwt.	4. 4. 0
Tin ore, 70 per cent, per ton	£133 to 135. 0. 0
Zinc, Vielle Montagne, per ton, f.o.b. Antwerp	29. 7. 0
Platinum, nominal	9. 5. 0

The differences on the month are thus:

Higher.

Borax, ton	£0.10. 0
Tin ore	1. 0. 0
Tin	5. 0. 0
Copper	1. 0. 0
Hematite	1 0
Cleveland	9

Lower.

Copper sulphate	£0.10. 0

The Testing Laboratory of the Conservatoire National des Arts et Mètiers in Paris.

The yearly report for 1911 of the Laboratoire d'Essais du Conservatoire National des Arts et Métiers has appeared.

This Testing Laboratory, founded in 1900, was organized in 1901 with the financial aid of the Paris Chamber of Commerce, for the purpose of permitting manufacturers, engineers and others to submit their products, of any kind, machines and apparatus, so as to have official tests made.

The domain of the Laboratory comprises the whole field of physics (except electricity), the metals, materials of construction, all machines, except electrical machines, and their accessories, fuels, etc. The Laboratory also carries out the official legal verification of alcoometers, densimeters, and thermometers. The work is distributed among five sections.

Not only the number of test orders, but the receipts of the Laboratory have increased during the past. The receipts have increased from $18,000 in 1910 to over $21,000 in 1911, not including the receipts for the verification of alcoholometers and thermometers which amounted to $5,400.

Recent Metallurgical and Chemical Patents.

Electric Furnaces.

New Refractory Compound of Silicon and Carbon.—Dr. Edward G. Acheson, of Niagara Falls, N. Y., describes a method of making a new compound which may be chemically identical, at least very nearly, with SiC, but is distinguished by greater toughness and smaller brittleness. Its toughness in conjunction with extreme hotness indicates abrasive qualities of exceptional value. It was obtained as follows: A mixture was prepared consisting essentially of pure silica sand and carbon commingled in the proportions theoretically required for the production of silicide of carbon, that is to say in the proportion of 62.7 parts of sand to 37.3 parts of carbon. To this mixture was added a second mixture consisting essentially of boric acid from which most of the water of crystallization had been expelled, and carbon, the boric acid and carbon being in the approximate proportions of 210 parts of B_2O_3 to 120 parts of carbon. These two mixtures were thoroughly commingled in various proportions, the proportions in one specific instance being 92 parts of the silica mixture to 8 parts of the boric acid mixture. The resulting mass was heated in an electric furnace of the resistance type, being disposed in proximity to the resistor and carefully shielded from the action of the air. The temperature was approximately that required for the production of carborundum and was maintained for several hours. Boron may be or may not be in the final product. In the latter case characteristic properties of the product are probably "due to the modifying influence, during the reaction, either of the boric anhydride or of the products of reduction thereof. In such case it is reasonable to suppose that other bodies may prove capable of exerting a like favorable effect upon the toughness of the product." (1,014,199, Jan. 9, 1912.)

Dense Silicon Carbide.—Mr. Frank J. Tone, the works manager of the Carborundum Company, of Niagara Falls, patents a kind of silicon carbide which is evidently identical with what is known abroad as silundum. If carbon, either in its amorphous form or in the form of graphite, in segregated or solid masses, rather than mixed with silica, in pulverized form, is heated in proximity to silicon or silicon compounds, the fused or volatilized silicon penetrates the pores of the carbon and forms silicon carbide in situ, and this product possesses new, peculiar and useful properties. For example, if a carbon rod or other carbon article be embedded in a mass of silica and carbon, or carborundum, or silica, or other silicious compound, and subjected to the temperature of formation of silicon carbide, there is produced to a greater or less depth on the surface of the rod a dense form of silicon carbide, which is non-porous and very solid. Chemical analysis shows that this product often contains free silicon in quantities up to four per cent, and Mr. Tone believes that this silicon when present may assist in cementing the silicon carbide crystals together. The product has a hardness about equivalent to that of silicon carbide produced in the ordinary manner, but has much greater toughness. If the carbon article is thin, it is possible to convert it entirely into dense silicon carbide. If the carbon piece is of some special form—as, for instance, in the form of a crucible or plate, it is possible to convert this, without changing its form, into dense silicon carbide. It is also possible to convert only the surface of the carbon article into dense silicon carbide, thus forming a silicon carbide lining or film on a carbon article. (1,013,700 and 1,013,701, Jan. 2, 1912.)

Cyanamide.—Dr. Albert R. Frank, of Spandau, Germany, points out that in the reaction between calcium carbide and nitrogen resulting in the formation of calcium cyanamide and carbon it is not necessary to heat the whole mass to the reaction temperature. It is only necessary to start the reaction at one single point by heating the mass at that point to the correct temperature. Then the reaction will proceed from there throughout the whole mass. (The reason for this is, of course,

that the reaction evolves enough heat to heat the surrounding parts to the temperature required to start the reaction and so on.) The reaction temperature is between 800 and 1100 deg. C. A method of electric heating is described in which the carbide is packed in a cylinder with a resistor rod in the center, the carbide surrounding the resistor. Nitrogen gas is introduced into the cylinder and when the resistor heats the particles next to it to the proper temperature the reaction starts and proceeds to the outside. (1,010,404, Nov. 28, 1911.)

Aluminum, Magnesium, Nickel.

Electric Melting in a Vacuum.—The use of electric heat applied in a vacuum for melting such metals ase are subject to oxidation when melted in air, is the basis of a patent granted to WILLIAM S. SIMPSON, of London, England. As shown in Fig. 1, the apparatus consists of a metal container *A* adapted

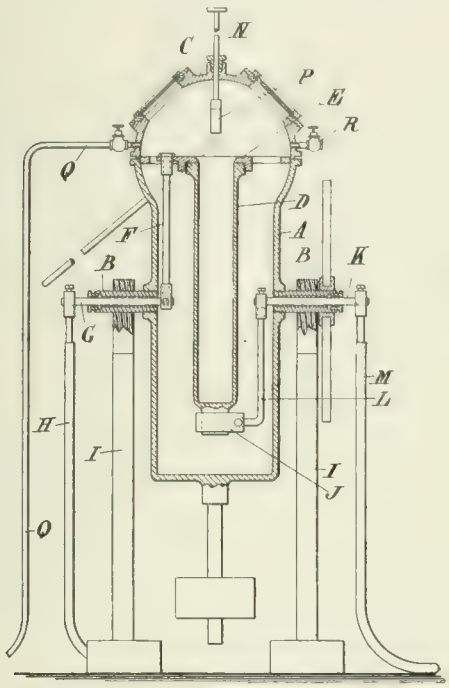

FIG. 1.—APPARATUS FOR ELECTRIC MELTING OF METAL IN A VACUUM.

to be swung on trunnions *B*. This container is covered by a cap *C* having observation ports. A crucible of carbonaceous material is shown at *D*, and the space between the crucible and container is packed with non-conducting, heat-insulating material, Electric current is applied to the top and bottom of the crucible at the ring *E* and clamp *J*, as shown, being conducted through the wires *H* and *M*, and passing through the trunnions. A stirrer is provided at *NP*. By use of this apparatus, metals such as magnesium, aluminum and calcium, which readily oxidize when melted in air, may be melted and alloyed in a vacuum. The generation of electric heat is effected with great economy, and there is little damage to the apparatus as a result of the heat. (1,015,091, Jan. 16, 1912.)

Electrolytic Furnaces.

Electrolytic Furnace Process for the Production of Cyanides and Cyanamides.—Mr. CHARLES E. ACKER, of Ossining, N. Y., to whom was due the only fused electrolytic cell for production of caustic soda and chlorine (which was in commercial use for several years in Niagara Falls until the plant burned down) describes a modification of the cell for the production of the cyanides and cyanamides of alkalies and alkali earth metals. One of the constructions is shown in Fig. 2. Fused sodium chloride or sodium hydroxide 7 is electrolyzed in a cell with anodes 5 and a layer 6 of fused lead in the bottom of the cell as cathode. The sodium set free at the cathode alloys with the lead and the sodium-lead alloy is carried off into a reaction chamber 10^3 where a reaction is brought about with nitrogen or ammonia and with carbon. The sodium is then returned to the cathode.

"Specific processes which may be carried out are the production of sodium cyanamide or cyanide by the injection of ammonia or nitrogen into the molten sodium-lead alloy resulting from the electrolysis of sodium hydroxide, or chloride upon a lead cathode, in the presence of charcoal or other carbonaceous reagent. When the electrolyte is molten sodium chloride and ammonia is used as a source of nitrogen, it is important to cool the alloy in transit from the electrolytic cell to the reac-

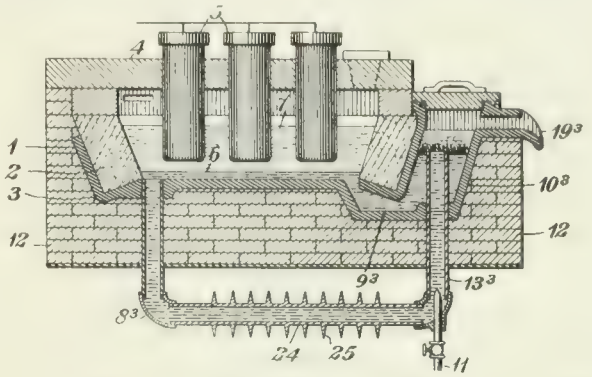

FIG. 2.—ELECTROLYTIC FURNACE FOR THE PRODUCTION OF CYANIDE.

tion chamber, and this cooling may be effected either by the transfer of heat to a returning stream of cooler residual metal, or otherwise, as by the heat radiating devices shown in the illustration.

"When the electrolyte is molten sodium hydroxide, it is unnecessary to cool the alloy, and its temperature is not sufficiently high to decompose the injected ammonia. Furthermore, instead of employing a simple electrolyte of molten common salt, other salts or compounds may be mixed therewith for the purpose of lowering the melting point or increasing the fluidity. The fluorides and chlorides of the alkali and alkaline-earth metals may be employed for this purpose, and the temperature of the alloys may thus be made so low that it will be practically unnecessary to cool the alloy before injecting the ammonia. The particular reaction which takes place in the chamber 10, due to the simultaneous or successive action of nitrogen or ammonia and carbon depends on the temperature in this chamber. If the temperature be low, say about 500 deg. C., the sodium in the alloy is initially converted by ammonia into sodium amide and this amide, in contact with the carbon, is then converted into disodium cyanamide, which is stable and will be discharged as its level rises above the outlet of the chamber. For the continuous production of cyanamides, sodium hydroxide may be employed as an electrolyte, and the alloy, at a lower temperature, passing to the reaction chamber may then be heated by hot residual metal returning from this chamber to the cell. The anodes in this case are preferably of iron, nickel or ferro-nickel, and a lining of solidified sodium hydroxide may be maintained on the side walls of the electrolytic cell, cooled by water circulated through them. For the continuous production of sodium cyanide, molten sodium chloride may be electrolyzed and the resulting alloy delivered, without cooling, into the reaction chamber, and there treated with nitrogen and carbon, the temperature in this chamber being sufficiently high to maintain the cyanide in the molten condition. The chamber may be heated by an alternating current passed through the supernatant molten cyanide, or sodium amide or disodium cyanamide may be produced, as an intermediate product, and then converted into cyanide, in the presence of carbon, by raising the temperature in the reaction chamber." (13,316, Nov. 21, 1911.)

Gas Reactions.

Ozonizer.—Mr. ROSS MORTIMER LEGGETT, of Ann Arbor, Mich., uses in his ozonizer a glass tube as dielectric with an

inside electrode consisting of a piece of sheet metal wrapped in tube form, with projections extending outward toward the glass tube. Around the outside of the glass tube a second electrode of woven wire is wound. The two electrodes are, of course, connected to the terminals of a high-tension circuit. The air to be ozonized is passed through the apparatus by means of a fan. (1,010,777, Dec. 5, 1911.)

Electrolytic Processes.

Electrolytic Amalgamator for the Precipitation of Gold.—An electrolytic amalgamator by Mr. JOHN FREY, of San Francisco, Cal., is shown in Fig. 3. A cylindrical cage 2, which revolves about the axle 5, acts as anode. The trough

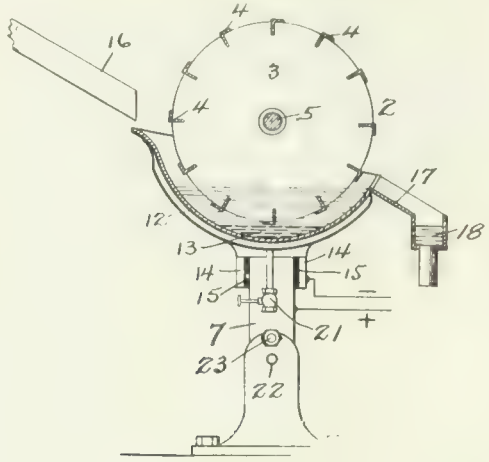

FIG. 3.—ELECTROLYTIC AMALGAMATION APPARATUS.

12, containing mercury, acts as cathode. The cylindrical cage 2 is formed of two end discs and parallel and longitudinal strips 4, all made of metal, so as to form a rigid structure, and act as conductors of the current. The drough 12 contains a quantity of mercury 13, but not so much as to cause a short circuit with the cage 2. The liquid mass to be treated as it comes from the stamp mill is fed by the spout 16 into the drough, and the residue is discharged over the apron 17. The apparatus is said to be particularly efficient when the gold occurs as free gold or fine float gold, and when a large percentage of slime occurs in the material coming from the stamp mill. With certain kinds of ores it is desirable to mix cyanide solution with the ore. (1,009,143, Nov. 21, 1911.)

Mercury Cathode Cell.—A patent by Dr. R. FRANK, of Grunewald, Berlin, Germany, describes a mercury cathode cell the principal feature of which is the continuous movement of the mercury from the compartments in which the sodium chloride is decomposed and sodium amalgam is formed into the other compartments in which the sodium amalgam is decomposed and sodium hydrate formed. The apparatus is shown in Fig. 4, the upper diagram being a horizontal section and the lower diagram a vertical section along the line 11. The vessel *A* is divided into four compartments, I, II, III, and IV. In the bottom of the receptacle *A* four grooves *F*, F^1, F^2, F^3 are provided, into which the partitions *C*, C^1, C^2, C^3 are so inserted that they do not engage the bottom of the grooves. Four slots are thus provided, which form traps between the different compartments but allow the passage of the mercury. The electrolysis of the alkaline-chloride is effected in the cells *I* and *II* and the amalgam formed therein at the cathode is decomposed by water in the cells *III* and *IV* and alkaline hydrate generated. The bottom of the receptacle *A* is covered with mercury which also fills the grooves *F* beneath the partitions *C*, C^1, C^2, C^3. During the electrolytic action the whole layer of mercury must be uniformly moved through all the compartments in order to convey the amalgam formed in the compartments *I* and *II* into the compartments *III* and *IV* for decomposition, as well as to return the regenerated mercury from the compartments *III* and *IV* to the amalgamating or electrolytic compartments *I* and *II*. This movement of the mercury is attained by providing the compartments or cells *III* and *IV* with cavities *D*, D^1, in which fluted drums *E*, E^1 revolve, their ribs *H* uniformly propelling the mercury in the cavities *D*. The drums are driven in opposite directions by means of pulleys *G*, G^1. (1,009,061, Nov. 21, 1911.)

Mercury Cathode Cell.—A patent by Mr. HENRY CROSTON, of New York City, describes details of a mercury cathode cell, the feature being the method of moving the sodium amalgam formed, so as to provide always a fresh mercury surface for the cathodic action. For this purpose scrapers are arranged, which reciprocate horizontally in the tank, in a longitudinal direction. (1,009,133, Nov. 21, 1911, assigned to General Chemical Company.)

Electrolytic Production of Oxygen and Hydrogen.—The electrolytic cell of A. TOMMASINI, of New York City, as shown in Fig. 5, contains vertical anodes 6 and cathodes in form of inverted U-shaped receptacles 5. The outside of these receptacles 5 is completely covered with an insulating cover 7 which extends to a point above the liquid line, and to a point below the lower edge of the cathode 5 proper, so that an overhanging apron 8 is provided. The oxygen is evolved at the plates 6 and accumulates in the space in top of receptacle 4, while the hydrogen accumulates in the top of the inverted receptacles 5 and is conducted off through the pipe 12 and the pipe 11 into the safety device 14. The head of water is less in the safety device 14 than in the receptacles 5, so that when the pressure of the hydrogen gas becomes so great as to tend to press the fluid out of the chambers 5 (which would result in the mixing of the hydrogen with the oxygen) the pressure of the hydrogen gas will first press the water out of the receptacle 19 and pass out of slots 20, so as to relieve the pressure in the receptacles 5. The aprons 8 at the bottom of the compartments 5 also prevent mixing of the two gases. (1,035,060, Aug. 6, 1912.)

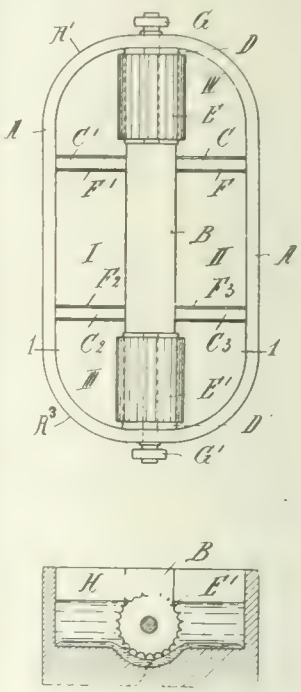

FIG. 4.—MERCURY CATHODE CELL.

Pickling Aluminium Before Plating.—A process of pickling aluminium prior to galvanizing or coating with other metals is patented by Mr. STEPHAN JAHN, of Charlottenburg, Germany. The aluminium to be coated is first cleaned and freed from grease. After this it is inserted into a heated bath "containing diluted acid of the halogen group with the addition of

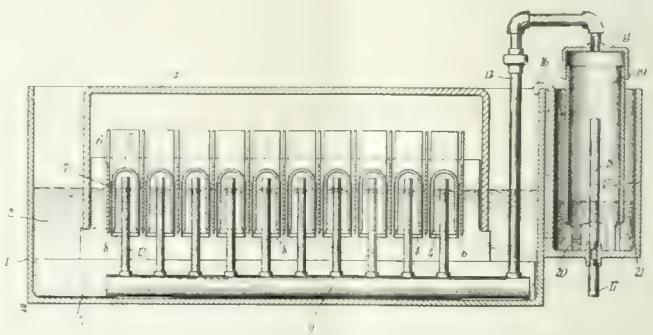

FIG. 5.—ELECTROLYTIC CELL FOR OXYGEN AND HYDROGEN PRODUCTION.

restraining agents." The latter serve to restrain or check the reaction so as to prevent the aluminium from being too readily attacked. Examples of bath compositions are: 500 grams hydrochloric acid, 1000 grams water, 150 grams ethyl alcohol, at 70 deg. C. (the ethyl alcohol being the restraining agent); or 10 grams hydrofluoric acid in 1000 grams water and 15 grams ethyl alcohol at 70 deg. C.; or 500 grams hydrochloric acid with 150 grams glycerine or with 30 grams of citric acid at 70 deg. C.; or 10 grams hydrofluoric acid with 15 grams glycerine or with 20 grams of citric acid at 70 deg. C.; or 200 grams of hydrochloric acid with 1000 grams of water at 40 deg. C. (1,011,203, Dec. 12, 1911.)

Iron and Steel.

Electric Steel Refining.—Mr. WILLIAM R. WALKER, of the U. S. Steel Corporation, claims the recarburiding of steel prior to transferring the metal to the electric furnace. Blown Bessemer metal, low in carbon, is sometimes transferred quite a distance to the electric furnace. A considerable amount of metal will solidify and form skulls in the transfer ladle. These skulls varying in amount will render the charge to the electric furnace variable. By raising the carbon content of the metal its melting point is lowered and hence the amount of skulling prevented or greatly lessened. (The reviewer might call attention to the fact that the text of the patent contains a mistake which reverses the sense of the explanation by saying "I raise the carbon and thus also its melting point.") Molten pig metal is blown in a Bessemer converter until the silicon is eliminated and the carbon reduced to a definite percentage, preferably to about 0.05 per cent. This can easily be gaged from the "drop" of the flame. The carbon is then raised to about 0.3 per cent as a rule, the best percentage of carbon being governed somewhat by the time during which the metal is to be held in the ladle before pouring into the electric furnace. The carbon may be added into the ladle in the form of anthracite, powdered coke or pig iron, preferably molten pig. The metal thus enriched in carbon with substantial precision is then charged into an electrically heated furnace, treated preferably with basic additions for removal of sulphur and phosphorus and brought into proper condition for casting into ingot molds. (1,014,425, Jan. 9, 1912.)

Pure Iron.—Mr. ARTHUR P. SCOTT, of Brackenridge, Pa., gives as one of the objects of his invention the preparation of an iron which is practically free from occluded slag particles and oxides. As the microscope discloses, these impregnate all iron heretofore produced to a greater or less extent. When removing carbon and manganese under a basic slag below a certain limit the iron takes up oxygen in the form of oxides and nitrogen. The inventor therefore melts down in an open hearth or electric furnace or in any combination of the two a charge of pig and scrap in the usual way, removing the ordinary impurities until the carbon has reached 0.20 per cent or any other point in any individual case just before the iron commences to suffer oxidation. He then adds an oxidizable agent such as titanium or ferro-titanium and by continuous injection of it protects the iron from oxidation and continues to oxidize the carbon to a point not over 0.10 per cent to 0.15 per cent. Forcing sticks of wood below the metallic bath helps to combine the smaller occluded particles of slag with the larger bodies and to bring practically all of the slag to the top. The ingots thus obtained are said to be practically free from blow holes and have little or no piping. The metal is highly malleable and ductile and by reason of its fineness is particularly receptive to metal coatings of any kind. (The reviewer considers 0.904 per centum of nitrogen as a printer's mistake.) (1,017,473, Feb. 13, 1912.)

Denitrogenizing Practically Pure Iron.—Nitrogen is the most noxious known impurity in iron. It is deleterious in amounts exceeding 0.007 per cent, causes brittleness, and makes the iron unreliable. Mr. ROBERT D. CAMPBELL, of Pittsburgh, Pa., describes a method to eliminate nitrogen with the aid of titanium or any of its alloys either completely or at all events to at least 0.004 per cent. He uses the improved open hearth or the electric furnace or any other methods or form of apparatus to melt and treat the iron. He has found that the common practice to use the ferro-titanium in a cold state is not necessary to be observed, that it is not safe, however, to preheat the alloy above 500 deg. C. He therefore keeps within this maximum and preheats the ferro-titanium. While in former processes using this element the metal never had a higher temperature than about 1575 deg. the denitrogenizing and deoxidizing effect of titanium becomes most effective at a heat between 1575 and 1700 deg. C. The amount of titanium used may be such as to pass off with the slag entirely or to provide for any desired percentage in the product. The inventor is able to produce pure iron containing in the aggregate not more than 0.10 per cent of C, Mn, Si, S and T and not exceeding 0.04 of oxygen and occluded slag. The qualities of the product are described as practically the same as in U. S. P. 1,017,473, abstracted above. (1,017,620, Feb. 13, 1912.)

Steel for Electric Purposes.—WALTER RÜBEL has found that manganese, silicon and phosphorus reduce very strongly the usefulness of iron for electrical purposes where this iron is subjected to alternating magnetization. Hysteresis and electric conductivity should be kept low so as to reduce the magnetic losses and the eddy currents. Slight contaminations through sulphur and carbon are less injurious. To obtain a satisfactory iron for dynamo sheets the inventor therefore removes the manganese silicon and phosphorus as completely as possible. He furthermore improves the quality of such iron which has been perfectly freed from injurious contaminations by the addition of 1 per cent of copper, which for certain purposes may be increased up to 3 per cent. To obtain the said purification of pig iron the author wants to use the basic Bessemer (Thomas) and the acid Bessemer process in rotation or reverse the order. He also admits electrical or Siemens furnaces suitable for carrying into effect the acid and the basic process. The addition of spiegeleisen must be entirely avoided and copper serves as deoxidizer. (U. S. P. 1,033,352, July 23, 1912.)

Manufacturing Steel.—Mr. HENRY D. HIBBARD, of Plainfield, N. J., divides the elimination of impurities from molten iron into two stages, the exothermic and the endothermic parts of the process. He needs two to three vessels to carry out the following process: Oxide of iron is heated or melted in No. 1 vessel; it can be dispensed with when the iron which is going to act on this oxide contains enough silicon to furnish a sufficient amount of heat by its own combustion to melt the oxide of iron. No. 2 is a closed reaction vessel in which most of the silicon is oxidized by exothermic reaction of pig iron on oxide of iron. The vessel is preheated to red or white heat respectively. No. 3 is a furnace of the open hearth type heated by fuel, electricity or any other suitable means. After finishing the reaction in No. 2 furnace the metal is transferred to No. 3 and the carbon oxidized endothermically by new additions of oxide of iron. Seven claims cover the variation of temperatures, vessels, application of heat and order of rotation of processes. (1,035,120, Aug. 6, 1912.)

Treatment of Iron Ores.—Mr. BIRGER FJELD HALVORSEN, of Christiania, makes use of a process similar to "pyritic smelting," in which the sulphur of one substance forms SO_2 with the oxide from another and produces a pure metal besides. In order to have SO_2 in such concentration that it can commercially be used for other purposes he subjects rich iron ores, preferably those which have been dressed by magnetic separation, to the smelting in an electric furnace. By removing the gangue prior to smelting and avoiding any fluxing material, he reduces the slag formed to a minimum and obtains a rich sulphur dioxide gas. The oxidic ore has to be used in excess. After all the sulphur has been expelled the refining is accomplished by adding fluxing material and lime and finishing the

metal in the usual way. High grade iron nickel ore are specially fitted for this treatment. (1,024,629, April 30, 1912.)

Method of Treating Steel.—The title of this patent is somewhat misleading as it does not deal with the thermal treatment of steel, but with a certain phase of the manufacture. The wearing and shock resisting qualities of steel are oftentimes improved by lowering the amount of carbon and correspondingly increasing the manganese. The inventor, Mr. Auguste J. Rossi, the distinguished pioneer of titanium, has found that he can obtain a better product by keeping the manganese in low limits, above 0.18 per cent and not over 0.60 per cent, and raise the carbon to heretofore unusual amounts. This is made possible by adding ferro-titanium in such amounts that the titanium in the product is less than 1 per cent and not enough to designate it as an alloyed steel. The titanium is supposed to combine with undesired elements and compounds and to insure their removal together with the slag. As an example he states that when adding from ⅔ per cent to 1½ per cent of a ferro-titanium containing 10 per cent to 12 per cent titanium to a 0.85 per cent carbon rail steel the steel rolled perfectly and the resulting rails showed qualities of endurance and of resistance to vibration hitherto unattained and otherwise unattainable. (1,028,389, June 4, 1912.)

Steel Metal.—Mr. Auguste J. Rossi adds a new divisional application to a former patent covering the use of titanium in steel making. The main feature of the inventor's claims is that manganese and silicon should be practically eliminated before the addition of titanium is made and that titanium produces such properties in the steel that these elements can be entirely dispensed with. While in common practice steel without 0.4 to 1 per cent of manganese is considered as unfit for rails and other purposes, the proper amount of titanium now takes care of the deoxidation as well as of imparting to the finished product the physical properties required. The metal can be produced by any of the well-known smelting and refining processes with the only exception that the recarburization has to be accomplished with other substances than spiegeleisen or ferromanganese. The silicon in the finished product ought not to exceed 0.02 per cent, the manganese not to exceed 0.2 per cent, and the titanium to remain below 2 per cent. The inventor is aware of the fact that aluminium containing from 0.75 to 2.50 per cent of titanium, when added to the steel, does not accomplish the same effect as his invention, as it does not bring enough titanium into the bath and as he dispenses with the use of aluminium altogether. Otherwise the amount of titanium used in his process and remaining in the steel is not sufficient to warrant the designation of his product as an alloy steel and he does not want to call it titanium steel. (1,029,637, June 18, 1912.)

Producing Metallic Iron and Alkaline Salts.—A patent has been granted to Mr. Edwin C. Eckel for smelting glauconite, a hydrated silicate of iron and potassium, in such a way as to reduce the iron and to volatilize the potassium salt. The potassium will be recovered in a dust-catcher, usually in the form of carbonate. The large deposits of glauconite, as the patent claims, are largely unused. (They could, however, be used for agricultural purposes). The average composition of the mineral is about 50 per cent silica, 30 per cent ironoxide, 6 per cent potassium, some phosphorus and 10 per cent water. Considered as an iron ore this would hardly be worth while touching; the simultaneous production of a potassium salt, however, should make it pay. The mineral is mixed with limestone and coke, f.-i. 10 tons of glauconite, 7½ tons of limestone and 5 tons of coal. This will produce slightly over 2 tons of pig iron and considerably over 1 ton of potassium carbonate. The slag will have the approximate composition, 53 per cent silica, 3 per cent alumina and 44 per cent lime and will be serviceable as raw material in several industries. (1,011,173, Dec. 12, 1911.)

Refining Iron and Steel.—Mr. Karl Fredrik Hiorth claims the regeneration of slag which has been used for dephosphorizing steel from, for instance, 0.06 per cent P. to 0.008 per cent P. The iron thus practically free of phosphorus is poured into a ladle either completely or by leaving a small amount of metal under the slag. In the first mentioned case some cheap iron may be charged into the furnace and in both cases carbon is used to reduce the phosphorus from the slag into the metal. The latter would then be a valuable product f.-i., for the basic Bessemer furnace. After pouring it off the purified metal could be returned to the furnace, could be deoxidized, alloyed, etc., and finished in the desired way. Instead of keeping the metal in the ladle during the regeneration of the slag it could also be charged into a second furnace and finished therein. Other valuable substances such as chromium, manganese, molybdenum, vanadium, wolfram and the like, which are taken up by the slag during dephosphorization of the metal, could be recovered in a similar way, separately or by groups, by carrying the treatment of the slag out fractionally. (1,028,070, May 28, 1912.)

Composition of Matter.—Mr. Robert M. Corban claims that his welding compound consisting of 75 per cent SiO_2, 15 per cent Al_2O_3, 2 per cent CaO and 8 per cent K_2O and Na_2O, will reconvert oxide of iron to a metallic state, when iron or steel have been "burnt" in forging and welding. To prepare the flux for use the ingredients are reduced to finely granular and preferably powdered form and thoroughly mixed. The "inventor" has found that above proportions admit of a considerable range of variation without affecting the results. (U. S. P. 1,034,979, Aug. 6, 1912.)

Reversing Valve for Regenerative Furnaces.—Mr. Hugo Gille has invented a new reversing valve of the bell type of light construction. It is characterized by a circular trough with sealing liquid and two transverse troughs forming a cross within this circle. They form four sector-shaped apertures, each of which in one position has to be connected to its neighbor at the left, after reversing to its neighbor at the right. Consequently the bell has one diametrical partition. This is built as a channel open to the atmosphere at the top and at both ends; it thus picks up sealing liquid each time it is dipped into one of the transverse troughs. Partition and liquid are thus efficiently cooled. The bell is suspended from a support by rods which receive a compulsory movement to turn the bell 90 per cent whenever the lifting mechanism is actuated. The lifting mechanism is described in detailed drawings. It consists either of a screw shaft driven by gear and pinion from an electromotor; a rider on this screw lifts the bell support by means of levers, or a hydraulic plunger which is forced alternately into two cylinders and which carries a block fixed to its center. This block performs the same duty as the rider on the screw shaft. (1,033,577, July 23, 1912.)

Charging Furnaces.—In modern blast furnace practice the material is delivered to the top of the furnace in skip cars and successive skip loads are dumped at the same side of the furnace. This produces an uneven distribution of material in the furnace as the coarser and heavier particles will go into the hopper on the side opposite the dumping, while most of the finer particles will dribble down more slowly into the near side of the hopper. Consequently the passage of the gases will be ununiform and the working of the furnace irregular. Mr. Frank C. Roberts provides two different means to overcome the evil effect of this segregation. He describes a charging device in which the receiving hopper is continuously rotated while receiving material from the skip or while unloading this material into a second hopper of the bell type, or in both instances. In the second charging hopper may or may not be assembled a plurality of skip loads before introducing them into the furnace. The second way to accomplish the purpose is the use of a rotary mixing chute through which the skip loads pass into the hopper. The mixing chute contains a diaphragm, and by rapid rotation the coarse and fine materials which strike the diaphragm are mixed and uniformly distributed in the hopper.

For details see the drawings in the original. (1,033,036, July 16, 1912.)

Dry Cleaner for Gas.—If a body of gas be given a vortex or spiral movement around an axis in a closed vessel, the dust and other impurities will tend, under the influence of centrifugal force, to move to the periphery of the moving body. If then means be provided to skim from the vessel the outer stratum of gas, the dust which is centrifugally concentrated there will be driven off from the body of gas in the vessel. Electrical means may be used, also, to agglomerate the fine dust into larger particles which will respond more readily to the effect of centrifugal force and gravity. This is the principle on which MARK W. JOHNSON, JR., of Birmingham, Ala., has devised a dry cleaner for furnace gases. With reference to Figs. 6 and 7, which illustrate the invention, 1 represents the central annular jet through which the gas to be cleaned is passed to the ring nozzle 3. On its way thither, the gas first passes an

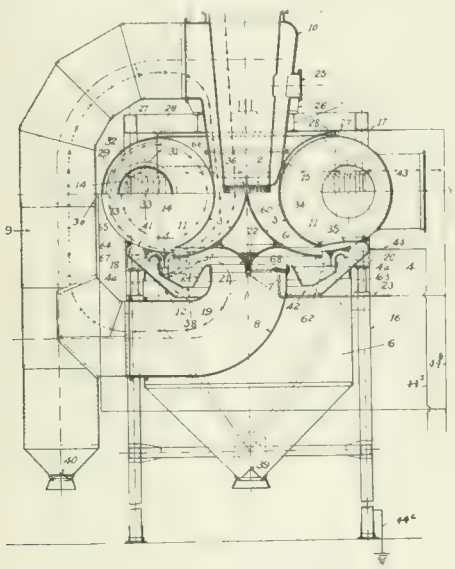

FIG. 6.—DRY GAS CLEANER.

electrode 2, consisting of a copper bar carrying numerous fine points extending downward, where the particles of dust become polarized by induction and agglomerated by electrical attraction. Passing the electrode, the particles are thrown against the lower curved surface of the ring nozzle 3. Part of the gas containing the most dust, is then caught under the knife edge of the dividing ring 4 and turned downward, striking the first deflector ring 5, passing thence into the ring port 37 into the circulation elbow 8. The practically static body of gas in the dust chamber 6 will exert a back pressure on the stratum of gas deflected by the knife edge against the ring 5, which back pressure will have a tendency to increase the deflection of the lighter and cleaner gas of the stratum toward the ring port 37. The cinder and dust will, however, pass along the plate 5 into the dust chamber, while the dirtier gas will tend to form eddy currents which pass off through the port 37. From the deflector 5; the dust which is separated will pass into the dust chamber through the port 38.

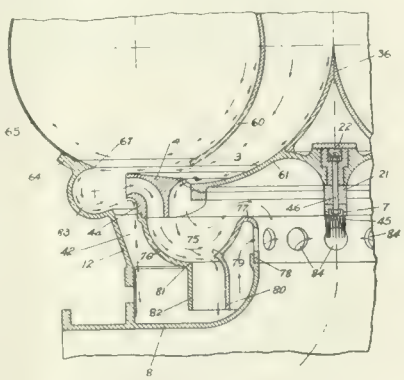

FIG. 7.—DRY GAS CLEANER.

As the gas enters the circulation elbow 8, it passes the second electrode 7, where any remaining dust is agglomerated as before. On its passage through the elbow it is thrown downward and caught in the lower end of the circulation pipe 9. The circulating gas will then again pass the electrode 2, and any remaining dust particles are thrown out and combined with the dust from gas entering through the nozzle 1. The gas now passes through the ring nozzle 3 as before, but is now in an upper stratum which escapes the knife edge and passes into the vortex chamber 11, where it begins to circulate rapidly in the form of a vortex spiral. In each revolution it passes the third electrode 13 where dust is agglomerated and thrown against the outer shell of the vortex chamber. Here it is swept around until it reaches the ring port 41 into which it is deflected by the edge 67, and through which they enter and are swept along until they enter the dust chamber by port 42. The cleaned gas will pass out of the vortex chamber through the ring 14, where it is turned by vanes 33 to the discharge chamber 15 and then through the outlet 43 to the gas main. By this process the inventor claims to clean gas without the use of sprays. (1,024,784, April 30, 1912.)

Cleaning Device for Water-Cooled-Wall Furnaces.—GEORGE J. RENNIE has invented a cleaning device for the narrow water troughs which encircle the blast furnaces of this thin-wall type. The water must flow slowly and at a certain speed through these troughs, and its temperature must not go below a certain limit, as it otherwise carries an uneconomical amount of heat away from the furnace. A heavy stirring of the water by quick circulation must therefore be avoided. The inventor uses a system of piping attached to the furnace structure and connected to a steam injector. At suitable places a flexible hose can be connected to the piping system, introduced into the bottom of the trough, and carry the mud off by suction. The trough can, therefore, be made deeper and narrower than in the former case, where laborious working with long handled spoons and shovels was necessary. (1,035,050, Aug. 6, 1912.)

Gold and Silver.

Treating Gold-Bearing Clay.—It is well known that difficulty is experienced in recovering gold from sticky clays. In order to obviate the trouble, and render the clay more amenable to treatment, JACOBUS VAN DER TOORN, of The Hague, Netherlands, proposes to knead the clay into a coherent mass and then heat it in kilns until it forms a hard stone-like clinker. It is claimed that this treatment at a high temperature changes the clay so that it does not again become sticky when crushed and ground in water, and the gold may be recovered in any desired manner. (1,033,359, July 23, 1912.)

Lead, Copper and Zinc.

Baghouse.—The use of the baghouse for collecting fume from lead smelters is well known. Formerly the bags were shaken by hand, but more recently mechanical means have been contrived to perform this unpleasant work. ALBERT J. MEIER, of Glendale, Mo., has patented means for mechanically shaking the bags in any section of a baghouse, and automatically cutting off the flow of fume from that section while the bags are being shaken. In Fig. 8, which is a vertical section of part of a baghouse, shows the invention. Referring to the drawing, *A* represents the bag chamber, containing bags 17, suspended from their closed ends at the rod 18, and fitting over thimbles in the floor between the bag chamber and cellar *B*. The flue through which the fume is led to the baghouse is designated at *G*. Leading from this flue are smaller flues *b* connecting with each division of the cellar.

The bars 18 are provided at one of their ends with rolls 22 adapted to be engaged by cams 23 on an operating shaft 24. This shaft extends across the building and is driven at a slow speed in a clock-wise direction, from a suitable motor, not shown. By this mechanism, the bars 18 will be shaken lengthwise against the tension of the springs 20, which support them, and the accumulation in the bags will be dislodged and caused to fall into the cellar.

While the bags of a division are being shaken it is necessary that the flow of fume be cut off from that division. In order to accomplish this automatically, a damper cam 31 is placed on the shaft 24, which operates a lever 30 and 30a supported at 29. The outer arm of the lever is connected with an endless cable passing over pulleys as shown, and connected with a sliding rod 33 of the damper 34 controlling the port *b*. Normally the damper is kept open by the weight 35, but when the damper cam 31 engages the lever, the cable operates the damper so that it is closed while the bags are being shaken. After the shaking operation is completed, the damper is released and returned to its open position. This construction can be extended to operate as many divisionse of a baghouse as desired, and the arrangement of cams on the shaft can be such that the different divisions will be shaken successively. (1,030,477, June 25, 1912.)

Copper Castings Free from Blow Holes.—At the Chicago meeting of the American Electrochemical Society, October, 1910, Dr. E. Weintraub, of the General Electric Company, presented the results of his efforts to produce copper castings free from activities. An abstract of his paper was published in

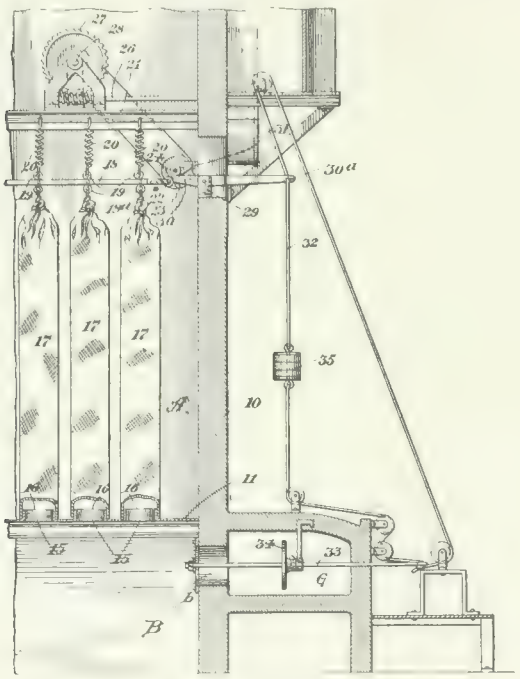

FIG. 8.—BAGHOUSE.

this journal, November, 1910, page 629. Recently Dr. Weintraub has procured United States patent on his method of improving copper castings, as outlined by him in 1910. Essentially the process consists in adding to molten copper of ordinary chemical purity a small quantity of boron, varying from 1/30 of 1 per cent to 1/10 of 1 per cent. This may be added in the form of a boron compound, such as a suboxide or carbide. Copper castings made from copper thus treated contain no cavities and show an electrical conductivity as high as 95 to 98 per cent, according to the Matthiessen standard.

As a convenient method of applying the invention, the boron material is placed in the bottom of a crucible mixed with pure charcoal, and then covered with the copper to be treated. During the process the deleterious gases are removed from the copper by the boron. The copper is not injured by an excess of boron, as it does not combine with the copper, but either oxidizes and collects as a slag or remains mechanically mixed in the copper.

While the method is described as being applicable in the foundry, it is to be understood that it is equally valuable in the smelting process, and can replace the process of "poling" now universally as the first step of refining copper as it comes from the converters. Poling is a rather crude and uncertain process, and the resulting copper has not a high conductivity. The boron method is more exact and can be applied to the manufacture of casting copper in the smelting operation.

Incidentally it may be mentioned that silver is similarly affected by the addition of a boron compound, and castings of that metal may thereby be greatly improved. (1,023,604, April 16, 1912.)

Coating Iron Articles with a Zinc Alloy.—A new process of providing iron articles with a protective coating, consisting chiefly of zinc, and resembling in some phases the well-known sherardizing process, has been patented by Prof. Charles F. Burgess, of the University of Wisconsin. The chief new feature is the alloy which is used for coating. For this purpose zinc dross, such as obtained as a waste product of the hot galvanizing process and consisting essentially of 97 and 93 per cent zinc and 3 to 7 per cent iron is used. This is crushed and placed into a rotary iron drum together with chunks of pure iron, such as wrought iron or electrolytic iron, and heated to about 850 deg. Fahr. In this way a saturated solution of iron in zinc is obtained with the composition of about $FeZn_{10}$. This is exceedingly brittle and easily brought into a granular condition. The iron article to be coated is then placed, together with this granular alloy, into a close drum, which may be rotated, and is heated as in sherardizing. Heating for two hours and to a maximum temperature of 700 deg. to 800 deg. Fahr. gives good results. For some purposes it is preferable to mix the $FeZn_{10}$ with about 5 per cent zinc. The advantage of this alloy is that it is exceedingly brittle, and, therefore, easily ground up in a rotating drum, that it is non-explosive and that it is not fused or sintered into a coherent mass, even when heated to 1300 deg. Fahr.; in this respect it is quite different from zinc dust. (1,014,946, 1,014,749 and 1,014,750, all assigned to the United States Sherardizing Company of New Castle, Pa., and 1,014.751, all of Jan. 16, 1912.)

Metallurgy of Zinc.—Improvements in the metallurgy of zinc have been proposed recently by F. L. Clerc, of Boulder, Colo. The first patent which was granted on his proposed copper-bottom furnace, was reviewed in this journal, November, 1911, page 609. More recently Mr. Clerc has presented his ideas more fully in articles printed in Metallurgical and Chemical Engineering, July and August, 1912, pages 399 and 463. We note an additional patent bearing on this subject, covering the ideas advanced in the article last mentioned. (1,012,816, Dec. 26, 1911.)

Aluminium, Magnesium, Nickel.

Aluminum Solders.—A new composition of matter has been patented by Charles R. Erkens, of New York City, and assigned to the Simplex Aluminium Solder Company, of New York City. The object of the invention is to provide a solder which will be useful in uniting pieces of aluminium without preheating the parts to be soldered, and which can be applied by an ordinary soldering iron. The composition contains 60 parts block tin, 15 of zinc, 10 of lead, and 5 each of antimony, bismuth and chromium; total, 100 parts. After melting and mixing these metals, the alloy is cleansed while molten by adding 35 grams of salicylic acid and 10 grams of calcium to each 5 lb. of alloy. As a suitable binding agent for impurities which form a slag to be skimmed from the alloy, 2 drams (17.72 grams) of sulphur is added. About 5 per cent of the oxidizing and cleansing agents will be retained in the alloy and will serve to take the place of the flux ordinarily used in soldering. (1,033,565, July 23, 1912.)

Preparation of Nickel for Catalyzing Purposes.—Finely divided nickel as prepared for catalyzers possesses pyrophoric properties which render the substance unsuited for indiscriminate use in air. Edwin C. Kayser, of Cincinnati, O., has devised a process for rendering finely divided nickel non-pyro-

phoric and stable. The patent has been assigned to the Procter & Gamble Company, of the same place. The feature of the invention consists in reducing a nickel compound in a current of hydrogen in the usual manner, and then passing carbon dioxide over the reduced nickel, while still hot, and continuing to pass it thus until the escaping gas is no longer inflammable. The nickel is then allowed to cool in an atmosphere of carbon dioxide, whereupon the resulting product is found to have lost its pyrophoric tendencies, and remains stable in the air for days. (1,001,279, Aug. 22, 1911.)

Purification of Clays.

Preparation of Fullers' Earth.—The removal of the deleterious mineral and organic materials from fullers' earth is a necessary step in the preparation of a product suitable for commercial purposes. CHARLES C. RUPRECHT, of Blakely, Ala., proposes to use the electric current in purifying and precipitating fullers' earth from suspension in water. Referring to Fig. 9, a mixing tank is shown at *A*, where the earth is mixed with water and formed into a "slip." From the mixer the slip passes by spout 4 to a series of settling vats *B*, *C*, *D*, arranged in cascade. In these vats, which are 30 ft. by 3 ft. by 3 ft., the sand is allowed to settle from the slip, which then passes on to the electrical treatment vat *E* where the purification of the clay from organic matter is accomplished. A plan view of the

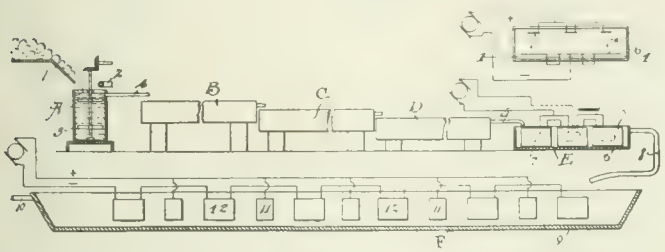

FIG. 9.—ELECTRICAL PURIFICATION OF FULLER'S EARTH.

arrangement of this vat is shown in upper right hand corner of the figure. Its dimensions are 16 ft. long by 3 ft. square. Three anodes of carbon, each 16 in. square, are suspended along one wall of the vat, and three cathodes of copper, each 3 ft. by 4 ft., are similarly suspended on the opposite side, spaced 2 ft. from the anodes. Between these electrodes the slip passes, at a fairly rapid rate of flow to prevent too great precipitation in the vat. To increase the conductivity of the electrolyte, some sodium chloride or sulphuric acid may be added.

The resulting electrolysis has the effect, in case salt is added, of forming chlorine products, some of which remain with the clay, and subsequently improve its bleaching quality. If acid is used, it has the effect of destroying organic matter. The current used is about 150 amp at 110 volts. A sufficient current density is about 1/5 amp per sq. in. of positive electrode surface.

From the vat *E*, the slip flows into the larger electrolytic vat *F*, where the velocity of flow is greatly reduced, and where the electric current effects a precipitation, or settling, of the earth. This vat may be 80 ft. long, 60 ft. wide and 5 ft. deep. Electrodes are arranged along the sides, the carbon anodes on one side being placed between the spaces between the copper cathodes on the other. An anode surface of 100 sq. ft. and a cathode surface of 150 sq. ft., with current at 110 volts, gives good results. In this vat the earth is precipitated and allowed to accumulate until it becomes necessary to clean the tank. The accumulation is dense and readily treated for the removal of contained water. (1,024,104, April 23, 1912.)

Sinter-Roasting and Agglomerating.

Process of Agglomerating Finely Divided Mineral Substances.—Recent developments in sinter-roasting fine ores, flue dust, etc., in pots or on chain-grates, have employed the principle of kindling one surface of the mass, and then propagating the combustion through it by blowing or drawing air from the kindled to the unkindled side. In patents granted to FREDERICK W. YOST, of Chicago, Ill., he discloses his idea of reversing the direction of the air blast, passing it from the unkindled to the kindled surface. By this procedure he claims that the products of combustion do not contaminate the zone of reaction as in the other type of roasting, and that the reaction is susceptible of more perfect control than is possible in the other method. Further, that the operation can be conducted in two stages; a heating and roasting operation propagated in one direction, and a clinkering action subsequently propagated in the opposite direction. The process is adapted to any of the types of roasters now known and used, and may be applied to the roasting of sulphide ores, agglomerating iron ores with added combustible matter, clinkering cement materials, etc. The patent specifications are voluminus, and contain from 35 to 40 claims each. (1,003,682-3-4, Sept. 19, 1911.)

Synopsis of Metallurgical and Chemical Literature.

Gold and Silver.

Solubility in Nitric Acid of Gold Contained in Copper Bullion.—Up to a very recent date gold has been held to be insoluble in pure nitric acid. Attention has been called, however, to the discrepancies existing between the all-fire and the acid-fire, or combination method assaying gold in copper bullion. More recently, F. P. Dewey has demonstrated that pure gold dissolves in small quantity, on long continued boiling, in pure nitric acid. In the *Bulletin* of the American Institute of Mining Engineers, July, 1912, DR. EDWARD KELLER takes up the subject and gives results of his observations on the solubility in nitric acid of gold contained in certain copper bullions.

Copper bullion usually is cast in comparatively thick pigs, or ingots, and thin slabs, or plates. Sampling is done by drilling according to templates. The drillings are ground to pass a 16 or 20-mesh screen, and, in the author's practice, the final sample is further divided into fine and coarse portions by passing through a 40-mesh screen. The fine part will contain foreign matter, oxides, slags and mold-wash, while the coarse will be clean metallic particles. Assays of the fine and coarse parts show the necessity of separate assays of the two, and the averaging of results according to their ratio.

Experience shows that the all-fire assay is the most accurate attainable, when slag and absorption losses are accounted for. In the nitric acid combination method, the conditions are variable, and varying quantities of gold are dissolved and lost. In the tests made by the author, the wet combination method was carried out as follows: One A. T. of copper was dissolved in 190 cc. distilled water and 90 cc. nitric acid (1.42 sp. gr.). The reaction was completed at a temperature of about 160 deg. F., after the first violent reaction was over. When all red fumes had disappeared, the solution was filtered on a triple S. & S., No. 597, 12.5 cm. filter covered with 2 g. test-lead. After incineration of the filter, and the addition of 20 g. test-lead, a sufficient quantity of silver, in the form of nitrate crystals, was added. From this point the assay was conducted according to the well-known fire method.

Inasmuch as the deficiencies of the fire treatment apply to both the all-fire and the combination methods, if we now determine the gold by the all-fire method and by the combination method, the difference should be equal to the loss by solution in the combination method.

The author's serious attention was first attracted to the solubility of gold in nitric acid by peculiar facts connected with the assay of two samples of bullion which were the same in origin, composition and metallurgical treament. Samples representing many million pounds of copper were assayed for gold by the all-fire and combination methods, with the result that, for bullion No. 1, the gold yield by the combination method showed a deficit of 13.71 per cent, as compared with the all-fire method.

while for bullion No. 2 the corresponding figure was 26.62 per cent. These figures may be regarded as denoting the solubility losses in the two bullions, but it is to be noted that the loss in one is nearly twice that in the other.

The only difference between these two bullions was that No. 1 was cast in 300-lb. pieces and No. 2 in 500-lb. This fact implied a difference in the rate of cooling, and led to the conclusion that gold in slowly-cooled copper bullion is more soluble in nitric acid than that contained in rapidly chilled copper. There was ample evidence that the gold solubility was not influenced by any mechanical differences in the samples. The conclusion was confirmed by noting that the solubility of the gold could be reduced to a minimum by instantaneously chilling a sample of bullion.

Synthetic experiments were made to determine the influence of increasing either the gold content or the impurity content of the bullion, but neither appeared to augment the quantity of soluble gold. In conclusion the author finds that: Gold contained in copper alloys or bullion is soluble in nitric acid in varying degrees; that the solubility diminishes with the rate of cooling, but that even quenched samples show soluble gold. The maximum of the deficit in gold recovered by the combination assay, as compared with the all-fire assay, is approximately 2 per cent. The highest amount of soluble gold was found to be 0.0017 per cent of the total bullion, and no increase in the gold or impurity content of the bullion was able to augment that amount. The author further calls attention to the trouble that may arise among assayers, on account of difference in the methods of sampling copper bullion. One assayer may have a shot sample, quickly quenched, while others may have samples from castings which have been slowly or quickly cooled. If assays are made by the combination method, the variation in the amount of soluble gold will give rise to apparently unaccountable differences.

Abrasion and Dust Losses in Ore Drying.—In preparing ore for dry treatment processes, such as magnetic separation, dry concentration, etc., it is customary to pass the crushed ore through a rotary drier or drop it down a shaft in which its progress is interrupted by baffles. In either case, a stream of hot gas flows in the opposite direction to the flow of ore. Loss of mineral by abrasion and dusting is one of the objectionable features of these processes, and unless provision is made to collect the dust, serious loss may result. In the *Bulletin* of the American Institute of Mining Engineers, July, 1912, Messrs. C. F. Dietz and D. V. Keedy give some examples of dust losses that have come under their observation, and outline the test of a dust-collecting plant, showing the saving that can be made by suitable apparatus.

In one case, a lead-silver ore crushed to 1½ in. size, was dried in a rotary drier. By taking weights and making assays, it was found that 3.8 per cent by weight of the material introduced into the drier was drawn ou by the draft. This amounted to a loss of 9.3 per cent of the lead content and 4.6 per cent of the silver. At the then prevailing metal prices, 7.6 per cent of the total value of the ore was taken out of the drier by the draft. Some of this was caught in a settling chamber and an additional quantity in the stack, but there was a total loss of 1.85 per cent of the money value of the ore.

In another instance it was found that the drier was acting as a crusher, reducing 12.3 per cent of the ore to sizes finer than existed in the original feed. This abrasion was responsible for heavy dust losses.

For the recovery of dust which is produced by abrasion and carried out of stacks, exhaust fans can be used, connected with a system of flues running to all points in the mill where dust is formed. The collected dust can be blown into a centrifugal dust collector, where it is settled dry, or moistened by steam jets and water sprays. This system can be used with great success, and mills kept free from objectionable dust which, aside from being a source of loss in itself, has an injurious effect on pulleys, bearings and belting.

Cyanidation-Amalgamation.—The metallurgical process used at the high-grade mill of the Nipissing mine, Cobalt district, Ontario, Canada, was specially devised to treat the high-grade silver ore from the mine, and is most interesting. The following details are taken from T. A. Rickard's description in the *Mining Magazine* (London), June, 1912. The ore contains native silver, argentite and arsenides of cobalt and nickel (6 per cent Ni, 7 per cent Co, 40 per cent As). The silver content averages 2600 oz. per ton. The ore is first crushed to 70-mesh and then ground in a tube-mill in charges of the following composition: 3½ tons ore, 4½ tons mercury, and a 5-lb. cyanide solution. Air is introduced to accelerate the reaction, and after 9 hours in the tube mill, 98 per cent of silver has been extracted from the ore, which is then passed to a settler where the amalgam separates by gravity. Clean-up pans and canvas drainers are used to recover the amalgam, and the pulp and solution pass to a vat which supplies a Butters filter. The clarified solution is precipitated in zinc boxes. The solid residue contains the arsenic, nickel and cobalt, and is stored, as there is no satisfactory method for treating it.

The amalgam, 80 per cent mercury and 20 per cent silver, is retorted in 450-lb. lots, and then the silver is melted in a reverberatory for 15 hours. The resulting metal is 999 fine. The furnace flue is equipped with water-jet condensers, whereby from 1000 to 2000 lb. of mercury is recovered monthly.

The process is noteworthy for the amount of mercury which is used, and for the rapidity with which silver is recovered and marketed. It is planned to erect a mill for the similar treatment of the dumps, which contain 80,000 tons of ore assaying 22 oz. silver per ton.

Retreating Rand Tailings.—It is generally claimed that current tailings from Rand cyanide mills contain but ½ dwt. gold per ton, worth about $0.50. Before the improvement in metallurgy, however, the tailings contained from twice to three times this amount of gold, and recent developments make it appear possible to retreat the old dumps and make a profit. In the *Australian Mining Standard*, June 6, 1912, a Johannesburg correspondent gives some details of the proposed method of treatment.

A new form of classifier designed by Prof. G. H. Stanley seems to be the invention about which the new treatment hinges. It is a hydraulic classifier with a screen attached to the fine overflow, with the object of preventing the loss of coarse material of low specific gravity carrying gold, such as usually escapes with slime. Thus the classifier makes three products; a coarse sand, being larger than 60-mesh, a fine sand which is smaller than 60-mesh, and the slime. In fourteen tests on old dump material, containing gold to the value of $1.25 per ton, the average value of the concentrate, or coarse portion, was $1.80; of the fine portion, $0.77. When the concentrate was reground and cyanided by agitation, a minimum extraction of 80 per cent was obtained in 8 hours' treatment. The fine portion gave an extraction of 67 per cent after 6 hours' treatment, and the slime yielded as high as 90 to 95 per cent of its gold. It is considered that an average extraction of 75 per cent can be relied upon, at an estimated cost of 2s. per ton ($0.50).

A company known as Sands Limited has been formed to acquire the rights to the classifier, and has secured options to treat about 15,000,000 tons of tailings. It is estimated that on the Rand alone there is about 70,000,000 tons of tailings that can be treated in this way. A large tonnage will have to be treated daily, say 2500 tons, in order to make a suitable profit.

Copper.

Treatment of Mine-Water.—The water from the Ashio copper mine of the Furukawa Mining Company, Japan, carries about 0.00025 per cent copper, representing more than 18 tons of copper per month. It contains, also, sulphuric acid, ferrous and ferric sulphates, ore-slime and basic iron sulphate. As the water is discharged into the Watarese river, from which water is subsequently taken for agricultural purposes, the mine-water

must be freed from suspended solid matter before being discharged. Several methods of doing this are described by J. W. RICHARDS, in the *Bulletin* of the American Mining Institute, June, 1912.

According to the first method the copper was not recovered. Milk of lime was run into the water and the mixture passed through six settling-ponds, and then through a sand-filter. In the first pond, sand and metallic hydrates settled, free from copper; in the next five ponds, slime, metallic hydrates carrying copper, and calcium hydrate settled. The effluent carried from 0.0001 to 0.00005 per cent copper. The precipitate recovered from the last five ponds contained so much alumina and silica as to be worthless for smelting, and the copper was lost.

In the second method, the water was allowed to run through four of the ponds, to give the soluble sulphates a chance to precipitate the hydrates and thus entrain colloids. The first pond collected sand and slime; the next three contained a precipitate carrying from 0.5 to 1 per cent copper and 70 per cent silica, which was worthless. In the fifth pond, milk of lime was added, producing in this and the sixth pond a deposit of calcium sulphate and metallic hydrates with considerable slime. It carried 4 per cent copper, 22 per cent iron oxide, 20 per cent alumina and more than 30 per cent silica, but was still too poor to smelt for the copper.

In the third method, practically all the copper was saved and the water suitably purified. The water was run through three ponds, in the first of which sand and slime settled; in the second and third, some precipitate of metallic hydrates carrying copper and slime high in silica. In the fourth pond milk of lime was added in small quantity, from 10 to 20 per cent of the whole amount required. This caused a precipitate consisting mostly of hydrated iron oxide free from copper, which also carried down colloidal matter consisting of alumina and silica. In the fifth pond the balance of the lime water was added, completely preciptating the metallic hydrates, which settled in this and the sixth pond. This precipitate was rich enough in copper and low enough in alumina and silica to pay for smelting. It contained from 5 to 6 per cent copper, 12 per cent iron, 6 per cent lime, 4 per cent alumina and 11 per cent silica. This method is now in use, and recovers about 18 tons of copper monthly, giving a clear waste water which is discharged into the river.

Electro-Analysis.

Platinum Electrodes of Light Weight.—On account of the high cost of platinum, various attempts have been made to substitute some other metal or substance for platinum in electro-analysis. Most of these efforts have not yielded satisfactory results, but MESSRS. F. A. GOOCH AND W. L. BURDICK feel that they have made some progress toward reducing the expense of electrodes by reducing the weight. Their experiments are described in the *American Journal of Science*, August, 1912.

Electrodes of platinized glass can be prepared by applying a viscous mixture of glycerine and dry chloroplatinic acid by means of an asbestos swab, the glass being previously raised to a temperature sufficient to volatilize the glycerine immediately. The resulting film of metal is burned into the glass at the softening point of the latter. Experimental results showed that inexpensive electrodes could be made in this way, but the metal film was not permanent and had to be renewed after a few analyses had been performed.

Small electrodes and a weighable cell proved so much better than platinized glass that further experiments with the latter were discontinued. Rotating cathodes of platinum gauze fused to a rod of lead glass proved satisfactory. The gauze was only 1 cm. square, and therefore comparatively inexpensive. On account of the tendency of metallic particles to become detached from the cathode when deposited under high current, this cathode is used in connection with a weighable cell made from the bulb of a thistle-tube, in which detached particles can be retained, washed and weighed.

"Exothermic Steel"

By WALTER O. AMSLER, D. Sc.

This steel derives its name from its peculiar method of manufacture. It is produced either direct from the ore or from metal already reduced by a heretofore unknown exothermic reaction, under the conditions prevailing in the electric furnace, which to some extent may account for its remarkable properties. The flux used to produce this exothermic reaction is readily obtainable at low prices. No electric current and but comparatively small quantities of flux are required.

This steel was first brought to the writer's attention about a year ago by Mr. George Fogler, the inventor. At that time the claims and descriptions of the process appeared rather absurd and the statements of results were hard to believe. Close investigation of this steel already in use and of the reactions and the theoretical side of the operation led to the conviction that the process has considerable merit.

It was found, for instance, that this steel is in use where it is subjected to the most violent shock, worse than is encountered in ordnance. In this work "exothermic steel" gives from two to five times the service of the best nickel steel forgings.

To demonstrate the extreme exothermic nature of the reaction of this flux on oxides of various metals a quantity of iron ore and flux was mixed in a No. 4 graphite crucible, which was then placed in an ordinary cast-iron "cannon ball" stove and well packed in coal. After about fifty minutes the crucible was removed to find the molten iron separated out under a covering of fluid vitreous slag. After pouring the metal into a chill mold, the fracture indicated a steel of about 150 to 200 carbon. Mill and hammer scale, open-hearth furnace slag and various ores respond in the same way. To prove the extreme heat that may be obtained by this reaction chromium and tungsten were reduced from their oxides and precipitated in the crucible in the same manner and in the same stove. Authorities give the melting point of tungsten at about 3000 deg. C., or about 5400 Fahr. As the tungsten was reduced in the presence of about 50 per cent iron, the temperature was probably lower than the figures given, but still considerably higher than that of the stove.

The process depends upon the exothermic reducing reaction between a metallic oxide and a compound silicate of aluminium by which the formation of aluminium oxide takes place. Other reagents are added to intensify or accelerate the action of the aluminium compound in the flux upon the oxygen in the ore or in the metal bath. The usual reagents are feldspar and bauxite together with a quantity of limestone to make a fluid slag. In practical operation not all the reduction takes place by means of these reagents as the temperature would run too high, so enough carbon is charged to reduce a part of the oxide by formation of carbon oxides to keep the temperature within safe limits.

Feldspar is a compound silicate of aluminium and potassium ($KAl_2Si_3O_8$) and bauxite is a hydroxide of aluminium ($Al_2O(OH)_4$). The reaction breaks up both reagents to form aluminium oxide, Al_2O_3, a vitreous slag and gases. It is necessary to bring the temperature up to about 1500 or 1800 deg. Fahr. to start the reaction, after which the temperature rises rapidly and exortherimcally. The reaction may be represented by the following equations:

When using the usual iron oxide Fe_2O_3:

$$Fe_2O_3 + 2KAL_2Si_3O_8 + 2Al_2O(OH)_4 + CaO = 2Fe + 4Al_2O_3 . 6SiO_2 . 2KOH . CaO + 3H_2O.$$

In the presence of carbon:

$$2Fe_2O_3 + 2KAl_2Si_3O_8 + 2Al_2O(OH)_4 + 2C + CaO = 4Fe + 4Al_2O_3 . 6SiO_2 . 2KOH . CaO + CO + CO_2 + 3H_2O$$

An examination of these equations discloses that the slag is a vitreous mixture of alkaline nature having all the elements required to make glass. The carbon dioxide and water, of course, pass off as gas. During the formation of the slag and the re-

duction of the ore the bath boils violently, which insures a thorough mixture of the reagents.

The slag is very fluid, which, together with its alkaline nature, makes it particularly effective in removing phosphorus and sulphur from the metal

As will be seen the chemical nature of this slag makes it necessary to provide both the matte and the open-hearth furnace with a basic lining.

When making exothermic steel directly from the ore a stack furnace is used, the product of which is a matte. The matte is then charged into a basic open-hearth furnace where the metal is precipitated out of the gangue in the shape of a metal of unusual fineness.

Fig. 1 shows a general outline of the exhaust furnace used for making steel directly from the ores. It consists of a stack furnace with a water-cooled bosh and is provided with a basic

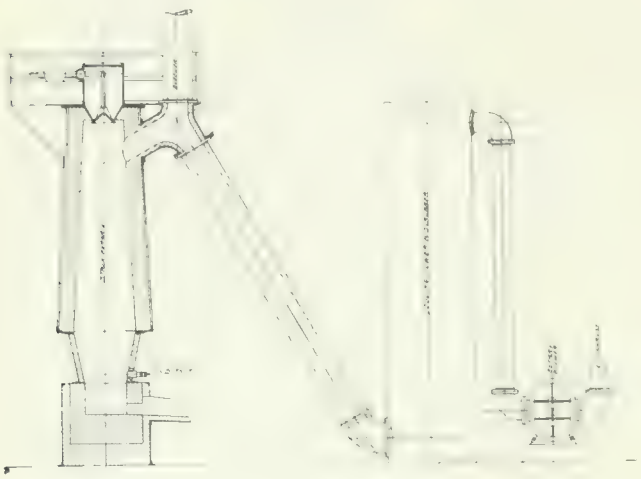

FIG. 1.—EXHAUST FURNACE.

lining at the hearth. The products of combustion are drawn off at the top and through the cooling tower or its equivalent by the exhaust blower.

The cooling tower and scrubber may be of the open type with sprays of water for cooling and scrubbing or arranged to cool by contact with cooled surfaces and deposit dust by centrifugal action.

Instead of the usual blast pipes at the tuyeres, oil or gas burners are provided. The function of these burners is to provide heat for starting the exothermic reaction and also to maintain this temperature should an excess of carbon bring it below the igniting point.

The products of this combustion ascending the stack act as a reducing agent upon the ore and make it possible to use less coke and more oil or gas fuel.

These oil or gas burners are specially designed for this furnace and are arranged to use air under pressure. The control is arranged so that an oxidizing or reducing flame can be produced at will.

A reducing flame will be required at most times, but the quantity of carbon and hydrogen introduced at the tuyeres is under constant control, as it should be.

If it were not necessary to keep the charge in the furnace in a porous condition the entire reduction excepting that done by flux might be accomplished by the fuel entering at the tuyeres.

Ten per cent of coke is charged with the ore to keep the burden open to the rising gases.

The charge is admitted as in usual blast furnaces through the bell and hopper device shown at the top, while the liquid matte is drawn off at the bottom at intervals as required. It will be noticed that hot-blast stoves are not used. The economy of using stoves and gas engines for operating on the waste gas is a matter for future consideration.

In some respects the action of this furnace and the method of operation are similar to the electric reduction furnace method where the coke charged is a little more than that theoretically required to reduce the ore, and the heat required for the reduction is supplied by an electric current. The difference is that in the exothermic process the coke and oil fuel are less than the theoretical amount required, part of the ore being reduced and the necessary heat being furnished by the exothermic reaction of the flux. Instead of using coke to the extent of about 75 per cent of the ore, but 10 per cent is required in the charge plus the equivalent of about 15 per cent of coke in the shape of oil or gas at the tuyeres, or a total of 25 per cent.

This represents therefore a saving of two-thirds of the fuel required in the present blast furnace made at an expenditure of about 13½ cents per ton of steel for flux to produce the heat corresponding to the electric current. It will be noticed that the heat is produced where required, that is, within the charge itself.

The slag is of a different nature than is usually encountered in steel processes. An examination of the equations will show that it is in the form of a glass, being a mixture of lime, potash and silica.

This slag acts as an effective protection to the metal as it passes down the shaft and into the matte in the crucible. It must be remembered that the metal does not appear in its free state in the stack furnace, but that it exists in a state of solution or similar condition, or perhaps even as a silicate of iron, although the writer is inclined to doubt this.

At any rate, the metal is thoroughly protected from the action of the oxygen and nitrogen by the reducing flux surrounding it.

A peculiar property of the process is that no precipitation of the metal takes place in the matte furnace as long as the fresh gangue is being added from the charge. However, when the matte is placed in the open-hearth furnace and brought up to the usual temperature it will swell up into a spongy mass and precipitate the metal. It is then drawn into the ladle and disposed of in the usual way. The open-hearth furnace is prepared before it is charged with sufficient carbon to give the desired temper to the metal. The results show that the metal in the bath is more uniform in carbon and other constituents than the open-hearth steel as made at present. The metal lies on the hearth as quietly as crucible steel and shows no violent

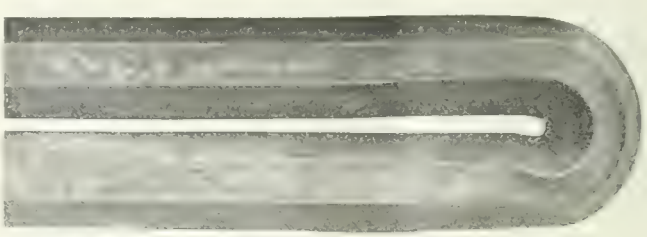

FIG. 2. 1-IN. OCTAGON BAR OF 116 CARBON STEEL BENT COLD.

boiling. This is to be expected as it has been kept away from the oxygen of the air and of the flame and is protected by the reducing slag. The unusual quietness of the metal is also apparent when the metal runs into and from the ladle. Piping and segregation of the ingot are practicaly eliminated.

This reaction may be applied to refining metals by elimination of oxides, in the open-hearth furnace or crucible furnace. In this case the flux is placed in the furnace with the charge. The reaction shortens the time of the melt about 25 per cent and gives a metal that is as quiet and free from "fire" as electric steel, in fact, it approaches the quality of exothermic steel made direct from the ore.

In the actual operation of the direct reduction process the following table shows a schedule of the charge used and the cost of the various constituents:

COST OF PRODUCING EXOTHERMIC STEEL DIRECT FROM THE ORE

TYPICAL CHARGE.

100 pounds ore at $3.75 per ton	$0.1675
2.5 pounds limestone at $2.00 per ton	.0025
10 pounds coke at $3.00 per ton	.0134
1 pound flux at $8.00 per ton	.0080
.67 gallon of oil at $.03	.0200
Labor and overhead charges	.0620
Total cost of matte containing 60 pounds metal	.2690
Cost per ton of 2240 lb. of metal in matte	10.05
Fuel required per ton in open-hearth furnace	.27
Labor and overhead charges	2.00
Cost of exothermic steel in the ingots per ton	12.32

These costs correspond to prices in the Pittsburgh district at the present time. There are many places where ore may be obtained at much better prices, such as the sand ores of the Western coast, and where oil is more available. The labor prices are probably higher than necessary after the plant is in operation on a commercial basis.

The nature of this flux and the process make it particularly valuable in reducing ores not available commercially for the present method. Silicious ores, carbonaceous ores, sulphide ores, etc., are readily reduced to very satisfactory grades of steel. The process is especially well adapted to the recovery of copper and precious metals from low-grade or sulphide ores.

Dr. Charles E. Munroe, of Munroe, Hall & Hopkins, witnessed many of the early tests made during the evolution of this process, both in the reduction of the ore direct to steel

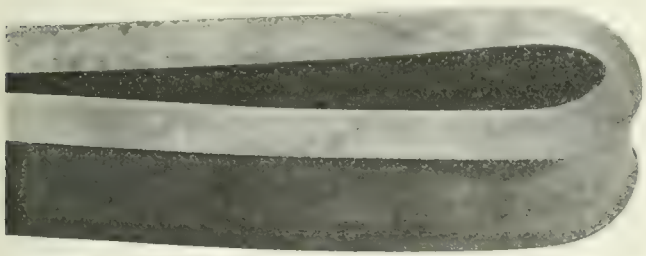

FIG. 3.—2-IN. X ½-IN. BAR OF 3.21 NICKEL STEEL BENT COLD

and in the refining of metal already reduced. Some of these tests were made at the George Washington University and others at the experimental plant in Pittsburgh. Dr. Munroe's assistance and advice were of the greatest value to the inventor in the early stages of the development of the process, at which time his knowledge of chemistry and theoretical metallurgy was less than at present. This assistance, together with the technical resources of the university, were of substantial aid in perfecting the process.

BENDING TESTS

No. 1—2" x ½" Flat Bar bent cold 180 deg. around a 1½" pin.

No. 2—1" Octagon Bar bent cold 180 deg. Flat without sign of fracture on outside of bent portion.

No. 3—2" x ½" Flat Bar bent cold 180 deg. around a 2¾" pin.

No. 4—2" x ½" Flat Bar bent cold 180 deg. around a ¾" pin.

No. 5—1⅛" x ⅝" Flat Bar bent cold 180 deg. around a 1¼" pin.

Test pieces marked "T" were heat treated by quenching in oil and drawing the temper to a dark straw color.

The physical properties of this steel are so unusual as to be almost uncanny. This is shown by some tests recently made of high carbon steels, the results of which are given. The

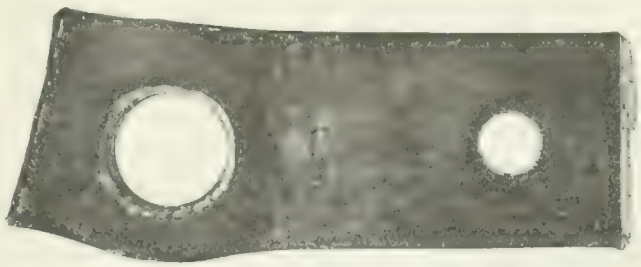

FIG. 4.—2-IN. X ½-IN. BAR OF 3.21 NICKEL STEEL DRIFTED COLD FROM 9/16-IN. TO 1 3/16-IN.

steel was made by the Braeburn Steel Company at their plant at Braeburn, Pa., under the personal supervision of the writer, who also weighed out the flux and had it placed in the charge at the proper place. The test pieces were prepared by him and the tests made by the Pittsburgh Testing Laboratory under his supervision. The analyses were made by the Braeburn Steel Company at their plant laboratory.

One certainly would not expect much toughness or elongation in steels of 100 carbon or better, but the tests show some remarkable results, such as an elongation of 29 per cent and reduction of area of 50.1 per cent in steel of 112 carbon. The same steel shows an ultimate strength 65 per cent higher

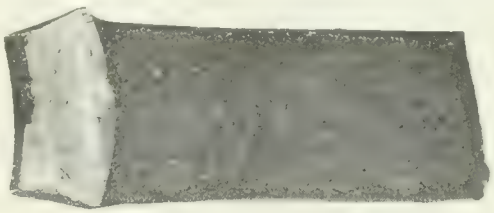

FIG. 5.—SAME BAR AS FIG. 6 SHOWING FRACTURE.

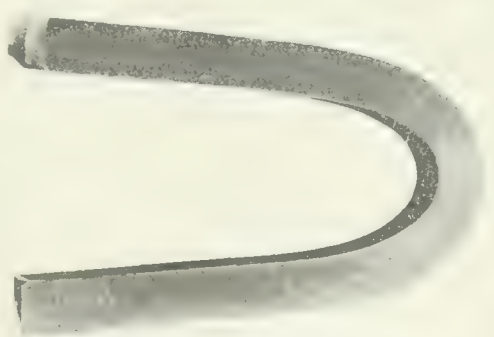

FIG. 6.—45-CARBON STEEL BENT COLD WITHOUT ANNEALING.

than the elastic limit, and a cold bend of 180 deg. around a 1½-in. pin. This steel heat treated and made so hard that a center punch refused to make a mark shows an elongation of 5.33 per cent and reduction of area of 18.7 per cent.

The bending of test piece No. 2 is shown in Fig. 2. This shows a 1-in. octagon bar of 116 carbon steel bent 180 deg. flat without sign of fracture on the outside. The operator of the

testing machine remarked, "I would believe the carbon had been determined by the color method by a blind chemist if it were not for the appearance of the fracture!" Fig. 3 shows a 2-in. x 2½-in. bar of specimen No. 4 of 3.21 nickel steel bent cold to a radius of about one-half the thickness of the bar. The piece shown in Fig. 4 is cut from the end of the bar in Fig. 3 and shows a cold drift from a 9/16-in. drilled hole to 1 3/16 in. Comparison of the holes will show the extent of the drift. This test was made by driving drift pins into the hole with a heavy sledge.

Fig. 6 shows a specimen of analysis No. 5 bent cold just as it came from under the hammer. It shows a bend of 170 deg. on a diameter of about three thicknesses. The size of this bar is ⅝ in. x 1 7/16 in., and it drifted cold from 9/16 in. to 15/16 in. before tearing out at the side. Many more examples might be submitted, but they would take too much space.

It will be noticed that the general composition of the steels in Nos. 3 and 4 is about the same except for the nickel and the results show that the carbon steel is every bit as good as the nickel. In fact, test piece No. 5 shows physical properties better than are usually expected of nickel steel. This bears out Mr. Fogler's contention that ordinary carbon exothermic steel gives better results than the usual nickel steel, especially as he has demonstrated it in practice.

The ability of this steel to meet the requirements of high-duty steels at a cost of manufacture less than that of the present steels will probably solve the rail problem, and many others where high wearing qualities and resistance to shock are necessary. It is not at all unlikely that with structural steels made by this process the allowable fiber stress will be raised from 16,000 to 20,000 lb. with its attendant saving in weight and cost.

Pittsburgh, Pa.

An Automatic Continuous Recorder of the Weight of Material on Belt and Bucket Conveyors, Cable Railways, Etc.

Scientific management has become a catchword in the operation of modern large-scale industrial plants, and not in the least in chemical and metallurgical works. Just as any industrial enterprise cannot be carried on satisfactorily without an exact method of bookkeeping so in modern chemical and metallurgical works accurate daily balance sheets of all phases of the operation are needed. These balance sheets must cover two phases especially, namely, first, the quanities of the materials which enter the process and of all the products, and, second, the quantities of the energy (fuel, electric energy, etc.) involved in the process and the changes of the energy during the process.

While in power plants exact records are now used everywhere by means of recording wattmeters, etc., the same principle of exact continuous records has not yet been applied to the weighing of materials. True, on a smaller scale, especially where very expensive products are involved, it has always been customary to carefully weigh the raw products, but in operations on a larger scale careful weighings have been often considered to be too troublesome, so that instead more or less inaccurate estimates have been relied upon. The reason has been that while it was understood to be highly desirable to weigh carefully all the materials, that it was thought to be too troublesome and too expensive. The ordinary weighing hopper scale has done excellent service, but the careful and expensive attendance is required and the delays involved in the weighing have proven in some respects troublesome.

The Merrick weightometer, which will be described in this article gives an accurate continuous record of the weight of material transported by belt and bucket conveyors, cable railways, and overhead transporters. It permits continuous and accurate control of the quantities of raw materials or supplies brought into a plant, of the outgoing material loaded into boats, carts or stock-bins, and also of all the partly finished materials which are being transferred from one department to another. A secondary advantage which, however, will be appreciated by many superintendents, is that the weightometer gives exact information on the total of material handled by rubber belts, etc., during their total life, so that it is possible to get from the record a reliable estimate of the advantages of the different types of belts.

The weightometer (Fig. 1) consists of a pair of weighing levers *L*, a steelyard or beam *B*, similar in principle to those of the usual platform scale, but of special design so that a short section or portion of the conveyor can be suspended from the weighing levers.

The weight of the load on this suspended portion of the conveyor, regardless of its distribution, is at any instant automatically counterbalanced by the buoyancy of a cylindrical iron float suspended from near the long end of the weighing beam

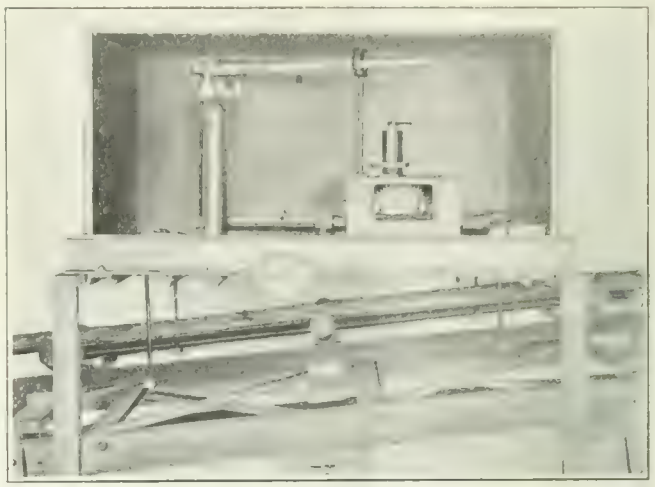

FIG. 1. VIEW OF WEIGHTOMETER ON BELT CONVEYOR. FRONT SHEET OF CASING REMOVED.

and partially immersed in a bath of mercury. Any increase or decrease of load on the levers will either raise or lower the float in the mercury until the loss or gain in buoyancy compensates for the variation in load.

The function of this float is to insure that the movement of the beam from its zero position, or position when the conveyor is empty, be proportional to the weight of material at any instant on the suspended portion of the conveyor.

The extreme end of the beam is connected with a totalizing mechanical integrator, which derives its other factor from the travel of the conveyor by means of suitable gearing from a bend pulley on the return belt or a sprocket wheel if on a bucket conveyor.

This integrator thus continuously totalizes the product of two quantities, one proportional to the weight of material suspended and the other to the travel of this material. The result, therefore, represents the total weight of material and is plainly indicated by a register in units and tenths of units of either a short ton, long ton or metric ton.

For cases where the material handled adheres to the conveyor in a varying amount, an attachment is added that automatically counterbalances the variable weight of the empty conveyor. This avoids frequent adjustment to meet the changes in the weight of the empty conveyor and material that may adhere thereon.

It is, of course, easy to transmit by electro-magnetic means the reading of the scale register to the office of the superintendent, or to any other point distant from the scale itself, so that the superintendent or manager knows always what is going on.

The integrator (Fig. 2) consists of an aluminum disc X around the periphery of which are mounted rollers Y free to revolve. These have their axes tangential to the edge of the disc, and form practically a continuous annular roller which cannot move around the disc.

The disc is fixed on a shaft that revolves in bearings on the frame Z. This frame is mounted with a bearing at either end so that it can rotate about an axis coincident with the plane of the disc and at right angles to the axis of the disc. On one

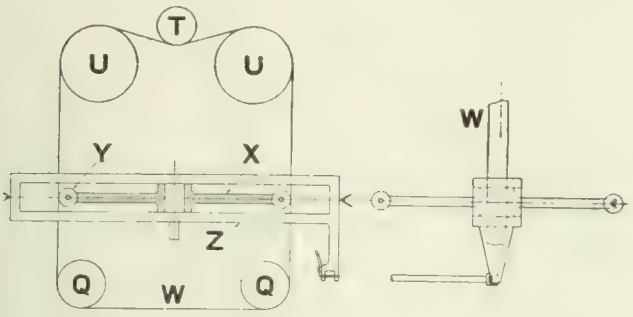

FIG. 2.—DIAGRAMMATIC SKETCH OF INTEGRATOR.

end of this frame is an arm the extremity of which is connected by a link to the long end of the beam. Thus any movement of the beam caused by an increase of the load on the belt tilts the frame through an angle whose sine is proportional to the vertical movement of the float, and again proportional to the load on the suspended portion of the conveyor.

Four pulleys UU, QQ, guide a small endless belt W around the disc and touching the rollers thereon at two points diametrically opposite and on the axis of the frame.

Pressure rollers behind the belt (not shown in the diagram) keep the belt and disc rollers in contact. A weighted take-up pulley T assures an even tension in the belt and takes care of any stretch. The two pulleys UU are geared together and are driven by means of mitre gears from a bend pulley under the return belt. The integrator belt thus travels at a speed proportional to that of the conveyor.

So long as the plane of rotation of the roller Y is parallel to the direction of the integrator belt the motion of the latter will only affect it to the extent of revolving the roller on its own axis. This condition corresponds with the zero position of the beam or when there is no load on the conveyor. If, however, the beam is deflected by the loading of the belt, the frame Z and disc X will be correspondingly tilted. This will incline the axes of the roller Y with respect to the integrator belt. Then, besides rotating them, the belt will push the rollers sideways across its face at a rate proportional to their inclination. As the rollers cannot slide on the disc they will rotate it around its axis. Consequently the speed of rotation of the disc is proportional to the deflection of the beam, the weight is carried on a screw and is similar to that on the ordinary platform scale, as turning the screw moves the balance weight.

It is interesting to note that the Merrick weightometer has passed the experimental stage for a few years and has proven exceedingly simple in operation. The chief practical advantages are that the operation is entirely automatic, so that there is no expense for any attendance. It is very easily installed, and the only supports required for the weightometer are quite simple and inexpensive, due to the simplicity of its design and construction. It has been possible to make it durable and robust.

The recording being continuous, the accuracy is not affected by vibrations of the beam whether due to irregular loads or lack of rigidness of the structure. These vibrations are necessarily an equal distance either side of the true position and the average result unchanged by them.

As structures on which the conveyor and weightometer are erected are seldom ever free from vibration, this feature constitutes a prominent point of advantage.

The Merrick weightometer is built by Herbert L. Merrick, of Passaic, N. J.

The Western Metallurgical Field.

Search for Tin.

Tin has been attracting considerable attention in the West and strong efforts are being made to develop a production more in keeping with consumption in the United States. In South Dakota, Texas, Washington and Alaska tin has been found and some mining has been carried on. In Texas especially competent engineers who have examined the lode, near El Paso, consider the possibility of developing a satisfactory ore body to be excellent. The owners, however, have never been willing to spend the necessary amount of money in underground development and the effort to make the mine produce before it was ready has resulted in discouragement.

On Seward Peninsula, in Alaska, both lode and stream tin are found. Dredging last year resulted in the shipment of 90 tons of concentrate from Buck Creek, worth $590 per ton. The concentrate was sent to England for treatment, but future shipments are to go to Tacoma, Wash. Lode mining has been less successful despite the fact that the deposit is said to be 10 ft. wide and to have been traced 3000 ft. It is said to average 2 per cent tin and 1 per cent tungsten. The character in depth has not been determined.

Near Hot Springs stream tin has been known for at least three years and under the guidance of Falcon Joslin, of Fairbanks, a Mr. Robinson has been making a careful search for the lode. It was announced some time since that it had been found and details are now at hand. The ore body is associated with an "altered rhyolite" occuring as a dike which has been traced 10,000 ft. across the heads of Sullivan, Tofy and Idaho gulches. The actual ore body has been shown by trenching and cross-cuts to be 12 ft. wide and to extend 3700 ft. along the strike. The average value has not been determined, but cassiterite occur in the rock in microscopic particles and ore is certainly of value.

Encouraging Outlook in Alaska.

Alaska is well on the way of a busy season. It is announced that twelve new dredges are to be erected at Nome; the Guggenheims have bought the most important claims at Iditarod and are slipping one of the Dawson dredges down; hydraulicking on the Kenai peninsula started early; Ruby Creek is sending out good reports and some gold; the Perseverance and the Sheep Creek properties at Juneau have come under control of B. L. Thane and associates and will doubtless be placed in good shape, and the new concentrator at the Bonanza mine, Kennicott Mines Company, has begun work. It is interesting to note that this concentrator, which handles the second grade of the much-discussed Bonanza mine, works on material containing 25 per cent copper. The product assays 65 per cent copper and 18 oz. silver. W. H. Seagraves, formerly of Ely and later at La Touche, is now in charge at Kennicott. He has started work on the Jumbo, a claim near the Bonanza. It is expected that copper shipments from the Bonanza this year will total 40,000,000 lb. as against 23,000,000 lb. last year.

Revival of California Miners' Association.

California mining men propose to revive the California Miners' Association which did such valiant work in the old days of contest between the farmers and the hydraulic miners. Of recent years the Association has had only a nominal existence. It is proposed to revive it and to call a meeting next November to which other Western states will be asked to send delegates, with a view to arranging for proper exhibits and representation at the Panama-Pacific Exposition.

That the latter must include a first-class exhibit relating to mines and mining, is felt to be a matter of first importance to the Western mining industry in particular, and such an exhibit can only be assured by arranging promptly for wide and hearty co-operation. Since, however, the Association is to be revived, it is likely that so viril an organization as it long was, will find many fields of usefulness. The committee in charge consists of Charles G. Yale, E. B. Braden, and W. C. Ralston.

Another matter which is attracting attention in San Francisco is the International Engineering Congress which is to be held in 1915. A strong local committee has been formed and the bulk of the required guarantee fund is already in hand.

Treatment of California Zinc-Copper Ores.

Zinc ores are the subjects of much investigation in California just now, though not yet a source of profit. Considerable quantities of zinc ore have been developed in Shasta County, all of the copper mines containing a good deal of zinc, while several have proved in depth to contain more zinc than copper. The ores cannot be treated in ordinary Belgian furnaces, since the blende is associated with so much chalcopyrite and pyrite, and there is no source of fuel supply in the district.

Much study has been devoted to methods other than ordinary smelting. Two of the companies, the Afterthought and the Bully-Hill, announce that they have met with enough sources to justify development. The Afterthought Copper Company operated its copper smelter at Ingot, 20 miles east of Redding, for a time on ore averaging 3.4 per cent copper, 15.3 per cent zinc, 6.4 oz. silver and 60c. gold per ton, but later shut down. For some time S. E. Boetherton, who is general manager and metallurgist for the company, has been at work upon a method for treating the ore, and it is now announced that a 25 or 50-ton plant will soon be constructed. The details of the process are kept secret since it is not yet fully protected by patent. The Afterthought company has purchased a lumber railroad from a local company and is extending it to the smelter at Ingot. The Bully Hill Copper Mining & Smelting Company, which formerly operated a copper smelter at Winthrop, has also been studying the problem, and J. B. Keating, the manager and metallurgist, is said to have had a large measure of success in devising means of treating the ore. Here again the method is kept secret.

The mammoth plant of the United States Smelting, Refining & Mining Company, may be said to be making use of the zinc content of its ores, since the 4 per cent of zinc in the smelting charge of the copper furnaces serves to neutralize the SO_3 produced in smelting and permits the filtering of the smelter furnace in a baghouse. It was hoped at the time of starting the copper smelter that a method of recovering the zinc from the baghouse fume, which contains 40 per cent $ZnSO_4$ and 20 per cent ZnO, could be devised, but no profitable method has yet been evolved.

C. J. Reed, of San Francisco, has also been at work upon a wet method for the extraction of zinc from its ores and has taken out a number of patents. A 1-ton experimental plant has been erected on San Francisco bay, but no statement has been given out as to the results attained. Engineers who have investigated the proposed process are of the opinion that it is extremely good from a chemical standpoint, but likely to introduce mechanical difficulties from the standpoint of construction and operating costs. It is too early to form an opinion. The developments so far are said to have been satisfactory.

The situation is somewhat complicated, to the producer of zinc, by the fact that there exists no great market for spelter on the Pacific coast. Zinc is chiefly used in making brass and galvanized iron; the brass industry is concentrated on the eastern seaboard, while the making of galvanized iron naturally centers around the steel plants of Pennsylvania, Ohio and Illinois. The zinc producer in California has no advantage of local markets, therefore, but has to meet the disadvantage of a longer shipping distance.

Advanced Cyanide Practice.

Within a period of five years, practice in cyaniding gold and silver ores has undergone such radical changes from the mechanical point of view, that machinery and methods which were regarded as standard a few years ago are now regarded as obsolete. Perhaps no other branch of metallurgy has changed so completely in such a short time, or has been so uniformly successful in the field to which it is adapted. In catalog No. 10C, just issued by the Colorado Iron Works Company, of Denver, Colo., may be found a brief sketch of modern cyanide practice and equipment. This booklet will be interesting and valuable to both the layman and professional metallurgist, for it embodies a concise statement of the principles of cyanidation, as discovered by MacArthur and Forrest, and gives examples of approved mechanical application of those principles according to modern ideas.

Among the principal features of present-day cyanide practice may be mentioned sand and slime classification, slime agitation and filtration, and continuous counter-current decantation. The mechanical means of accomplishing these steps, and the arrangement of mills embodying them, are all illustrated and described in the catalog. The Akins classifier, Akins-Rothwell agitator, Rothwell slime thickener, and Portland slime filter are all machines which have been developed by the company's metallurgists, and have found extended application in modern cyanide mills.

The subject of cyaniding by continuous decantation has been discussed in this journal, several methods having been proposed by Mr. John E. Rothwell.[1] In addition to these, the catalog mentioned contains another method devised by H. B. Lowden and J. E. Rothwell, in which the principle of counter-currents is applied in a simple manner. The scheme is illustrated in Fig. 1.

In this, the thickening tanks are dispensed with and a quiet space provided within each agitation tank. This annual space is furnished with inclined baffles, similar to those employed in the Rothwell thickener, which greatly increase the settling area, and the solution drawn off is substantially clear and practically no solids are carried back by it. To remove any turbidity of the solution previous to precipitation it is passed through a clarifying filter previous to going to the gold tank. The method of operation is as follows:

A, B, C, are Akins-Rothwell agitation tanks arranged for continuous series agitation and each fitted with an inner cylinder A_1, B_1, C_1, and an overflow launder L_1, L_2, L_3. In the annular area between the cylinder and the curb of the tank are placed inclined baffle plates, the tops of which are submerged.

The slime pulp to be treated flows from the grinding mill to the space within the inner cylinder A_1, in which it is kept agitated by pneumatic or mechanical means, or both. A definite proportional part of the pulp is cut out continuously by the cutting vane and passed on to the space in the inner cylinder B_1, in which the same operation takes place, the pulp passing to tank *C* and so on to the subsequent tanks of the series.

While this operation is going on, barren cyanide solution is passed from tank, *W*, through the meter, *M*, into the space in the inner cylinder of tank *C*, or the last tank of the series when more than three tanks are used, and this solution mixes thoroughly with the pulp being agitated, thus diluting the values carried in solution. Separation of the solids from the liquid is made by gravity in the quiet annular space 3, the solids remaining in the tank while the solution overflows the weir into the launderer L_3 in quantity equal to the inflow from *W*. From the launder L_3 the solution flows to the space in the inner cylinder B_1 of tank *B*, in which the action and operation are the same as in *C*, the overflow going from the space 2 to the inner cylinder A_1 of tank *A*.

[1] This journal, Vol. IX (1911), pp. 373 and 439.

The counter current solution, passed from *W* into *C*, diluting the values in solution in that tank, flows back through the series of tanks, coming progressively in contact with richer pulp and gathering values in its course, finally overflowing from L_1 carrying a maximum value. This is the solution which is precipitated, for which purpose it is passed through the clarifying filter, *F*, to remove any turbidity and thence to the gold tank, *G*, from which it flows to the zinc-boxes, *Z*, in which the gold and silver are precipitated. The barren solution from the zinc boxes flows to the tank, *S*, from which it is pumped back to the tank, *W*, is built up in cyanide strength and re-enters the circuit.

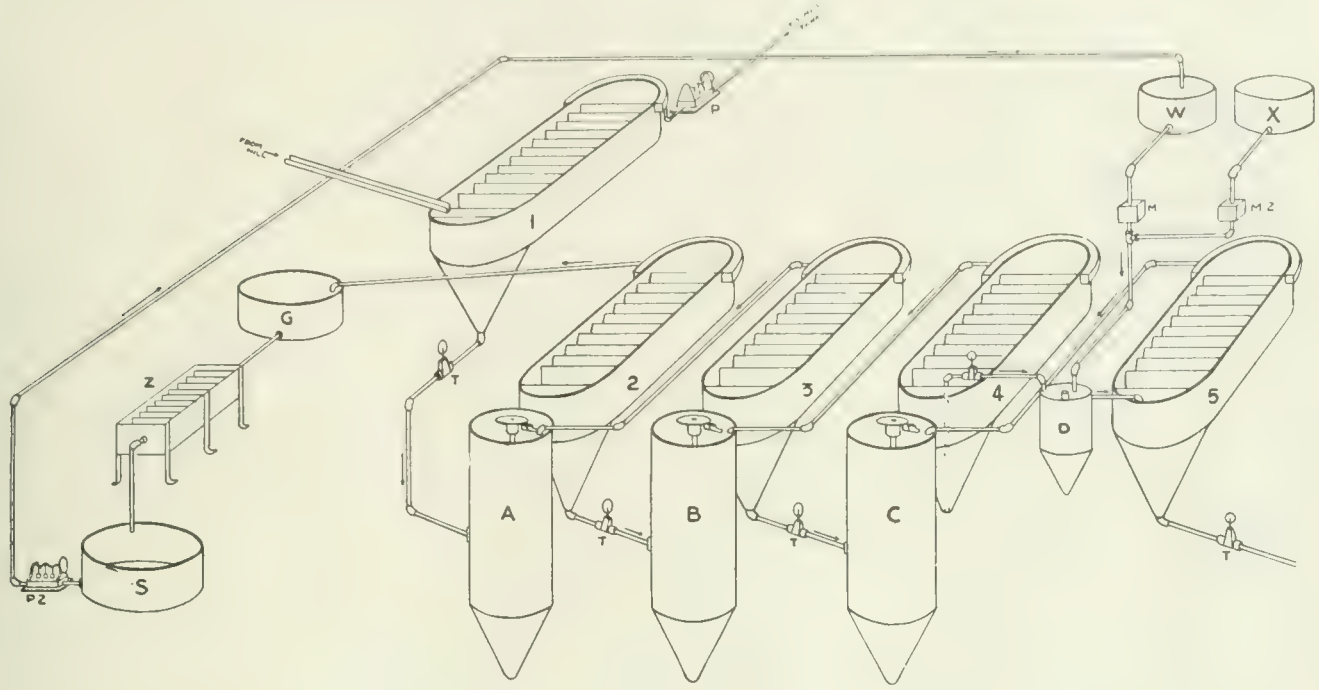

FIG. 1.—ROTHWELL-LOWDEN COUNTER-CURRENT METHOD OF CONTINUOUS AGITATION.

In the meantime the pulp has been passing through the series of tanks in a direction opposite to the flow of the solution, whereby it progressively comes in contact with solution lower in dissolved values and higher in free cyanide as the pulp becomes reduced in value, finally passing from *C* into the collecting tank, *D*, from which it goes to the slime filter. This filter separates the pulp and washes from it the soluble values it carries, delivering the solids to waste. The filtrate, being low in value, passes back to the grinding mill circuit, where it is built up in cyanide strength and resumes its flow through the system.

In addition to the foregoing, the catalog contains useful tables on capacities of tanks, equivalent rates of flow of water, slime density relations, and other information of value to the engineer.

A Recent Evaporator Test

In the following article we give the results of an interesting recent evaporator test, made by Mr. Charles L. Weil, consulting engineer of the Diamond Crystal Salt Company, of St. Clair, Mich. The evaporator under test was a quadruple-effect evaporating system at Ludington, Mich., constructed by the Rapid Evaporator Company, of Detroit, Mich., under the Faller patents. This 24-hour test was made on June 28 and 29, with a shut-down of two hours on the night of June 28.

The essential features of the test in question were the determination of the pounds of salt made per pound of steam used and the conditions maintained with respect to incrustation of heating surfaces during the making of the salt. The test also furnished data as to the rate of salt making for these specific pans or effects, for the amount of salt in barrels or tons that could be made with a ton of specific coal and as to the ratio of steam supplied to water evaporated.

In order to determine the steam used the drip from the "steam belt" of the first effect "pan" was conducted, alternately, to two calibrated measuring tanks, passing on its way through a cooling coil, and thus a record was secured of the weight of steam used. The temperature of the water running into the tank was taken each time a tank was filled. The calibration gave a value for the weight of water in a tank, when filled to a specific mark, of 1550 lb. of water at 128 deg. Fahr.

The records gave a total of 33 29/44 loads or tanks, each of 1550 lb., or a total of 52,172 lb. of condensation for the 24-hr. run. A check of the measurement showed that it had been quite accurate.

The determination of the amounts of salt made in the different effects showed that 11,241 lb., 6940 lb., 12,003 lb., and 18,454 lb. were made in the first, second, third, and fourth effects respectively, for the entire period of 24 hours.

The total "moist" salt made was, therefore, 48,638 lb. The moisture in five samples was 7.21, 6.11, 6.39, 4.72, 4.44 per cent, average 5.77 per cent. If "commercially dry" salt is assumed to carry 5 per cent moisture, the 48,638 lb. of "moist" salt produced correspond to 48,263 lb. of "dry" salt. Since the total steam used was 52,172 lb., the number of pounds of salt made per pound of steam is 0.925 lb.

With steam supplied at atmospheric pressure, the figure is 0.921 lb. of dry salt per pound of steam at atmospheric pressure. It should be noted, however, that during the test the drip from the first effect steam belt was caught and measured, and not passed on to the second, third and fourth effects as is the custom in this system in regular practice. If an allowance is made for this in a conservative way, the amount of salt made per pound of steam would have been increased 9 per cent by passing the drip through the several effects, giving 1.004 lb. of salt per pound of steam.

On the foregoing basis, the results of the tests are, therefore, as follows:

20,080 lb. or 71.7 bbls. (of 280 lb. each) of salt are made by 20,000 lb. of steam or 71.7 bbls. (of 280 lb. each) are made by 1 ton of coal, where coal will evaporate 10 lb. of water from and at 212 deg. Fahr.

In Mr. Weil's report on the test, attention is called to the

fact that the system, at the time of the test, had been operated the greater part of one year without "scaling" the tubes. Investigation showed a slight scale on the tubes of the higher temperature "effects," that is, the first and second pans. This slight scale undoubtedly decreased the efficiency of the system. Taking this into account and also the conservative estimate made of the effect of the drip in the second, third, and fourth pans, Mr. Weil concludes he may safely place the ratio under consideration, in comparison with similar tests, having especially prepared apparatus, as, using a coal as above, *seventy-five barrels of salt per ton of coal.*

The brine used during the test was saturated and fed to the pans at a temperature of 160 deg. Fahr.

The ratio of evaporation, steam to steam, was approximately 1 to 2¾.

The total amount of salt made during the 24 hours run was 172 bbl.

The matter of incrustation of heating surfaces in the case of these pans is one of great interest. No arrangement is provided for boring or scaling the tubes and although the pans are reported to have been run the greater part of one year and never scaled, still the tubes show but a very light scale. A sample of this scale was analyzed and found to consist chiefly of calcium carbonate.

An explanation, in part, of the scale is to be found in the daily use in these pans of tri sodium phosphate, though it is claimed to be used but in limited quantities, say 25 to 30 lb. during one day.

With regard to the auxiliaries, it is noted that provided the power required for driving same, calls for a steam consumption within the requirements of steam from the first effect apparatus, then the only heat loss experienced would be that due to condensation and radiation in connection with the engines driving these auxiliaries and this would be a loss incidental to all such systems, but relatively low in amount in the case of a "quadruple" system. In this case the auxiliaries were electrically driven and a special determination of the power, showed, not allowing for efficiency of motors, that the average horsepower required to drive the auxiliaries, is 58 hp. The available steam for this amount of power, for use in the pan should be, using a fairly efficient engine, within the requirements of the system.

Consequently, no unusual loss of heat is anticipated in connection with driving the auxiliaries.

The following table gives analyses of the "raw" and heated brine used and also an analysis of one sample of the salt made:

	Raw Brine.	Settled Brine.
Specific gravity at 15 deg. C.....	1.2019	1.2093
Total Solids	25.65%	26.740%
Calcium Sulphate ($CaSO_4$, $2H_2O$).....	0.58%	0.559%
Calcium Chloride ($CaCl_2$, $6H_2O$)	0.16%	0.188%
Magnesium Chloride ($MgCl_2$, $6H_2O$)....	0.05%	0.051%
Sodium Chloride (NaCl).....	24.86%	25.942%

Sample No. 1 of salt shows 0.77%, calcium sulphate $CaSO_4$. $2H_2O$.

As to the evaporator design it is interesting to note that each pan contains 402 copper tubes, 3 in. inside and 3⅛ in. outside diameter.

The 402 copper tubes have an effective length of 38½ in. Consequently the heating surface is, very nearly, 1055 square feet. This is, relatively, a larger amount of heating surface than Mr. Weil has met with, for corresponding outputs in his experience.

The salt produced was a high-grade "granulated salt" with respect to color and coarse "grain."

Mr. Weil concludes, that while we have no acknowledged standard method of testing such apparatus as that we have under consideration, yet the results of evaporation (75 bbl. of salt per ton of "10-lb." coal) are excellent and that the salt produced is of a superior nature.

Synthetic Rubbers.

It will be interesting to read the following British press views on the synthetic rubber situation.

In the *Engineering Supplement* of the London *Times* of July 19, Prof. Henry E. Armstrong writes as follows under the heading "The Production of Rubber—With or Against Nature":—

"The question whether ultimately rubber will be produced with advantage by artificial means is one which has many sides that may well be discussed at the present time. In every case the foundations of success are laid beforehand, and as we have sown so probably shall we reap; if it appear that we have not always sown well, by taking stock of the situation we may find ways in which we can do better in future.

"The problem is one of great public and practical importance. The capital at stake is very large already and will become far larger. As its qualities are recognized and it is cheapened in cost, the uses of rubber will be multiplied and the demand will enormously increased. But, be it remarked at the outset, it is useless to think of present prices ruling in the future; at no distant date, rubber will be regarded as so indispensable that, in some way or other, the cost must needs be lowered.

"*Chemical Processes and Their Chances.*—The statements made recently at the Society of Chemical Industry, regarded from the practical side, though suggestive, are incomplete. Nothing that is new in principle was brought forward. Processes were outlined of an interesting character from a scientific point of view, but definite information on which judgment of their practical value could be based was wanting. In such a case, as in many others, before it can be eaten the hare must be caught. The primary difficulty in manufacturing rubber artificially is to find suitable raw material. It is said the difficulty is overcome, and we are told that it is to be starch, which is first to be converted into butylic alcohol by a fermentation process. Chemists have long been familiar with methods of making the alcohol by bacterial action, but these have never been applied except on a laboratory scale. Step number one, therefore, will be the foundation of a new fermentation industry. Though difficulties as often disappear as they appear on translating laboratory practice into work practice, fermentation processes of promise have ended in practical failure before to-day, as in the case of citric acid, for example. The question of patents will also have to be considered. There is no novelty in making "higher alcohols" by means of organisms; the most that can be done probably is to protect the use of a particular organism in a particular way for a particular purpose, and it is by no means certain that the field is not fairly open to all whom it may concern.

"Much importance is attached also to the discovery that sodium is a particular effective agent for use in converting the very volatile hydrocarbon isoprene and similar substances into rubber or a rubberlike material. It is more than probable that the conversion may be effective equally well by other means. Apparently the polymerization process is one in which the active agent is either an alkali or an acid: the principle involved in the use of such materials cannot now be protected by patent, and it will, therefore, be open to chemists to discover various ways in which they can be applied with advantage.

"The material ultimately produced from butylic alcohol is not ordinary rubber but a rubber-like material, and doubtless not the only one to be found. In other words, the field may be a large one, and it may be possible to make such materials in a considerable number of ways. Though all to the good, so far as the public are concerned, this circumstance may effect materially the value of any individual set of processes that it is proposed to apply in practice. In fine, it is probable that success will depend more effective organization that on the possession of any particular set of patents.

"*German Resources.*—It is well, therefore, that there should

not be excessive jubilation by English chemists at a victory or two gained in the laboratory over German chemists. There is reason to believe that the German works have knowledge at their disposal which render them independent of Professor Perkin and his associates. Moreover, the technical resources at the command of the Germans are far greater than any we possesses [in Great Britain]. Here comes the point at which we have failed to sow properly. The Germans are fortunate in possessing a large number of works which are simply University laboratories turned into huge manufacturing establishments, such as the Badische, Anilin und Soda Fabrik, Bayer and Co., and Meister, Lucius and Co. There is not one such establishment now in English hands.

"When 20 or more years ago it was a question of developing the manufacture of artificial indigo, it was a small matter for a firm of such consequence as the first above mentioned to spend nigh on a million pounds sterling in bringing the process to perfection, and in the end they merely add a new section to their works. So it will be with artificial rubber; if desirable processes will be perfected, at whatever cost, and another new department will be created in the works. The German manufacturers have an extraordinary fund of experience and an army of drilled and disciplined workers at their command; everything, in fact, is organized up to the hilt, and the development of the artificial rubber industry will be a matter of small concern to people equipped as they are.

"Here [in Great Britain] the industry must be started, not as a branch industry, but *ab ovo* and independently; its complete organization must be effected practically without external assistance. The expenditure before success is assured will necessarily be very large, and probably many fingers will be burnt in the preliminary work. When success comes what will be the position? The three months' start which has been the cause of jubilation will have been sacrificed, and one or other or several of the German firms will be far ahead and possibly will have acquired a commanding grip of the market.

"Why is it that we [in Great Britain] are so much behind? Our present inability to manufacture coal-tar colors is the consequence of breakdown not on the scientific side but on the business side. We fail because we remain Philistines—because our schools and universities are governed by literary ideals alone. If we desire to recover our position we could not do so now without the sacrifice of millions probably—simply because the Germans have acquired control of the markets of the world and could and would undersell us everywhere. As we have sown so must we reap. If we are to repair our past errors we must be prepared to take heavy risks and lose much in the process; in one way or another, we must pay for our mistakes. The rubber industry perhaps offers an opportunity and it is one that should be taken at all risks—but with eyes open to the risks.

"*Artificial Versus Natural Rubber.*—Will artificial rubber succeed in competition with natural rubber? Perhaps not if there be actual competition. But the question is—may there not be room for both? The answer is in the affirmative; both natural and artificial rubber should be remunerated industries if from the outset producers of the two articles work together and do not allow an unholy spirit of competition to arise. Here again a lesson can be learned from Germany. In early days the firms there were all in competition and there was endless litigation over patents; in consequences the prices of dye-stuffs were reduced to figures which were absurd, taking into account the skill and knowledge involved in their manufacture, and were unnecessarily low even from the dyer's point of view, in view of the fact that a little dye-stuff goes a long way and that its cost bears a small proportion to the total cost of manufacture of the dyed goods. Of late years, recognizing the absurdity of the position, the German manufacturers have combined and agreed to work together. Litigation is rarely heard of. At the same time we have been misled into altering our patent laws in a manner entirely favorable to foreign interests, by nominally requiring that goods sold here should be manufactured here. Technical compliance with the Act involves so little that it is practically inoperative, but it has been the last straw in upsetting struggling industries here, and, what is worse, has been greatly to the advantage of our competitors in foreign markets.

"But is it desirable to make rubber artificially? The question may seem to be of little more than academic interest considering the progress already made. The Germans will make rubber if we do not; indeed they are doing so already. Yet it is worth while perhaps to think the question over and consider whether, in the long run, it pays to make rubber from starch.

"We are competing with Nature in many directions at present and it is very desirable to discuss whether in the future it will be either desirable or possible to work so much against her. Practically all the natural coloring matters are now supplanted by artificially-made dye-stuffs, which, in the case of the more important, such as indigo and madder, are identical with the natural products. The alkaloid quinine, which is extracted from cinchona bark, though not displaced and in no way equalled yet, has many rivals made in Germany, which are often used when formerly it alone was prescribed. These coloring matters and drugs are in most cases made from that universal provider, coal-tar, and the manufacture of dye-stuffs from coal-tar and the consequent displacement of natural colors may be justified on at least two grounds: (1) Constituents of coal-tar which are otherwise of little value, if not valueless, are made use of as raw materials; and (2) the land on which madder and indigo were grown is now set free and can be used in raising food crops.

"*Starch Too Valuable.*—But rubber, we are told, is to be made from starch. In making it from this material we shall not only be withdrawing land now used in raising food crops, but in a sense we shall be using up food crops (potatoes and cereals) as the raw material. The question is how long this will be desirable and possible. As we increase in numbers the difficulty of securing adequate food supplies is bound to increase. Moreover, there is a direction in which there will be a use for starch in the future which also may militate against its use as the raw material of artificial rubber. Taking into account the rapid development of the internal combustion motor and the fact that petrol will not be available for ever at present rates of consumption, it is more than probable that alcohol will come into use in its place at no distant date. The only way in which it will be possible to meet requirements will be to ferment starch and sugar produced for the purpose in hot countries, where large crops can be grown. All the indications point to a shortage of sugar and starch in the future and to an increase in their value.

"But after all, in using starch to make rubber we shall only be copying the plant, as this also makes the rubber more or less directly from starch. It is not a case of utilizing a waste product—such as coal-tar was when dye-stuffs were first made from it, and such as it would be still in the absence of the color industry—but a material is to be used which is of particular value for other purposes already. Ethically we shall probably be making a mistake in not availing ourselves to the full of the activity of the plant; but, apart from this, it may be well that, when everything is taken into account, the plant is able far more effectively than man to make rubber from starch. It is of the utmost importance, from this point of view, that the production of natural rubber should be made a scientific industry. In the case of indigo the margin in favor of the artificially made material is not so very great; had the planters taken time by the forelock it is not improbable that they would have held their own. It will be well if rubber planters take the lesson of indigo to heart and learn without delay to set and keep their house in perfect order."

* * * *

The London *Truth* of July 3rd writes as follows under the heading "Synthetic Fiddlesticks":—

"In reading through the mass of synthetic advertising twaddle with which, much to the alarm of rubber investors, Mr. E. Halford Strange has flooded the press of this country [England], I felt that sooner or later the boundless imagination of this enthusiast would lead him to extend his claim far beyond such prosaic substances as fusel oil and synthetic rubber. And, indeed, Mr. Strange has rapidly developed into a synthetic whole-hogger. After explaining to the representative of a weekly contemporary that the aim of his group of multi-millionaires was not wholly financial, Mr. Strange is reported to have said: 'Yes, we have commenced the attack on other attractive problems—the synthetic manufacturer of glycerine, of fats, of copals for varnish-making, of gutta-percha. Later we may venture to attempt the production synthetically of the nitrogenous constituents of food itself—proteid. This proteid is the expensive nitrogenous constituent of food. Synthetic proteid, if successfully produced, would probably become as great an industry as synthetic rubber, but it will be of vastly greater importance to the human race. It would mean the sudden cheapening of food itself, and another line of defense for these islands in case of war.'

"It will be seen that this Mr. Strange means not only to render possible the manufacture of cheap explosives from acetone, and to supply us, at much reduced prices, with faithful imitations of numerous industrial commodities of undoubted utility, but his future ambition apparently is to feed the whole human race with his synthetic products. With the value of his scheme in case of war the military authorities will perhaps deal, but unless forcible feeding is to be generally resorted to, I imagine that in times of peace the demand for roast-beef—even though its succulent and tender qualities may be most faithfully reproduced—will not seriously be effected by synthetic production.

"Why this alarming and apparently universal synthetic campaign, with its army of distinguished professors marshalled by Mr. Strange, should have opened with an attack on so harmless a substance as rubber has not been without mystery. But the history of the movement is thus unfolded in the prospectus of the Synthetic Products Co., Ltd.:—'In the autumn of 1909 Mr. E. Halford Strange, M. Sc., a director of Strange and Graham, Ltd., of 50 City Road, E. C., in common with the rest of the world, had his attention drawn to the high price of rubber, and it occurred to him that an organized attempt might be made towards the synthetic manufacture of rubber.'

"I half suspect that it was for the rise Linggis which attracted Mr. Strange's attention, and had news reached him that oats were rising in value the rubber market might have been spared this onslaught.

"In view of the great names associated with these wonderful discoveries, and with the prominence given to them in the press throughout the country, it was with no small amount of curiosity that I attended last week's laboratory demonstration, and I must admit that if I left the City Road cellars—the home of the rubber bogey—with precious little respect for the substance Mr. Strange was pleased to call rubber, I was not without admiration of that gentleman's marvellous imagination. Although column after column has appeared in the press about this new product, I was assured that the total output of the factory to date did not exceed 2 lb., and, stranger still, that the product had not been put to a single physical or mechanical test, the experiments so far having been wholly chemical. It appeared to me inconceivable that the product about which so much has been written should not have been compared with natural rubber, say in a simple stretching test, but I was emphatically told that on this point—the chief point so far as commercial value is concerned—no information was available.

"Fortunately, I was afterwards allowed to handle a small piece of vulcanized 'pure synthetic,' and in face of the unconvincing answers to my questions I was not surprised on simply bending the material between my thumb and forefinger to see it break, readily and cleanly, into two distinct pieces. This miserable substance, which has been trumpeted as 'tenacious,' 'nervy,' etc., is no more equal to fine hard Para or plantation rubber than brown paper is the equal of shoe leather. To discuss the cost of production of such rubbish, and to argue as to the length of time it will take before it competes with natural rubber, is to throw dust in the eyes of the public who are asked to subscribe for shares in the new company.

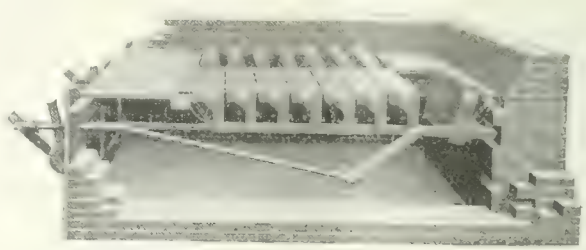
"Before going to the public for so large a sum as £450,000 it might have been expected that a respectable quantity of the material would have been manufactured and thoroughly tested by trade experts, and that it would have been submitted to the Mincing Lane dealers for valuation. The result of any such test would, in my opinion, have proved without doubt that the material is valueless, and that commercially we are no nearer the synthetic production of rubber than we were thirty years ago. The prospectus now before the public differs in some material respects from the draft to which I referred last week. The clause relating to the underwriting of the issue has now been omitted, and apparently the attempt to secure support in this direction proved hopeless. In the place of this, in return for £1800 paid to the vendor syndicates Mr. P. B. Reckitt secures 3000 fully paid "A" shares in the new company, or say, at the rate of 12s. per share, and Mr. Humphery gets at the same heavy discount 1500 of the shares, for which the public are asked to pay 20s. Another alternation is made of far greater significance. In the draft it was stated in big black type, 'It is now established that the product is real rubber.' After this and similar phrases have been used in the most reckless fashion for advertising purposes, they are quickly withdrawn, and the public are supplied with the prospectus of a company which does not claim to produce real rubber, but a substance which 'recalls' rubber.

"The manner in which the names of distinguished scientists have been used in connection with this promotion labels Mr. Strange as a dangerous enthusiast, and investors will be foolish in the extreme if they entrust the new company with a single penny of their money."

A New Rocking and Dumping Grate

The adjoining illustration shows an improved feature in a rocking and dumping grate. It consists of a large rear dump grate, which is operated independently from the main grate surface.

By means of this double-capacity dump grate the largest clinker formations can be quickly and easily disposed of at the rear of the furnace, where combustion terminates. The residue of combustion must be disposed of after the fuel has performed its heat-producing function, and two ways only are available, namely, to dump into the ash pit or clean out through the fire doors.



ROCKING AND DUMPING GRATE

In modern furnace practice the dumping process is considered the only right method. There is a considerable loss in furnace efficiency by the forward cleaning of the fires, because it disturbs combustion, and with the opening of the fire doors the heat-producing function of the furnace is destroyed and the loss represents both fuel and labor in getting the combustive areas of the furnace back to a normal active state again.

From the illustration it can be seen how convenient it is to clean these grates, especially the rear portion which ordinarily receives the least attention, because it is out of reach of the fireman. But with this wide dump grate it is really the easiest portion of the grate surface to clean.

A combination of this rocking and dumping feature entitles this grate to recognition as a modern device for coal-burning furnaces; and while it is a hand-firing device it embodies three prominent features of a mechanically fed furnace. First, the agitation and breaking up of the fuel bed by the rocking movement; second, the tendency of the rocking motion to shift the fuel to the rear, and, third, the large dumping grate at the rear of the furnace which enables the operator to dump the accumulation of clinker and ash.

This grate is made by the Kelly Foundry, of Goshen, Ind. It is made to fit any size of furnace and with air space best adapted to the kind of fuel used. It is self-contained and does not require any alterations in the ordinary furnace to install.

Sixth Congress of the International Association for Testing Materials

The Sixth Congress of the International Association for Testing Materials will be held in New York City, at the Engineering Society's Building, 29 West Thirty-ninth Street, in the week of September 2nd to 7th. Admission will be restricted to members of the International Association and of the American Society for Testing Materials which is so affiliated with International Association, and to duly appointed delegates from foreign countries and scientific bodies.

The Congress fee is $5.00 for members and $3.00 for ladies accompanying members. Any other person may become a member of the Congress by payment of the current year's dues of the International Association for Testing Materials ($2.00) in addition to the Congress fee.

On **Monday, Sept. 2,** the headquarters at 29 West Thirty-ninth Street will be open all day for the registration of members, for the acceptance of the credentials of delegates, and for the convenience of foreigners and strangers in the city, in securing lodgings, etc.

In the evening of Monday, September 2, there will be an informal reception under the joint auspices of the American Society for Testing Materials, the American Institute of Electrical Engineers, The American Society of Mechanical Engineers, and the American Institute of Mining Engineers. Evening dress will not be required.

On **Tuesday, Sept. 3,** the Congress will convene at 10 o'clock, at which time there will be addresses of welcome by the President of the American Society, and by National, State, and Municipal officials. The various sections will then arrange for their sessions in their respective section rooms. The section sessions will convene at 2 p. m. and continue until 5 p. m. In the evening there will be a reception by the officials of the city in the Public Library Building, Fifth Avenue and Forty-first Street. Evening dress will not be required.

On **Wednesday, Sept. 4,** section sessions will take place from 10 to 12 a. m. The afternoon and early evening will be occupied by an excursion to West Point.

On **Thursday, Sept. 5,** there will be section sessions beginning at 10 a. m. and 2 p. m. In the evening there will be a reception tendered to the foreign members by the American Society of Civil Engineers, in its building at 220 West Fifty-seventh Street. Evening dress will be in order.

On **Friday, Sept. 6,** there will be section sessions in the morning and early afternoon, and an evening excursion down the harbor.

On **Saturday Sept. 7,** morning, at 10 o'clock, there will be a general session at which the sections will report, and resolutions upon their recommendations will be presented. The Congress will adjourn at noon.

The Museum of Natural History will receive the Members of the Congress for Testing Materials together with those of the International Congress of Applied Chemistry at 3 p. m. The Museum of Art will receive the Members of the Congresses at 8 p. m. Evening dress will not be required.

The technical proceedings of the Congress will be unusually valuable. There are about 170 foreign and about 35 American papers to be presented.

President Taft is the patron of the Congress.

Dr. Henry M. Howe is the Chairman and Mr. H. F. J. Porter, 29 West Thirty-ninth Street, New York City, is the secretary.

Personal.

Mr. **Walter W. Davis,** manager for the Smuggler Leasing Company, at Aspen, Col., has been obliged to undergo a minor surgical operation in a Denver hospital. He is now well on the road to recovery.

Mr. **W. H. Storms,** state geologist for California, has made a professional trip to the new camp of High Grade, in northern California, for the purpose of investigating conditions there.

Mr. **Thomas H. Leggett** has severed his partnership with Mr. Fred Hellman, and has become consulting engineer for the American Smelting & Refining Company, with offices in New York. Mr. Hellman will continue in private consulting practice at 60 Broadway, New York.

Mr. **G. H. Clevenger,** metallurgical engineer, recently made a trip to Denver from California on professional business.

Mr. **Victor G. Hills,** of Denver, has returned from his recent trip to Alaska.

Mr. **Otto Wertenweiler** will have charge of the construction of the new mill being built at the Commonwealth mine, Pearse, Ariz., for the Montana Tonapah Mines Company.

Mr. **H. Kenyon Burch** has been appointed chief mechanical engineer for the Inspiration Consolidated Copper Company, which is engaged in the construction of a large concentrating mill in Arizona.

Mr. **Charles Butters** recently visited the high-grade mill of the Nipissing mines, at Cobalt. Mr. Butters is responsible for the novel features of the metallurgical process used there.

Mr. **E. L. Wolcott,** assistant secretary of the American Mining Congress, was a speaker at a meeting of Utah mining men in Salt Lake City, called for the purpose of organizing an association for mutual benefit in matters relating to mining legislation.

Mr. **A. O. Krieger** has severed his connection with the Busch-Sulzer Brothers-Diesel Engine Company, and has opened an office at 916 Victoria Building, St. Louis, for the sale of the Tacchella oil burning device, which is especially suitable for japanning and annealing ovens and for domestic heating purposes.

Mr. **H. W. Hardinge** has returned to New York from an investigation of the iron mines in northern Norway.

Prof. **Wilh. Palmaer** of the Institute of Technology of Stockholm, Sweden, has arrived in this country to attend the Congress of Applied Chemistry as the official delegate of Sweden. The time before the Congress convenes he is spending in the study of recent electrochemical developments.

Geheimrat **Dr. C. Duisberg,** of Germany, has arrived in this country and is at present in Yellowstone Park. He will attend the New York celebration of the Verein Deutscher Chemiker, of which he is president, and at the Congress of Applied Chemistry he will deliver one of the four general public lectures as the representative of Germany.

Digest of Electrochemical U. S. Patents.

Prior to 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (*Continued*)

578,171, March 2, 1897, Charles P. Turner, of New York, N. Y.

Relates to electrolytic apparatus for the separation of metals from their ores. The apparatus comprises a tank to contain the electrolyte, a cathode, and an anode in the form of a receptacle suspended in said tank. The receptacle is preferably made in the form of a cage having its frame composed of metallic bars covered with a fabric such as hair, cotton or linen cloth and of a fineness that will keep the granulated or pulverized ore from sifting through the lining into the electrolyte. The lining, as well as the metal bars, is covered by a conducting substance which will preserve the metal and cloth from corrosion, and at the same time is a good conductor of electricity.

579,872, March 30, 1897, Joseph Henry Haycraft, of Adelaide, South Australia, assignor to The Haycraft's Gold Extraction Company, Limited, of same place.

Relates to extracting gold and silver from finely-divided ores. The apparatus consists of a heated pan having a well of mercury at the center and provided with a revolving stirrer terminating in shoes of carbon arranged so as not to meet in the center of the pan. Suitable connections are made with a dynamo, the pan being the cathode and the stirrer with its arms the anode. The process is as follows: A charge of finely-divided ore placed in the pan is covered with hot water, mercury is added equal to about 5 per cent of the charge of ore and also about 1 per cent of chlorid of sodium and about one-eighth per cent of chlorid of barium. The temperature of the contents of the pan is raised until the water commences to boil gently. The stirrer is caused to revolve slowly and a current of electricity is passed continuously through the charge to yield chlorin. The mercury is charged with gold, and the amalgam is separated in the usual way. Though described with respect to chlorin, the process answers with bromin and salts yielding bromin.

581,160, April 20, 1897, Henry Hirsching, of Salt Lake City, Utah.

Relates to a process for obtaining copper, silver and gold from ores. The apparatus consists of a lixiviation-vat provided with a false perforated bottom, also covered with burlap to obtain a good filter. I provide the top of the vat with a removable cover, and a tube is provided for supplying air or gases through the bottom. A tank below can be used for precipitating purposes, according to the sulfid method or for depositing the copper and disengaging copper by electric action. The process is as follows: A solution of ammonia or carbonate of ammonia is prepared, to which is added, if desired, nitrate of ammonia or a nitrate of an alkaline metal. The powdered crude or calcined ore in the lixiviation-vat is charged with the above solution, allowing sufficient time for a thorough mixture and for the conversion of the copper into the soluble copper salt. The metal solution is discharged from the solution into the tank; I then wash the ore with water, and a current of electricity is turned on. Pure metallic copper is deposited on the cathode.

582,077, May 4, 1897, Emanuel Motz, of Brewermine, South Carolina.

Relates to the extraction of precious metals from their ores and apparatus whereby the extraction is facilitated. A charge of ore is placed in a drum, also an aqueous solution of cyanid of potash with mercury to amalgamate the precious metal in the ore. Compressed air is then forced into the drum or receptacle to increase the pressure therein, so as to force the solution into the crevices and pores in the ore. An electric current is passed through the ore, the terminals being copper plates. The ore is subjected to the simultaneous action of atmospheric oxygen, cyanogen, mercury, and the electric current, the precious metals being deposited in the form of amalgam on one of the electrodes. The rotating drum contains a core carrying cathode plates, and also, on its inner periphery, are anode plates separated by wood shelves. These shelves serve to lift the ore during the rotation and to spill it through the compressed air, absorbing oxygen, and into the cyanid solution. When the operation is completed, the contents of the drum are washed onto a filter, the slimes subsequently being washed down a sluiceway in which the amalgam may be recovered.

584,242, June 8, 1897, Pedro G. Salom, of Philadelphia, Pennsylvania.

Relates to the manufacture of commercial lead from lead ore without the employment of heat. Lead ore reduced preferably to a powdered state is placed in a vessel, and connected with the negative pole of the dynamo. In the electrolytic fluid is an anode of a plate of lead connected to the positive pole of the dynamo. Current passing through the positive electrode and the electrolyte to the negative electrode will liberate hydrogen, which acts to reduce the metal from the ore under treatment; if the ore be a sulfid, sulfur combining with the hydrogen passes off as sulfureted hydrogen, leaving spongy metallic lead.

585,355, June 29, 1897, Charles Anthony Burghardt and Gilbert Rigg, of Manchester, England.

Relates to the recovery of metallic zinc from ores of zinc or metallic zinc and metallic copper from zinc ores containing copper or metallic copper from copper ores. The ore, whether cupriferous or otherwise, is first roasted and converted into the oxides of these metals. The ore is now crushed into powder and placed in the tank with a stirrer. A concentrated solution of ammonia or ammonium carbonate is then poured on the ore; next the surface of the liquid is covered with a layer of paraffin oil. The stirrer is now set in motion, and the oxides of zinc and copper are rapidly dissolved. The stirrer is stopped and the solution allowed to settle and suspended matter falling to the bottom may be separated by filtration.

To remove the oxides of iron from the solution, hydrated oxide of tin is added, preferably at a temperature of about 40 deg. C.; the solution is kept well agitated and in a few hours the iron is precipitated as oxide; the clear solution is run into a fresh tank, but if the ore in the first place contained copper there is placed in the tank plates of metallic zinc or zinc and tin acting as a couple. The copper begins to deposit in hard, bright scales. The solution is thus freed from copper. In the zinc-depositing tanks the solution is subjected to electrolysis and is covered, as before, with a layer of oil and maintained at a temperature of about 40-50 deg. C.

585,492, June 29, 1897, Jean F. Webb, of St. Louis, Mo.

Relates to the recovery of precious metals from solutions, such as cyanide of potassium. A filter with a series of cells or compartments is filled alternately with carbon and zinc and the solution is caused to pass in a downwardly direction through the carbon and in an upwardly direction through the zinc. The compartments when thus filled become positive and negative cells, and a solution of cyanide of potassium containing precious metals generates an active electric current and hastens the precipitation of the precious metals held in solution. It is intended that the greater portion of the precious metals held shall be deposited in the carbon, and this object is further assisted by introducing a small perforated pipe into each zinc compartment through which at intervals a strong current of compressed air is turned. This air rising through the zinc clears it of the brown powder-like deposit of precious metal, forcing the deposit upward and over with the upward flow of the solution and into the carbon. The richer upper portion of the carbon can be taken off from time to time for burning and smelting, and at long intervals a general clean-up will be necessary.

588,076, Aug. 10, 1897, Bernard Mohr, of London, England.

Relates to the treatment of ores containing the sulphides of lead and zinc and of other metals with acid sulphate of sodium. The zinc contained in these ores is converted into soluble sulphate of zinc; the pulverized ore and acid sodium sulphate, about 10-15 hundredweight per ton of ore, are fused together. The mass is then dissolved in hot water to which, if necessary, a small quantity of sulphuric acid is added. This solution is electrolyzed until most of the zinc is deposited. The liquid is then concentrated until it is of the necessary strength for fusing with a fresh batch of the sulphide ores. The insoluble residue consisting of the sulphides of lead and of other metals is refined and desilverized. Any silver present in the solution may be precipitated by usual well-known means and the zinc is then electrolytically deposited.

588,740, Aug. 24, 1897, Beda Becker, of Eupen, Germany.

Relates to the treatment of gold and silver ores for the extraction of the precious metals therefrom. Ore is crushed to the desired extent and then introduced into a vat with a solution of cyanide of potassium, which is kept in a constant state of circulation by a suitable pump. The vat is of conical shape and the circulating pump has its suction pipe connected with the top of the vat, while the discharge side is in connection with the bottom, so that the circulation is in an upward direction, thus causing a very rapid action of the cyanide to take place. Plates for amalgamating the free gold are arranged around the sides and bottom of the vat and adapted to be removed from time to time. The solution is forced in a rotary motion and thus imparts a slight centrifugal action to the particles held in suspension which tends to bring the particles into contact with the sides of the vat. When the cyanide solution is treated electrolytically the vat is combined with a second vessel in which the anodes and cathodes are suspended; the solution circulates from the amalgamating vat into the electrolytic vat and then through the pump back into the amalgamating vat. As the circulation takes place any particles of free gold will, owing to their great specific gravity and to the rotary motion imparted to the liquid, be deposited on the amalgamated plates to form an amalgam, while at the same time the fine gold and particles of gold which are combined with the gangue will be wholly or partially dissolved.

590,801, Sept. 28, 1897, Wilfred L. Brown, San Francisco, Cal.

Relates to treating rebellious ores containing precious metals by an alternating current; the precious metals being saved by amalgamation. The apparatus consists of a tank having removable amalgamating plates placed upon the interior sides and a pipe laid along the middle of the bottom of the tank, perforated with slits so that jets of water forced through them will impinge upon the amalgamating plates. The amalgamating plates are connected as electrodes and are preferably of cast iron which extend throughout the length of the tank. These plates converge downward, but do not touch, leaving circulating passages for the fluid. The ores in a finely divided state are placed in the tank and a sufficient quantity of water added to render the mass fluid. A suitable compound is placed in the tank, which exerts a chemical action on the ore. With ores having iron as a base black oxide of manganese is added; oxygen is liberated which combines with the iron, making an oxide of iron. The electric current causes the compound to separate into its constituent elements, which has affinity for the base of the ore. Chemical reaction therewith takes place, separating precious metals. A continuous circulation of the fluid contents of the tank against the amalgamating plates and then between the electrodes is maintained.

591,141, Oct. 5, 1897, Joseph W. Richards, of Bethlehem, Pa.

Relates to processes in which a metal is recovered from solution by means of electrolysis, and the main feature lies in the anode employed in the electrolysis. By way of example, the extraction of gold from a cyanide solution will be described. The apparatus consists of a tank, the bottom of which is filled with sodium amalgam. Above this is hung a series of cathodes with the amalgam as the anode. A porous diaphragm is interposed between these electrodes, dividing the tank horizontally. Through the upper of these compartments flows the cyanide solution carrying gold. The lower compartment is filled with any suitable electrolyte, such as a solution of cyanide of sodium. The electrolytic current causes decomposition of the double cyanide salt, gold being deposited and a proportionate quantity of sodium set free from the amalgam. As the process proceeds the amalgam is constantly replaced by fresh from an external source.

592,055, Oct. 19, 1897, Ernest C. Ketchum, of Boston, Mass.

Relates to a process of treating mixed sulphide ores containing lead and zinc. It consists in first roasting the ores; then subjecting the roasted ores to a solution of caustic alkali in the presence of heat to remove from the ores the lead and zinc; then subjecting the caustic solution containing the lead and zinc to electrolytic action in one or more cells to remove the lead, the anodes of which cells are immersed in a volume of pure caustic solution separated by a porous medium from the electrolyte containing the lead and zinc; then subjecting the caustic solution or electrolyte containing the zinc only to electrolytic action in one or more cells to remove the zinc.

592,973, Nov. 2, 1897, Emanuel Motz, of Brewer Mine, S. C., assignor of one-half to Henry F. Welch, of Charleston, S. C.

Relates to an improved electrolytic apparatus for the separation of metals from their ores and solutions. It consists of a series of undulatory communicating passages or channels, each having a contracted outlet and each having opposing walls composed of an anode and a cathode respectively, and forming a frame or sluice composed of any desired number of removable sections connected together. The upper face of the bottom of the frame or sluice is made undulatory or corrugated. On the curved face an amalgamated copper plate is disposed, being convex in conformity with the face of the bottom and constituting the negative electrode. The spaces between the end sections of the apparatus are made to form mercury wells, in which excess of mercury in the apparatus may collect without electrically connecting the plates of one set with those of another. The positive electrodes or anodes, preferably of lead, are placed over an eccentric to the cathode plates in the bottom of the frame or sluice. The frame is disposed in an inclined position so that the electrolyte and door will flow by gravity and will be effectually agitated without the aid of auxiliary agitating means. By contracting the outlets of the respective communicating passages, the force of the flow from one passage to the next will be increased and the agitation of the electrolyte and pulp will be proportionately augmented. In operating, the ore will first be finely divided, then mixed with a solvent and fed into a sluice (the electrical circuit having been closed). In the passage of the pulp through the apparatus the larger particles of gold will be caught mechanically by the copper plates and be amalgamated thereon. The finer particles are forced upward against the anode and thus held in the zone of intensest action of the solvent agents, thereby being quickly dissolved and carried down to the cathode by the electric current.

594,611, Nov. 30, 1897, Stephen H. Emmens, of New York, N. Y.

Relates to the removal of zinc from zinc-bearing ores, such as zinc and lead sulfids, as, for example, the zinc and lead sulfid ores of Broken Hill, Australia. The ore is first crushed to from 20 to 30 mesh. The crushed ore is roasted in a reverberatory furnace to convert the zinc sulfid into zinc sulfate.

A series of vats is provided, each having a sheet lead anode at the bottom, and a horizontal cathode plate of zinc or other suitable metal suspended in the upper portion. Each vat has an inlet extending to the bottom of the vessel and an exit pipe from the top of the vat so arranged that a flow of liquid may traverse the vats in an alternately descending and ascending manner. The vats are filled with crushed and roasted ore, and

water caused to flow through, first, vat No. 1, which in the beginning is not made a part of the electric circuit. The water dissolves the zinc sulfate, and the solution passes into vat No. 2, which is made part of the electric circuit. An electrolytic action is set up depositing metallic zinc on the cathode and setting free a corresponding quantity of sulfuric acid. The solution thus acidified flows into vat No. 3, which is not then part of the electric circuit, and becomes neutralized by dissolving zinc oxid and basic zinc sulfate. It next flows into vat No. 4, which is part of the electric circuit, where it deposits a further quantity of zinc and again becomes acidified. The flow of a solution thus alternately neutralized and acidified continues through the whole series of vats. At suitable intervals of time vats 2, 4, etc., are cut out of the electric circuit and the electric current is caused to pass through vats 1, 3, etc. This change is effected by suspending each neighboring pair of cathodes from the vats of a metallic beam, pivoted in the center. By turning the beam on its pivot, one cathode is depressed in the solution to the vat to which it belongs and the cathode at the other end of the beam is raised out of the solution in its vat, thereby closing or opening the electric circuit in either vat.

The flow of the solution is continued and the electric current changed from vat to vat until the metallic zinc is deposited and the zinc sulphate in the solution amount together to a quantity showing that the zinc-contents of the ore have been removed sufficiently to render the residual ore fit for smelting.

BOOK REVIEWS.

Higher Mathematics for Chemical Students. By **J. Riddick Partington**, B. Sc. 12mo, 272 pages, 44 diagrams; price $2.00 net. New York: D. Van Nostrand Company.

A short but trenchant introduction shows the author to have very clear-cut and fruitful ideas of the function of mathematics in chemistry. He believes it "clear, however, that the distinguishing of the whole development of theoretical chemistry and physics is the elimination of the anthropomorphic elements, especially specific sense-impressions, from the concepts." Starting from this, he proceeds to elaborate the fundamental principles of higher algebra, geometry, and the calculus in terms of number and quantity, fixed, progressive and continuously changing, as illustrated in the fundamental facts of chemical statics and dynamics. The thesis is worked out very satisfactorily; it will be a useful text-book for chemical students, and may give new points of view and excite a fresh interest among the older generation of chemists.

* * *

Chemical Arithmetic and Calculation of Furnace Charges. By **Regis Chauvenet**, LL.D. Octavo (15 x 23 cm.), 302 pages; price $4.00. (Philadelphia: J. B. Lippincott Company.

The book is in two distinct parts; the first 200 pages forms an elementary statement of the principles of chemical calculations, the other 100 are concerned with the application of these to smelting ores and forming slags. The first part is similar to numerous text-books of elementary chemical calculations previously published, except that it is elementary to the verge of peurility; it is a chemical A, B, C and first primer. Students, who need such pedagogical coddling must be in reality veritable mental weaklings. This mental flabbiness, if it is a fact, damns our elementary educational system, and proves the urgent necessity of more *virile* tone and teaching in our elementary schools.

As for the last third of the book, the technical part, it is concerned with smelting of ores, principally smelting to matte, and gives for a student or a practical furnace man a clear and useful knowledge of the subject. The author is quite right in advising the abandoning of calculations of *excess* silica or base when figuring out a furnace charge; but the method of valuing fluxes or ores by excess lime or excess silica per unit weight is of importance for comparing the values of different materials for the furnace, and should be taught in that connection. This part of the book is elementary, but also goes thoroughly into the subject; it is the outcome of much practical experience and is a valuable contribution to metallurgical literature.

Annual Tables of Constants and Numerical Data, Chemical, Physical and Technological. Compiled and published by an International Commission appointed by the Seventh International Congress of Applied Chemistry, under the patronage of several governments, scientific societies and individuals. Vol. I, 1910. Large quarto, 22 x 27 centimeters, 727 pages, price $6.00, postage, $0.54 extra. Chicago: University of Chicago Press, 1912.

This patiently-awaited volume fulfills all expectations; in fact, it exceeds them. Nearly 300 scientific publications of 1910 were read by over 150 scientists (most of them men of international reputation), and the result is a work such as could have been achieved in no other possible way. It seems to us as nearly perfect as anyone has a right to expect.

It must be clearly understood that this is not a complete tabulation of constants *to date*, but only a compilation of such as were published as *new* in 1910. Volume II will be a similar review of 1911. The work informs the scientist of *new* determinations; it does not mention the older ones. For data previous to 1910, standard tables, such as Landolt-Börnstein-Meyerhoffer, must be used. This work *supplements* such tables.

It is the intention to publish in Volume II an alphabetical reference index of all subject matter in both volumes, and to continue such a complete index in each succeeding volume. This is to decrease the labor of searching through several large volumes to find the information one seeks. The difficulty is real, but the remedy proposed is a makeshift which will not give complete satisfaction.

We have a more radical remedy to submit to the commission. It is as follows: What the scientist needs and should have is a hand-book of *complete* data revised as frequently as practicable; too many supplements are a weariness to the flesh. A combination is necessary; a good set of tables should be taken as the basis, and every five years, let us say, it should be revised to date.

To be more specific, let us suggest that it should be practicable to arrange with the publishers of the Landolt-Börnstein-Meyerhoffer Tabellen to put them into the hands of the International Commission in 1915, so that volume V of the "Annual Tables" shall be a complete revision and compendium of "Constants" to that date. Thus volumes I, II, III and IV will have served the very useful purpose of furnishing us with the newest data until the revision of the "Tables" appears, and then the labor of using five volumes will be dispensed with by the possession of the one revised edition. Volumes VI, VII, VIII and IX would be again "Annual Tables," while Volume X, for 1920, would be another revised set of "Tables." This is a scheme which can be worked for a century, whereas "Annual Tables" only, every year for a century, would be a waste of paper and ink; the "Annual Table" system decreases in usefulness each year, and eventually will break down of its own weight.

The remedy is the revision of a standard set of tables every five years.

The above is not meant for criticism of Volume I; it is beyond criticism. But Volume I is part of a system which, to reach its highest usefulness, should be planned so as to include the periodical issue of complete "Tables," worked over with as great thoroughness as the "Annual Tables." Then will the chemist and the physicist be indeed magnificently provided with complete data in the most available and practical form.

Eighth International Congress of Applied Chemistry

When this journal appears the Eighth International Congress of Applied Chemistry is nearing its end. There remains only one day of professional sessions and the final official closing day. The bulk of the work has been done. Nevertheless, it is still far too early to justify even an attempt of a final summing up.

A few facts, however, stand out clearly. The Congress was really an enormous undertaking. A glance over the report in this issue shows its bewildering scope. The professional sessions were well attended, although naturally not to the same extent in all sections. Possibly there were really too many sections. In the different joint sessions of the Section on Electrochemistry with the American Electrochemical Society and with the Congress Sections on Mining and Metallurgy, on Physical Chemistry and on Paper the attendance varied between 200 and 300 and some papers brought out a real lively discussion.

The general public lectures by official representatives of the different countries were brilliant and delightful. Especially Dr. Eyde's inspired address with his grand peroration on the need of the young man in pioneer work will never be forgotten.

It is but fair to give the highest credit to the officers of the Congress, especially to the president, Dr. Nichols, and the secretary, Dr. Hesse, for the immense amount of work which the preparation of the Congress involved for them. As the one grand successful feature stands out the fact that the bulk of the papers was printed in advance and was available before the start of the Congress in form of twenty-four finely printed volumes. And then all the social functions were delightful. That in such an immense undertaking something would go wrong occasionally was to be expected; there was indeed some confusion at the registration in Washington and in New York as well as in starting the professional meetings on the first days (and this confusion may be reflected somewhat in the arrangement of our report of the sections for the first two days), but any accidents that did happen were due not to lack of organization, but rather to overorganization. Really too much had been attempted in some respects as was most clearly evident from the almost general failure of the ingenious scheme of reporting the discussions by phonograph. But all such little accidents served only as the proper relief to bring out more brilliantly the real big achievements and the success of the Congress as a whole.

The report in this issue contains the proceedings up to the last night, Wednesday, Sept. 11. We have endeavored to give a summary of the proceedings of each of the twenty-four sections of the Congress, elaborating on those sections which have special interest to our readers. Thus electrochemistry and metallurgy and special meetings of the sections on silicate industries, on inorganic chemistry, etc., have been reported quite

fully, giving abstracts of all the important papers and discussions. The Section on Electrochemistry was very well attended and had one of the best programs. The Section on Mining and Metallurgy had a number of excellent papers by leading men in copper and lead smelting, which made one overlook the lack of papers by Western men. The great cyanide industry was wholly unrepresented in spite of the fact that great advances in cyanidation have been made in this country.

For the other sections we have in general given merely the programs so that if anyone is interested in any of the varied papers he will know that the subject was presented and the paper is obtainable. The proceedings are reported day by day. As a matter of course, quite a number of abstracts of interesting papers have had to be deferred until later issues.

The routine of the report of the sectional proceedings has been relieved by extensive and interesting reports of the general lectures which were delivered by representatives of France, Germany, Great Britain, Italy and Norway.

Interpersed through the reading matter we present the photographs of the four officers of the Congress, of the presidents of the national chemical societies and of other national societies which joined the Congress in its work, and finally the photographs of the presidents of the twenty-four sections of the Congress. To those who were present at the Congress meetings these portraits will serve as pleasant reminders of the leading men in their respective fields whom they met and mingled with.

Altogether this issue represents weeks of effort on the part of the staff of this journal to provide a useful report and a pleasant souvenir of a great convention.

Two Aspects of "Conservation"

Scarcely any feature of the Congress of Applied Chemistry is of such general interest and significance as the provision of a section on Political Economy and Conservation of Natural Resources of which the distinguished and able Director of Mines is the President. He is to address the Congress on "Our National and State Governments in Relation to Mineral Waste." Our foreign visitors will be able to obtain from it a pretty clear idea of some of the lines along which this nation is attempting to remove the old stigma that it is as wasteful of as prolific in natural resources. No one could state the case better than Dr. Holmes; and no one has worked harder or more successfully in the interests of this branch of "conservation" than his associates and assistants. He has excellent results to point to and a most interesting program to outline for future work. The extent to which his program goes may be somewhat of a surprise even to our European friends, accustomed as some of them are to a considerable degree of paternalism in government. Even in Europe, however, a program against which the criticism could be leveled that its logical result is to bring the government into competition with individuals, would be considered somewhat advanced.

In a few days our visitors will be at Niagara Falls. Much is there of which we are proud—the magnificent group of electrochemical industries, without a parallel of its kind in diversity and magnitude, and economically of importance only to be measured by a realization of what the artificial abrasives, aluminium, artificial graphite, caustic soda and chlorine, the ferro alloys, and its other products mean to industry in its larger aspect. A bold directness is perhaps the characteristic virtue of American engineering; and a better example could scarcely be found of that simplicity which is the truest efficiency than this group of electrochemical plants.

We regret that with one or two exceptions the policy of these plants will not permit of their inspection by our visitors; firstly, because we can think of no example which would demonstrate to such a degree the application of the American type of industrial genius to chemical industry; secondly, because otherwise it might have been possible so to distract our visitors' attention as to prevent their thorough realization of the horrible spectacle of economic waste presented by the present condition of the Falls. We do not imagine for a moment that the unique *scale* of the waste will appeal to them as an element of beauty any more than it appealed to Lord Kelvin when he stated that "the great cataract can never be beautiful until it has ceased to be an awful and unlovely example of waste," or any more than the tremendous scale of a conflagration consuming for spectacular purposes a million tons of coal a week would appeal to the aesthetic sense of the Director of the Bureau of Mines.

As we cannot cover up the matter, we may as well apologize most humbly for its existence. It will probably be well known to our visitors that the present cessation of power development is due to an international agreement between the United States and Great Britain. The ways of governments are notoriously beyond rational analysis and need not demand any particular attention from a technical journal; but the ways of engineers are very much its concern and our apologies are entirely due to the fact, which we state with shame, that the engineers of this country have as a body allowed the question of restriction of power development at Niagara Falls to go against them by default. It is possible that organized effort on their part might not have averted the calamity, though, having in mind the enormous force which engineering and technical societies in this country have shown themselves able to exert in other matters, we do not believe it. In any case, the deplorable fact is that nothing of the kind was done, and we are left with this frightful instance of what a handful of self-seeking mountebanks can achieve politically in the absence of opposition from those from whom it should have come to explain to our visitors as well as our embarrassment permits.

Industrial chemists are logical folk; their training teaches them to be such, the conditions of their work forces them to be such. We consequently imagine that our distinguished visitors will derive considerably more amusement than edification from this charming example of consistency in "conservation."

Post Nubila Phoebus in the Metal Market

In any civilized era, all industrial advance is conditioned on the production of metals in sufficiently large amounts. This is a truism extant when Tubal Cain formed the first steel trust and no less true to-day. Now, as indicators of tidal flows of industrial events, the prices and the price-governed production and consumption of the primary metals are sure and positive. With this general viewpoint in mind let us examine briefly the present condition of the markets for iron, steel, copper, lead, and zinc.
